The longitudinal complex is associated with the second step. One can consider on $\Sigma$ an "exterior derivative operator $D$ along the gauge orbits." This operator is defined on functions on $\Sigma$ as

$$Df = \mathbf{X}_\alpha(f)C^\alpha \qquad [15]$$

where the 1-forms $C^\alpha$ dual to the $\mathbf{X}$'s are called ghosts. In the physical context, the form-degree is the pgh described earlier, and so $\mathrm{pgh}(C^\alpha) = 1$. The action of $D$ on the ghosts is given by

$$DC^\alpha = -\tfrac{1}{2}C^\gamma{}_{\alpha\beta}C^\alpha C^\beta \qquad [16]$$

The longitudinal complex $\mathcal{L}_\Sigma$ is the complex of exterior forms along the gauge orbits. In our representation used here, it is given by the space of polynomials in the ghosts $C^\alpha$ with coefficients that are functions on $\Sigma$. The exterior derivative $D$ is defined on this space by extending the formulas [15] and [16] so that it is an odd derivation. One clearly has (on $\Sigma$)

$$D^2 = 0 \qquad [17]$$

The functions on the quotient space $\Sigma/\mathcal{O}$ are just the elements of the zeroth cohomological group $H^0(D, \mathcal{L}_\Sigma)$,

$$H^0(D, \mathcal{L}_\Sigma) = C^\infty(\Sigma/\mathcal{O}) \qquad [18]$$

In general, $H^k(D, \mathcal{L}_\Sigma) \neq 0$.

### Koszul–Tate Differential $\delta$

The Koszul–Tate differential $\delta$ implements the first step in the reduction procedure. More precisely, it provides an algebraic resolution of the algebra $C^\infty(\Sigma)$ of the smooth functions on the surface $\Sigma$.

That algebra can be identified with the quotient algebra

$$C^\infty(\Sigma) = C^\infty(M)/\mathcal{N} \qquad [19]$$

where $\mathcal{N}$ is the ideal of functions that vanish on $\Sigma$. The Koszul–Tate complex $\mathcal{K}$ is defined by adding one new generator for each equation $f_a = 0$ defining $\Sigma$, denoted $t_a^*$ and assigned r-degree 1. In the algebra $C^\infty(M) \otimes \wedge(t_a^*)$ (where $\wedge(t_a^*)$ is the exterior algebra on $t^*$), one defines $\delta$ through

$$\delta f = 0 \quad \forall f \in C^\infty(M), \qquad \delta t_a^* = f_a \qquad [20]$$

and extends it as an odd derivation. It is clear that $r(\delta) = -1$ and that $\delta^2 = 0$. Because the functions on $M$ are annihilated by $\delta$, they are clearly cycles at r-degree zero. Because the left-hand side $f_a$ of the equations $f_a = 0$ are exact (equal to $\delta t_a^*$), the ideal $\mathcal{N}$ coincides with the set of boundaries in degree zero.
Thus,

$$H_0(\delta, \mathcal{K}) = C^\infty(\Sigma) \qquad [21]$$

We see accordingly that $\delta$ successfully enforces the restriction to the surface $\Sigma$ through its homology in degree zero.

However, if the equations $f_a = 0$ are not independent, this is not the end of the story. Indeed, any identity $Z_A^a f_a = 0$ on the functions $f_a$ leads to a nontrivial cycle $Z_A^a t_a^*$ in r-degree 1, $\delta(Z_A^a t_a^*) = 0$. This is undesirable. To cure this drawback, one introduces further generators $t_A^*$ in r-degree 2, one for each identity $Z_A^a f_a = 0$, and defines

$$\delta t_A^* = Z_A^a t_a^*, \quad r(t_A^*) = 2 \qquad [22]$$

in order to "kill" the unwanted cycles $Z_A^a t_a^*$. The Koszul complex $\mathcal{K}$ is thus enlarged to contain these new (even) variables and redefined as

$$\mathcal{K} = C^\infty(M) \otimes \wedge(t_a^*) \otimes S(t_A^*) \qquad [23]$$

where $S(t_A^*)$ is the symmetric algebra in $t_A^*$. The operator $\delta$ is extended to $\mathcal{K}$ as an odd derivation. One has $\delta^2 = 0$ and the property [21] is unaffected by the inclusion of the new generators. Furthermore, by construction,

$$H_1(\delta, \mathcal{K}) = 0 \qquad [24]$$

If there is no "identity on the identities," we shall assume that the process stops. Otherwise, one needs to introduce further generators in r-degree 3 and possibly higher. When all the appropriate variables are included, there is no homology at higher r-degree. Thus,

$$H_k(\delta, \mathcal{K}) = 0, \quad k > 0 \qquad [25]$$

### Combining $\delta$ with $D$

We now turn to the problem of combining the Koszul–Tate complex with the longitudinal complex, so as to implement the full reduction. To that end, we define $\mathcal{C}$ by adding the ghosts to $\mathcal{K}$,

$$\mathcal{C} = \mathcal{K} \otimes \wedge(C_\alpha) = 0 \qquad [26]$$

We then extend the action of the Koszul–Tate differential in the simplest way which preserves all gradings, namely

$$\delta C_\alpha = 0 \qquad [27]$$

It is clear that the homology of $\delta$ in $\mathcal{C}$ is given by

$$H_0(\delta, \mathcal{C}) = \mathcal{L}_\Sigma, \qquad H_k(\delta, \mathcal{C}) = 0 \quad (k > 0) \qquad [28]$$

One can also extend the longitudinal derivative $D$ to the whole complex $\mathcal{C}$ because the vector fields $\boldsymbol{X}_\alpha$ are defined throughout $M$ and so, the definitions [15] and [16] make sense in $\mathcal{C}$. One defines the action of $D$ on the generators $t^*$ by requiring that

$$D\delta + \delta D = 0 \qquad [29]$$

This is easily verified to be possible. However, the (odd) derivation so obtained fails to be a differential in $\mathcal{C}$ when the vector fields $X_\alpha$ do not close off the surface $\Sigma$. In that case, the gauge transformations are not integrable off $\Sigma$; one says that they form an "open algebra." One has then $D^2 = 0$ only on $\Sigma$, or, more precisely,

$$D^2 = -\delta s_1 - s_1 \delta \qquad [30]$$

for some (odd) derivation $s_1$ (that vanishes in the "closed algebra" case). But this situation is precisely the one discussed earlier, with the Koszul–Tate differential being indeed $\delta$, as anticipated by the notation, and the longitudinal differential $D$ playing the role of $s_0$ (the degrees also match). Applying the theorem discussed there, we can conclude:

**Theorem 2** *There exists a differential $s$ in $\mathcal{C}$,*

$$s = \delta + D + s_1 + \cdots, \qquad s^2 = 0 \qquad [31]$$

*such that*

$$H^0(s, \mathcal{C}) = C^\infty(\Sigma/\mathcal{O}) \qquad [32]$$

This is an immediate consequence of Theorem 1 and eqns [18] and [28]. The differential $s$ is known in the physical applications described below as the BRST differential.

## Hamiltonian BRST Construction

As a first application of the above setting, we consider the Hamiltonian description of gauge systems. As already known, gauge systems are characterized in the Hamiltonian description by constraints and, for this reason, are called "constrained Hamiltonian systems." Furthermore, the gauge transformations generate gauge orbits on the constraint surface and the physical observables are the functions on the quotient space of the constraint surface by the gauge orbits.

A further important feature arises in the Hamiltonian formalism: the gauge transformations are canonical transformations that are generated by the first-class constraints. Assuming that all the second-class constraints have been eliminated and that the bracket being used is the Dirac bracket, one sees that there is a vector field $\boldsymbol{X}_\alpha$ for each constraint function $f_a, \alpha \equiv a$. (The functions $f_a$ are thus assumed to be independent since the vector fields $\boldsymbol{X}_\alpha$ are assumed to be so. If not, further variables are needed, but the analysis proceeds along the same ideas.)

This implies, in turn, that there is a pairing between the ghosts $C^a$ associated with the longitudinal exterior derivative and the generators $t_a^*$ of the Koszul–Tate complex. This pairing enables one to extend the bracket structure defined on the phase space to the pairs $(C^a, t_a^*)$ by declaring that these are canonically conjugate. The variables $t_a^*$ are the momenta conjugate to the ghosts, $[t_a^*, C^b] = \delta_a^b$. Accordingly, the complex $\mathcal{C}$ relevant to the Hamiltonian situation,

$$\mathcal{C} = C^\infty(P) \otimes \wedge(C^a) \wedge (t_a^*) \qquad [33]$$

has a phase-space structure (here, $P \equiv M$ is the manifold obtained after eliminating the second-class constraints, equipped with the Dirac bracket). The space $\mathcal{C}$ is known as the "extended phase space." The r-degree is called "antighost number" in the Hamiltonian context.

By the general theorem described in the previous section, one knows that the cohomology at gh = 0 of the BRST differential is isomorphic to the algebra of the observables. Thus, there are two alternative ways to describe this physical algebra, either through reduction, by eliminating the redundant (gauge) variables, or cohomologically in an extended space containing additional variables, the ghosts, and their momenta.

There is an additional interesting feature of the BRST construction in the Hamiltonian case: the BRST transformation is a canonical transformation in the extended phase space, in the sense that

$$sF = [\Omega, F] \qquad [34]$$

for some "BRST generator" $\Omega$ of ghost number 1 $(F, \Omega \in \mathcal{C})$. The nilpotency $s^2$ of the BRST differential is equivalent to

$$[\Omega, \Omega] = 0 \qquad [35]$$

That $s$ is canonically generated implies that the cohomological BRST groups come with a natural bracket structure: the Poisson bracket of the extended phase space passes on to the BRST cohomological groups. In particular, $H^0(s, \mathcal{C})$, equipped with this bracket structure, is isomorphic (as Poisson algebra) to the algebra of physical observables.

## Lagrangian BRST Construction

The analysis of the Lagrangian BRST construction, due to Batalin and Vilkovisky (1981) ("antifield formalism"), proceeds in the same way because the covariant description of the space of observables involves also the same geometric ingredients. The surface $\Sigma$ is now the "stationary surface," that is, the space of solutions to the equations of motion. The space $M$ in which it is embedded is the space of all field histories. The gauge symmetry acts on this space. Furthermore, the gauge vector fields are tangent to $\Sigma$ since a solution is mapped on a solution by a gauge transformation. The integral submanifolds are the gauge orbits. The observables are the functions on the quotient space.

Since the equations of motion follow from an action principle, there are as many equations as there are fields $\varphi^i$. The corresponding generators $t_a^*$ in the Koszul–Tate complex (at degree 1) are called "antifields conjugate to the fields" and are denoted $\varphi_i^*$. The r-degree is known as "antifield" (or also "antighost") number. The gauge symmetry of the action implies Noether identities on the equations of motion. These are, therefore, not independent. According to the above general discussion, there are further generators in the Koszul–Tate complex, at degree 2. More precisely, there are as many new generators in degree 2 as there are Noether identities or independent gauge symmetries. These are called antifields conjugate to the ghosts and denoted $C_\alpha^*$.

In the longitudinal complex, one has the ghosts $C^\alpha$, with as many ghosts as there are gauge symmetries. Thus, the BRST complex is the space

$$\mathcal{C} = C^\infty(M) \otimes \wedge(C^\alpha) \otimes \wedge(\varphi_i^*) \otimes S(C_\alpha^*) \qquad [36]$$

where $M$ is the space of all field histories. There is now a natural pairing between the original field variables $\varphi^i$ and the antifields $\varphi_i^*$, as well as between the ghosts $C^\alpha$ and the antifields $C_\alpha^*$. One thus defines a bracket in which the fields $\varphi^i$ and the ghosts $C^\alpha$ on the one hand, and the antifields $\varphi_i^*$ and $C_\alpha^*$ on the other, are declared to be conjugate. This bracket is denoted by parentheses,

$$(\varphi^i, \varphi_j^*) = \delta_j^i, \qquad (C^\alpha, C_\beta^*) = \delta_\beta^\alpha \qquad [37]$$

However, since the bracket pairs variables with degrees that add up to $-1$, it is in fact an "odd bracket," called the "antibracket."

The BRST differential is again canonically generated, but this time in the antibracket,

$$sF = (S, F), \quad F \in \mathcal{C} \qquad [38]$$

where the generator $S$ is an even function of the fields, the ghosts and the antifields, with $\mathrm{gh} = 0$ (the ghost number is carried by the odd antibracket). The nilpotency $s^2 = 0$ of the BRST differential is equivalent to the crucial "master equation,"

$$(S, S) = 0 \qquad [39]$$

Because the BRST differential is canonically generated, there is a natural bracket in cohomology. This bracket is not the Poisson bracket of observables (at $\mathrm{gh} = 0$) because it changes the ghost number by one unit. One can, however, relate it to the Poisson bracket of observables (Barnich and Henneaux 1996); furthermore, it plays an important role in the study of the consistent deformations of the action.

## Spacetime Locality

In the context of local field theory, one is often interested in a particular class of functions of the field histories, namely the so-called space of local functionals. A local functional is, by definition, the integral of a local $n$-form (where $n$ is the spacetime dimension). A local $n$-form reads, in local coordinates,

$$\omega = f(x)\ \mathrm{d}^n x \qquad [40]$$

where $f(x)$ depends on the fields at $x$ as well as on a finite number of their derivatives. When the ghosts and the antifields are included, the local functions depend on them in the same way.

The previous general cohomological result was derived in the space of all function(al)s, without locality restriction. When changing the space of cochains, one may change the cohomology. For instance, a local functional which is BRST-trivial in the space of all functionals may become nontrivial in the space of local functionals. This indeed happens here because the homology of the Koszul–Tate differentials usually no longer vanishes at strictly positive r-degree in the space of local functionals, where it is related to local conservation laws. As a result, the analysis of the BRST cohomology in the space of local functionals is an interesting and nontrivial problem. In particular, the cohomological groups $H^k(s)$ in the space of local functionals may not vanish at negative ghost numbers.

## BRST Quantization

The quantization of a dynamical system can proceed along different lines. For gauge models, the path-integral approach is most efficiently pursued in the context of the antifield formalism. We shall briefly outline here the general principles underlying the

operator approach, which is based on the Hamiltonian formalism.

In the operator approach, all the variables, including the ghosts and the conjugate momenta, are realized as operators in a space endowed with a nonpositive-definite inner product (because of the ghosts and the gauge modes). Real dynamical variables become formally Hermitian operators. Ignoring anomalies, the BRST generator $\Omega$ becomes an operator that fulfills the conditions

$$\Omega^* = \Omega, \qquad \Omega^2 = 0 \qquad [41]$$

(which allows for nontrivial solutions $\Omega \neq 0$ because the inner product is not positive definite). The second relation is a consequence of the classical Poisson bracket relation $[\Omega,\Omega] = 0$ and the fact that the graded Poisson bracket of two odd objects becomes the anticommutator.

To remove the ghost and gauge redundancy, which has no physical content, one must impose a condition that selects physical states. The appropriate condition is motivated by the general cohomological result connecting the BRST cohomology with the algebra of physical observables. One imposes the condition

$$\Omega|\psi\rangle = 0 \qquad [42]$$

Because of [41], states of the form $\Omega|\chi\rangle$ are solutions of [42], but they have a vanishing inner product with any other physical states, including themselves. They are called null states. The physical states are given by the BRST state cohomology. The physical operators are given by the BRST operator cohomology at $gh = 0$ and induce a well-defined action in the state cohomology. In particular, the Hamiltonian, being gauge invariant in the original theory, is represented by a BRST cohomological class, so that the time evolution maps physical states on physical states.

The whole scheme is (formally) consistent because exact BRST operators have vanishing matrix elements between states annihilated by the BRST operator $\Omega$, while null states $|\phi\rangle$ are such that $\langle\psi|A|\phi\rangle = 0$ whenever $A$ is a BRST-closed operator, $[A, \Omega] = 0$, and $|\psi\rangle$ a physical state. Problems may arise, however, if the classical relations $[\Omega, \Omega] = 0$ and $[H,\Omega] = 0$ are not satisfied in presence of extra terms of order $\hbar$,that is,

$$\Omega^2 \neq 0 \quad \text{or} \quad H\Omega + \Omega H \neq 0 \qquad [43]$$

In such cases, one says that they are anomalies. These are usually fatal to the consistency of the theory.

## Some Applications

The number of applications of the BRST formalism is so large that it would be out of place to try being exhaustive here. Some of its main successes are outlined here, with suggestions for "Further reading."

### Renormalization of Gauge Theories

First, there is the original context of perturbative renormalization and anomalies for gauge theories of the Yang–Mills type. The relevant cohomology here is the BRST cohomology in the space of local functionals involving the fields, the ghosts, and the antifields. The antifields are also known in this context as Zinn-Justin sources for the BRST variations of the fields and ghosts, since Zinn-Justin was the first to introduce them (with that meaning). Many authors have contributed to the full computation of the local BRST cohomology. A review is given in Barnich *et al.* (2000), where extensions to other theories are also indicated.

### String Theory

Modern string theory would be inconceivable without the BRST formalism. This started with the pioneering paper by Kato and Ogawa (1983), where the critical dimension of the bosonic string was derived from the condition that $\Omega^2$ should vanish (quantum mechanically), and where it was shown that the string physical states could be identified with the state BRST cohomology. The reader is referred to excellent monographs on modern string theory (see "Further reading").

### Deformations of Gauge Models

The study of consistent deformations of a given gauge theory (i.e., the problem of introducing consistent couplings) is also efficiently dealt with in the BRST context. References to applications may be found in Henneaux (1998).

## $C^*$-Algebras and their Classification

**G A Elliott**, University of Toronto, Toronto, Canada

The study of algebras of Hilbert space operators, closed under the adjoint operation and in the weak operator topology, was begun by John von Neumann shortly after the discovery of quantum mechanics, and partly with the aim of understanding the monolithic ideas proposed by Heisenberg and Schrödinger.

Seventy-five years later, the theory of these algebras has become a monolith in its own right (*see* von Neumann Algebras: Introduction, Modular Theory and Classification Theory; von Neumann Algebras: Subfactor Theory), with more internal structure and with more external reference to physics and, as it turns out, to other areas of mathematics than could possibly have been imagined at the outset. (The most striking example of an application to mathematics is perhaps the discovery of the Jones knot polynomial (*see* The Jones Polynomial); note that this has also had repercussions for physics.)

Twenty-five years after the beginning of the theory of von Neumann algebras, as these algebras are now called, Gelfand and Naimark noticed that a second class of algebras of operators on a Hilbert space, closed under the adjoint operation, was worthy of study, namely those closed in the norm topology. Gelfand and Naimark made two important discoveries concerning this class of operator algebras, now called $C^*$-algebras.

First, Gelfand and Naimark showed that, in the commutative case, at least when the $C^*$-algebra is considered only up to isomorphism – with its identity as a concrete algebra of operators suppressed – the information contained in a $C^*$-algebra is purely topological. More precisely, Gelfand and Naimark showed that the category of unital commutative $C^*$-algebras, with unit-preserving algebra homomorphisms (these necessarily preserve the adjoint operation), is equivalent in a contravariant way (i.e., with reversal of arrows) to the category of compact Hausdorff spaces, with continuous maps. The compact space associated with a unital commutative $C^*$-algebra under the Gelfand–Naimark correspondence may be viewed as the space of maximal proper ideals, with a natural topology (the hull-kernel, or Jacobson, topology), and is called the spectrum. This space may also be viewed as the set of (unital, linear, multiplicative) maps from the algebra into the complex numbers, in which case the topology is that of pointwise convergence.

Second, using this result, Gelfand and Naimark proved that arbitrary $C^*$-algebras could be axiomatized in a simple way abstractly, as $^*$-algebras – that is, as algebras over the complex numbers with a conjugate linear anti-automorphism of order 2 – with certain special properties. It is now known that the only property that needs to be assumed is the existence of a (necessarily unique) Banach space norm related to the $^*$-algebra structure by means of the so-called $C^*$-algebra identity:

$$\|x^*x\| = \|x^*\|\,\|x\| \qquad [1]$$

This is clearly related to – and in fact implies – the normed algebra inequality

$$\|xy\| \leq \|x\|\,\|y\| \qquad [2]$$

One reason that the Gelfand–Naimark axiomatization of $C^*$-algebras is important is that it underlines how natural it is to consider a $C^*$-algebra abstractly, i.e., independently of any particular representation. Indeed, while one of the fundamental phenomena of von Neumann algebra theory (discovered by Murray and von Neumann) is that, essentially – in rather a strong sense – there is only one way to represent a given von Neumann algebra on a Hilbert space (and there is even a canonical way, called the standard representation!), it is an equally fundamental phenomenon of $C^*$-algebra theory that, except in extremely special cases, this is no longer true.

For instance, although the $C^*$-algebra of compact operators on a given Hilbert space has, up to unitary equivalence, only a single irreducible representation – this is what underlies the fact, proved by von Neumann, referred to as the uniqueness of the

Heisenberg commutation relations for a quantum-mechanical system with finitely many degrees of freedom – as soon as one considers a physical system with infinitely many degrees of freedom, one finds that the naturally associated $C^*$-algebra has infinitely many – indeed, uncountably many – unitary equivalence classes of irreducible representations, and it is impossible to parametrize these in any reasonable way.

This striking dichotomy presents itself also in other contexts, more elementary perhaps than the physics of infinitely many degrees of freedom. Consider the dynamical system consisting of a circle and a fixed rotation acting on it. If the rotation is of finite order – i.e., if the angle is a rational multiple of $2\pi$ – then the naturally associated $C^*$-algebra is relatively easy to study. In the case of angle zero, it is the unital commutative $C^*$-algebra with Gelfand–Naimark spectrum the torus. In the general case of a rational angle, the space of unitary equivalence classes of irreducible representations is still naturally parametrized by the torus. (And this is the same as the space of primitive ideals – the kernels of the irreducible representations – with the Jacobson topology.)

In the irrational case – the case of a rotation by an irrational multiple of $2\pi$ (still elementary from a geometrical point of view; note that the calendar is based on such a system!) – the irreducible representations are no longer parametrized up to unitary equivalence by the torus – and the space of primitive ideals consists of a single point – the $C^*$-algebra is simple. (But it is decidedly not simple to study!)

This fundamental dichotomy in the classification of $C^*$-algebras – conjectured by Gaarding and Wightman in the quantum-mechanical setting and by Mackey in the geometrical one – was established by Glimm. Glimm proved (in the setting of separability; most of his results were generalized later to the nonseparable case) that a large number of *a priori* different ways that a $C^*$-algebra could behave well were in fact one and the same behavior: either all present for a given $C^*$-algebra, or all catastrophically absent!

Some of the properties considered by Glimm, and shown to be equivalent (for a separable $C^*$-algebra) were as follows. First of all, every representation of the $C^*$-algebra on a Hilbert space should be of type I, i.e., should generate a von Neumann algebra of type I. (A von Neumann algebra was said by Murray and von Neumann to be of type I if it contained a minimal projection of central support one, i.e., a projection not contained in a proper direct summand and minimal with this property.) Second, in every irreducible representation (not necessarily injective) on a Hilbert space, the image of the $C^*$-algebra should contain the compact operators. Third, any two irreducible representations with the same kernel should be unitarily equivalent. Fourth, it should be possible to parametrize the unitary equivalence classes of irreducible representations by a real number in a natural way (respecting the natural Borel structure introduced by Mackey).

The first of the equivalent properties listed above, that all representations of a $C^*$-algebra should be of type I, suggested a name for the property – that the $C^*$-algebra itself should be of type I. This property of a $C^*$-algebra, identified by Glimm – or, rather, its opposite, which as mentioned above is much more common (just as irrational numbers are more common than rationals, or systems with infinitely many degrees of freedom are, at least in theory, much more common than those with finitely many degrees of freedom) – is a fundamental unifying principle of nature.

Besides commutative $C^*$-algebras – as mentioned above, just another way of looking at topological spaces (compact Hausdorff spaces, that is) – and besides the $C^*$-algebra associated to a rotation or to a physical system with infinitely many degrees of freedom, what are some of the naturally occurring examples of $C^*$-algebras – of type I or not!

First, let us take a closer look at what arises from a system with infinitely many degrees of freedom – in the fermion case. As shown by Jordan and Wigner, one obtains what, as a $C^*$-algebra, is very easy to describe, namely, just the infinite tensor product in the category of unital $C^*$-algebras of copies of the algebra of $2 \times 2$ matrices over the complex numbers. As it happens, in work earlier than that referred to above, Glimm had considered such infinite tensor product $C^*$-algebras, also allowing the components to be matrix algebras of order different from two. This raised a problem of classification – for those $C^*$-algebras, all of which were simple and not of type I. (The only simple unital $C^*$-algebra of type I is a single matrix algebra, or a finite tensor product of matrix algebras!)

In a pioneering classification paper (the first paper on the classification of $C^*$-algebras being perhaps that of Gelfand and Naimark, in which the commutative case was described), Glimm obtained the classification of infinite tensor products of matrix algebras, showing that it was a direct extension of the classification of finite tensor products, i.e., just of the matrix algebras themselves. As described later by Dixmier, Glimm's classification was as follows. Given a sequence $n_1, n_2, \ldots$ of natural numbers (equal to one or more), form the infinite product in a natural way – just by keeping track of the total number of times each prime number appears in the

finite products $n_1 \ldots n_k$ (a multiplicity which may be either finite or infinite). Call such a formal infinite product a generalized integer – or, perhaps, a supernatural number! Two (countably) infinite tensor products of matrix algebras are isomorphic (just as in the finite tensor product case) if and only if the corresponding supernatural numbers are equal.

In formulating Glimm's classification of infinite tensor products of matrix algebras in this way, Dixmier pointed out that each supernatural number determines a subgroup of the rational numbers (those with denominator dividing the supernatural number) and that every subgroup of the rational numbers containing the integers arises in this way. He then gave an alternative derivation of Glimm's theorem by recovering this subgroup of the rational numbers as a natural invariant of the algebra, namely, as the subgroup generated by the values on projections of the unique normalized trace. (By a trace is meant here a unitarily invariant positive linear functional.) This could even be interpreted as an alternative statement of Glimm's theorem.

Soon afterwards, Bratteli considered an extension of Glimm's class of $C^*$-algebras, namely, the inductive limits of arbitrary sequences of finite-dimensional $C^*$-algebras, and gave a classification of these algebras in terms of the embedding multiplicity data in the sequences. This was exactly analogous to the original classification of Glimm, but now vastly more complex, with the multiplicity data of the sequence encoded in what is now called a Bratteli diagram. (Note that a finite-dimensional $C^*$-algebra is just a direct sum of matrix algebras over the complex numbers.) Bratteli diagrams have proved to be very important, and in particular have been shown by Putnam and others to be useful for the study of minimal homeomorphisms of the Cantor set.

Bratteli's extension of Glimm's tensor product classification was followed by a corresponding extension by the present author of Dixmier's approach to Glimm's result. It was no longer possible to express the appropriate data in terms of traces (even in the case of a unique normalized trace). Instead, the present author recalled the concept of equivalence of projections introduced by Murray and von Neumann forty years earlier, together with the fact, proved by Murray and von Neumann, that equivalence is compatible with addition of orthogonal projections. (Two projections in a $^*$-algebra are equivalent if they are equal to $x^*x$ and $xx^*$ for some element $x$.) The resulting elementary invariant – the set of equivalence classes of projections with the operation of addition whenever defined (whenever the equivalence classes to be added have orthogonal representatives) – one might refer to this as a local abelian semigroup – which was used by Murray and von Neumann to divide von Neumann algebras into what they called types I, II, and III – was shown by the author to determine Bratteli's algebras up to isomorphism.

Bratteli called his algebras approximately finite-dimensional $C^*$-algebras, or AF algebras. The author referred to his invariant simply as the range of the (abstract) dimension, and pointed out that this structure determined an enveloping ordered abelian group, which he called the dimension group. It was soon noticed that the dimension group was related to the $K$-group introduced by Grothendieck in algebraic geometry (*see* $K$-Theory), and by Atiyah and Hirzebruch (*see* $K$-Theory) in topology.

Grothendieck's $K$-group was defined for an arbitrary ring with unit, and Atiyah and Hirzebruch in effect considered the special case of the ring of continuous functions on a compact Hausdorff space – in other words, a commutative $C^*$-algebra – in the process showing that the deep phenomenon of Bott periodicity could be expressed in terms of this invariant. The invariant itself (see below) is essentially the same as that of Murray and von Neumann. In the special case that the ring is an AF algebra, the $K$-group coincides with the dimension group. (The $K$-group has a natural ordered, or pre-ordered, structure, although this was often suppressed.)

Let us consider the definition of the $K$-group of a not necessarily unital $C^*$-algebra; it is in this setting that the statement of Bott periodicity attains its simplest form.

First, in the unital case, one constructs the abelian local semigroup (addition just partially defined) of Murray–von Neumann equivalence classes of projections, as described above in the case of an AF algebra. Let us call this the dimension range. As stated above, for AF algebras this is all that needs to be done – the enveloping group of the dimension range is already the $K$-group. In the general case, one must repeat the construction for the algebra of $2 \times 2$ matrices over the given algebra, with the given algebra considered as embedded as the upper left-hand corner of the matrix algebra. The dimension range of the given algebra then maps naturally into (but not necessarily onto) the dimension range of the matrix algebra. One should then repeat this construction, doubling the order of the matrix algebra at every stage (or, alternatively, increasing it just by one). The enveloping group of the (algebraic) inductive limit of this sequence of local semigroups is then the $K$-group of the given algebra. (Alternatively, one may just consider immediately the $^*$-algebra of all infinite matrices over the given

$C^*$-algebra with only finitely many nonzero entries, and form the dimension range of this $^*$-algebra – and the enveloping group of this abelian local semigroup, now in fact a semigroup.)

In the case of a nonunital $C^*$-algebra, one adjoins a unit (as may be done, for instance, by representing the $C^*$-algebra faithfully on a Hilbert space, and showing that the $C^*$-algebra obtained by adjoining the identity operator is independent of the representation – actually, one need only check that the $^*$-algebra structure is unique, as the $C^*$-algebra norm on a $C^*$-algebra is always determined by the $^*$-algebra structure). The $K$-group of the resulting unital $C^*$-algebra then maps naturally into the $K$-group of the natural one-dimensional quotient, and the kernel of this map is, for reasons that will become clearer later, defined to be the $K$-group of the nonunital algebra.

Atiyah and Hirzebruch in fact referred to the $K$-group of the $C^*$-algebra as $K_0$ – the reason being that there is another very natural group to consider, namely, the $K$-group of the suspension of the $C^*$-algebra. (The suspension, $SA$, of a $C^*$-algebra $A$ is defined as the $C^*$-algebra of all continuous functions from the real line $\mathbb{R}$ into $A$ which converge to zero at $\pm\infty$, with the pointwise $^*$-algebra operations and the supremum norm. It may also be defined as the (unique) $C^*$-algebra tensor product $A \otimes C_0(\mathbb{R})$, where $C_0(\mathbb{R})$ denotes the suspension of the $C^*$-algebra $\mathbb{C}$ of complex numbers.) Denoting the $K_0$-group of the suspension of a given $C^*$-algebra by $K_1$, one might expect this process to continue, but in fact it is periodic $(K_0, K_1, K_0, K_1, \ldots)$. Bott periodicity states that there is a natural isomorphism of $K_2$ with $K_0$. ($C^*$-algebras can also be defined with the field of real numbers as scalars, and in this case the period of Bott periodicity is eight.)

Another way of stating Bott periodicity, or, more precisely, of embedding it into the $K$-theory of $C^*$-algebras, is as follows. Given a short exact sequence of $C^*$-algebras,

$$0 \to J \to A \to A/J \to 0 \qquad [3]$$

i.e., given a $C^*$-algebra $A$ and a closed two-sided ideal $J$ (the quotient $^*$-algebra is then a $C^*$-algebra with the quotient norm) – $A$ is sometimes referred to as an extension of $J$ by $A/J$ – consider the natural short (not necessarily exact) sequences

$$K_0(J) \to K_0(A) \to K_0(A/J) \qquad [4]$$

and

$$K_1(J) \to K_1(A) \to K_1(A/J) \qquad [5]$$

($K_0$ and $K_1$ are functors!). There exist natural connecting maps $K_1(A/J) \to K_0(J)$ and $K_0(A/J) \to K_1(J)$ – the first referred to as the index map, and the second (sometimes referred to as the odd-order index map) obtained from this immediately from Bott periodicity (as stated above) – such that the periodic six-term sequence

$$\begin{array}{ccccc} K_0(J) & \to & K_0(A) & \to & K_0(A/J) \\ \uparrow & & & & \downarrow \\ K_1(A/J) & \leftarrow & K_1(A) & \leftarrow & K_1(J) \end{array}$$

is exact. (The periodicity stated above can also be recovered from this.)

Given that the functor $K_0$ classifies AF algebras, one might expect the functor $K_1$ to be useful for classification purposes also. In fact, this is the case. (Indeed, as shown by Brown, the $K_1$-functor is already important for the theory of AF algebras – in spite of, or even because of (!), the fact that the $K_1$-group of an AF algebra is zero.) Using the six-term exact sequence of Bott periodicity described above, corresponding to an extension of $C^*$-algebras, together with results of the present author, Brown showed that any extension of one AF algebra by another is again an AF algebra.

A rather large class of simple unital $C^*$-algebras has by now been classified by means of the invariants $K_0$ and $K_1$ – together with the class of the unit in $K_0$, and the order (or pre-order) structure on $K_0$ – and also taking into account the compact convex set of tracial states on the $C^*$-algebra (a positive linear functional on a $C^*$-algebra is called a trace if it has the same value on $x^*x$ and $xx^*$ for every element $x$, and a tracial state if it is a state, that is, has norm 1, or has value 1 on the unit in the case the algebra has a unit). In addition to the set of tracial states, together with its natural topology and convex structure, one should also keep track of the natural pairing between traces and $K_0$ (any trace on a unital $C^*$-algebra has the same value on two equivalent projections – equal to $x^*x$ and $xx^*$ for some element $x$ – and hence gives rise to an additive real-valued functional on $K_0$).

In terms of these invariants (which might, broadly speaking, be called $K$-theoretical), it has been possible to classify the simple unital $C^*$-algebras (not of type I) arising as inductive limits (i.e., as the completions of increasing unions) of sequences of finite direct sums of matrix algebras over separable commutative $C^*$-algebras, these assumed to have spectra of dimension at most three, on the one hand (work of the present author together with Guihua Gong and Liangqing Li, a culmination of earlier work of these authors together with a number of others), and, on the other hand, it has been possible (work of Kirchberg and Phillips, also based on earlier work by a number of authors) to classify the

$C^*$-algebra tensor products (in a natural sense) of these $C^*$-algebras with what is called the Cuntz $C^*$-algebra $O_\infty$ (see below). In the first of these two cases, the compact convex set of tracial states – always a Choquet simplex – is an arbitrary (metrizable) such space.

In the second case, this space is empty (as it is for $O_\infty$ in particular). In both cases, $K_0$ and $K_1$ are arbitrary countable abelian groups, with the proviso that $K_0$ is not the sum of a torsion group and a cyclic group. In the first case, the order structure on $K_0$, the class of the unit element, and the pairing of $K_0$ with the space of traces have certain special properties; as it turns out, these can be expressed in a simple way. (The class of the unit need only be positive and nonzero.) In the second case, the order structure on $K_0$ is degenerate – every element is positive – and the class of the unit can be arbitrary (including zero!).

Let us just note that the Cuntz $C^*$-algebra $O_\infty$ is the unital $C^*$-algebra generated by an infinite sequence $s_1, s_2, \ldots$ of isometries with orthogonal ranges (in other words, elements $s_i$ such that $s_i^* s_i$ is the unit and $s_j^* s_i = 0$ if $j \neq i$). One need not require the $C^*$-algebra to have the universal property with respect to these generators and relations as it is in fact unique (up to an isomorphism preserving these generators). In particular, this $C^*$-algebra is simple. (If one considers a finite sequence of isometries with orthogonal ranges, and assumes in addition that the sum of these is the unit, one also obtains a simple $C^*$-algebra, the Cuntz $C^*$-algebra $O_n$, $n = 2, 3, \ldots$). The $K_0$-group and $K_1$-group of $O_\infty$ are, respectively, $\mathbb{Z}$ and 0. (The $K_0$-group and $K_1$-groups of $O_n$ for $n = 2, 3, \ldots$ are, respectively, $\mathbb{Z}/(n-1)\mathbb{Z}$ and 0.)

Both classes of $C^*$-algebras considered in the classification result stated above, although described in rather a concrete way (in terms of inductive limits and tensor products), can also be characterized axiomatically, in a way that makes it clear that they are, in fact, much more general than they seem. (These axiomatizations are due to Lin and to Kirchberg and Phillips. Typically, the abstract axioms are easier to establish in a given case than the inductive limit form described above.)

In view of this, and the fact that one of the axioms is a notion of amenability (the analogous property for $C^*$-algebras of a notion that has also been considered for von Neumann algebras) and since amenable von Neumann algebras (on a separable Hilbert space) have been classified completely (in remarkable work of Connes, together with many others, starting with Murray and von Neumann – and, one must also mention, ending with Haagerup, who settled a particularly stubborn case), it is natural to ask whether the $K$-theoretical invariants described above might be sufficient to classify all amenable separable $C^*$-algebras, say, those which are simple and unital.

The work of Villadsen has shown that additional invariants must in fact be considered, if one is to deal with arbitrary amenable simple $C^*$-algebras, and this has been confirmed in subsequent work of Rørdam and of Toms. (Villadsen's examples were obtained by removing the condition of low dimension on the spectra of the commutative $C^*$-algebras appearing in the inductive limit decomposition considered above.) The very nature of these authors' work, however, has been to introduce additional invariants, all of which it seems natural to consider as, broadly speaking, $K$-theoretical. (And all of which, as it happens, are already familiar.)

The question of the classifiability, in terms of simple invariants ($K$-theoretical in nature, at least in the broad sense, and including the spectrum which is indispensable in the nonsimple case), of all (separable) amenable $C^*$-algebras would therefore still appear to be on the agenda.

Already, in any case, just like the analogous question for von Neumann algebras (now settled), this question would appear to have had a noticeable influence on the development of the subject – not least in underlining the importance of $K$-theoretical methods, which have proved to be pertinent both in connection with the index theory of differential operators on geometrical structures – from foliations to fractals – and in connection with questions in physics, related to quantum statistical mechanics (*see* e.g., Quantum Hall Effect), to quantum field theory (e.g., the standard model), and even to string theory and $M$-theory.

# Calibrated Geometry and Special Lagrangian Submanifolds

**D D Joyce**, University of Oxford, Oxford, UK

## Calibrated Geometry

"Calibrated geometry," introduced by Harvey and Lawson (1982), is the study of special classes of "minimal submanifolds" $N$ of a Riemannian manifold $(M,g)$, defined using a closed form $\varphi$ on $M$ called a calibration. For example, if $(M,J,g)$ is a Kähler manifold with Kähler form $\omega$, then complex $k$-submanifolds of $M$ are calibrated with respect to $\varphi=\omega^k/k!$. Another important class of calibrated submanifolds are special Lagrangian submanifolds in Calabi–Yau manifolds, which is the focus of the section "Special Lagrangian geometry."

### Calibrations and Calibrated Submanifolds

We begin by defining "calibrations" and "calibrated submanifolds."

**Definition 1** Let $(M,g)$ be a Riemannian manifold. An "oriented tangent $k$-plane" $V$ on $M$ is a vector subspace $V$ of some tangent space $T_xM$ to $M$ with $\dim V=k$, equipped with an orientation. If $V$ is an oriented tangent $k$-plane on $M$ then $g|_V$ is a Euclidean metric on $V$; so, combining $g|_V$ with the orientation on $V$ gives a natural volume form $\mathrm{vol}_V$ on $V$, which is a $k$-form on $V$.

Now let $\varphi$ be a closed $k$-form on $M$. $\varphi$ is said to be a calibration on $M$, if for every oriented $k$-plane $V$ on $M$, $\varphi|_V \le \mathrm{vol}_V$. Here, $\varphi|_V=\alpha\cdot\mathrm{vol}_V$ for some $\alpha\in\mathbb{R}$, and $\varphi|_V\le\mathrm{vol}_V$ if $\alpha\le 1$. Let $N$ be an oriented submanifold of $M$ with dimension $k$. Then each tangent space $T_xN$ for $x\in N$ is an oriented tangent $k$-plane. We say that $N$ is a calibrated submanifold if $\varphi|_{T_xN}=\mathrm{vol}_{T_xN}$ for all $x\in N$.

It is easy to show that calibrated submanifolds are automatically "minimal submanifolds." We prove this in the compact case, but noncompact calibrated submanifolds are locally volume-minimizing as well.

**Proposition 2** *Let $(M,g)$ be a Riemannian manifold, $\varphi$ a calibration on $M$, and $N$ a compact $\varphi$-submanifold in $M$. Then $N$ is volume-minimizing in its homology class.*

**Proof** Let $\dim N=k$, and let $[N]\in H_k(M,\mathbb{R})$ and $[\varphi]\in H^k(M,\mathbb{R})$ be the homology and cohomology classes of $N$ and $\varphi$. Then

$$[\varphi]\cdot[N]=\int_{x\in N}\varphi|_{T_xN}=\int_{x\in N}\mathrm{vol}_{T_xN}=\mathrm{Vol}(N)$$

since $\varphi|_{T_xN}=\mathrm{vol}_{T_xN}$ for each $x\in N$, as $N$ is a calibrated submanifold. If $N'$ is any other compact $k$-submanifold of $M$ with $[N']=[N]$ in $H_k(M,\mathbb{R})$, then

$$[\varphi]\cdot[N]=[\varphi]\cdot[N']=\int_{x\in N'}\varphi|_{T_xN'}\le\int_{x\in N'}\mathrm{vol}_{T_xN'}=\mathrm{Vol}(N')$$

since $\varphi|_{T_xN'}\le\mathrm{vol}_{T_xN'}$ because $\varphi$ is a calibration. The last two equations give $\mathrm{Vol}(N)\le\mathrm{Vol}(N')$. Thus, $N$ is volume-minimizing in its homology class. □

Now let $(M,g)$ be a Riemannian manifold with a calibration $\varphi$, and let $\iota:N\to M$ be an immersed submanifold. Whether $N$ is a $\varphi$-submanifold depends upon the tangent spaces of $N$. That is, it depends on $\iota$ and its first derivative. So, for $N$ to be calibrated with respect to $\varphi$ is a first-order partial differential equation on $\iota$. But if $N$ is calibrated then $N$ is minimal, and for $N$ to be minimal is a second-order partial differential equation on $\iota$.

One moral is that the calibrated equations, being first order, are often easier to solve than the minimal submanifold equations, which are second order. So calibrated geometry is a fertile source of examples of minimal submanifolds.

### Calibrated Submanifolds and Special Holonomy

A calibration $\varphi$ on $(M,g)$ is only interesting if there exist plenty of $\varphi$-submanifolds $N$ in $M$, locally or globally. Since $\varphi|_{T_xN}=\mathrm{vol}_{T_xN}$ for each $x\in N$, $\varphi$-submanifolds will be abundant only if the family $\mathcal{F}_\varphi$ of calibrated tangent $k$-planes $V$ with $\varphi|_V=\mathrm{vol}_V$

is "reasonably large" – say, if $\mathcal{F}_\varphi$ has small codimension in the family of all tangent $k$-planes $V$ on $M$. A maximally boring example is the $k$-form $\varphi = 0$, which is a calibration but has no calibrated tangent $k$-planes, so no $\varphi$-submanifolds.

Thus, most calibrations $\varphi$ will have few or no $\varphi$-submanifolds, and only special calibrations $\varphi$ with $\mathcal{F}_\varphi$ large will have interesting calibrated geometries. Now the field of Riemannian holonomy groups is a natural companion for calibrated geometry, because it gives a simple way to generate interesting calibrations $\varphi$ which automatically have $\mathcal{F}_\varphi$ large.

Let $G \subset \mathrm{O}(n)$ be a possible holonomy group of a Riemannian metric. In particular, we can take $G$ to be one of the holonomy groups $\mathrm{U}(m)$, $\mathrm{SU}(m)$, $\mathrm{Sp}(m)$, $G_2$, or Spin(7) from Berger's classification. Then $G$ acts on the $k$-forms $\Lambda^k(\mathbb{R}^n)^*$ on $\mathbb{R}^n$, so we can look for $G$-invariant $k$-forms on $\mathbb{R}^n$. Suppose $\varphi_0$ is a nonzero, $G$-invariant $k$-form on $\mathbb{R}^n$.

By rescaling $\varphi_0$ we can be arrange that for each oriented $k$-plane $U \subset \mathbb{R}^n$, we have $\varphi_0|_U \le \mathrm{vol}_U$, and that $\varphi_0|_U = \mathrm{vol}_U$ for at least one such $U$. Let $H$ be the stabilizer subgroup of this $U$ in $G$. Then $\varphi_0|_{\gamma\cdot U} = \mathrm{vol}_{\gamma\cdot U}$ by $G$-invariance, so $\gamma \cdot U$ is a calibrated $k$-plane for all $\gamma \in G$. Thus, the family $\mathcal{F}_0$ of $\varphi_0$-calibrated $k$-planes in $\mathbb{R}^n$ contains $G/H$, so it is "reasonably large," and it is likely that the calibrated submanifolds will have an interesting geometry.

Now let $M$ be a manifold of dimension $n$, and $g$ a metric on $M$ with Levi-Civita connection $\nabla$ and holonomy group $G$. Then there is a $k$-form $\varphi$ on $M$ with $\nabla\varphi = 0$, corresponding to $\varphi_0$. Hence $\mathrm{d}\varphi = 0$, and $\varphi$ is closed. Also, the condition $\varphi_0|_U \le \mathrm{vol}_U$ for all oriented $k$-planes $U$ in $\mathbb{R}^n$ implies that $\varphi|_V \le \mathrm{vol}_V$ for all oriented tangent $k$-planes $V$ in $M$. Thus, $\varphi$ is a calibration on $M$. The family $\mathcal{F}_\varphi$ of calibrated tangent $k$-planes on $M$ fibers over $M$ with fiber $\mathcal{F}_0$; so, it is "reasonably large."

This gives a general method for finding interesting calibrations on manifolds with reduced holonomy. Here are the most significant examples.

- Let $G = \mathrm{U}(m) \subset \mathrm{O}(2m)$. Then $G$ preserves a 2-form $\omega_0$ on $\mathbb{R}^{2m}$. If $g$ is a metric on $M$ with holonomy $\mathrm{U}(m)$, then $g$ is Kähler with complex structure $J$, and the 2-form $\omega$ on $M$ associated to $\omega_0$ is the Kähler form of $g$.

  One can show that $\omega$ is a calibration on $(M,g)$, and the calibrated submanifolds are exactly the "holomorphic curves" in $(M,J)$. More generally, $\omega^k/k!$ is a calibration on $M$ for $1 \le k \le m$, and the corresponding calibrated submanifolds are the complex $k$-dimensional submanifolds of $(M,J)$.
- Let $G = \mathrm{SU}(m) \subset \mathrm{O}(2m)$. Then $G$ preserves a complex volume form $\Omega_0 = \mathrm{d}z_1 \wedge \cdots \wedge \mathrm{d}z_m$ on $\mathbb{C}^m$. Thus, a Calabi–Yau $m$-fold $(M,g)$ with $\mathrm{Hol}(g) = \mathrm{SU}(m)$ has a holomorphic volume form $\Omega$. The real part $\mathrm{Re}\,\Omega$ is a calibration on $M$, and the corresponding calibrated submanifolds are called special Lagrangian submanifolds.
- The group $G_2 \subset \mathrm{O}(7)$ preserves a 3-form $\varphi_0$ and a 4-form $*\varphi_0$ on $\mathbb{R}^7$. Thus, a Riemannian 7-manifold $(M,g)$ with holonomy $G_2$ comes with a 3-form $\varphi$ and 4-form $*\varphi$, which are both calibrations. The corresponding calibrated submanifolds are called associative 3-folds and coassociative 4-folds.
- The group $\mathrm{Spin}(7) \subset \mathrm{O}(8)$ preserves a 4-form $\Omega_0$ on $\mathbb{R}^8$. Thus a Riemannian 8-manifold $(M,g)$ with holonomy Spin(7) has a 4-form $\Omega$, which is a calibration. The $\Omega$-submanifolds are called Cayley 4-folds.

It is an important general principle that to each calibration $\varphi$ on an $n$-manifold $(M,g)$ with special holonomy constructed in this way, there corresponds a constant calibration $\varphi_0$ on $\mathbb{R}^n$. Locally, $\varphi$-submanifolds in $M$ resemble the $\varphi_0$-submanifolds in $\mathbb{R}^n$, and have many of the same properties. Thus, to understand the calibrated submanifolds in a manifold with special holonomy, it is often a good idea to start by studying the corresponding calibrated submanifolds of $\mathbb{R}^n$.

In particular, singularities of $\varphi$-submanifolds in $M$ will be locally modeled on singularities of $\varphi_0$-submanifolds in $\mathbb{R}^n$. (In the sense of geometric measure theory, the tangent cone at a singular point of a $\varphi$-submanifold in $M$ is a conical $\varphi_0$-submanifold in $\mathbb{R}^n$.) So by studying singular $\varphi_0$-submanifolds in $\mathbb{R}^n$, we may understand the singular behavior of $\varphi$-submanifolds in $M$.

## Special Lagrangian Geometry

We now focus on one class of calibrated submanifolds, special Lagrangian submanifolds in Calabi–Yau manifolds. Calabi–Yau 3-folds are used to make the spacetime vacuum in string theory, and special Lagrangian 3-folds are the classical versions of A-branes, or supersymmetric 3-cycles, in Calabi–Yau 3-folds. Special Lagrangian geometry aroused great interest amongst string theorists because of its rôle in the SYZ conjecture, providing a geometric basis for "mirror symmetry" of Calabi–Yau 3-folds.

### Calabi–Yau Manifolds

Here is our definition of Calabi–Yau manifold. Readers are warned that there are several different definitions of Calabi–Yau manifolds in use in the literature. Ours is unusual in regarding $\Omega$ as part of the given structure.

**Definition 3** Let $m \geq 2$. A Calabi–Yau $m$-fold is a quadruple $(M, J, g, \Omega)$ such that $(M, J)$ is a compact $m$-dimensional complex manifold, $g$ a Kähler metric on $(M, J)$ with Kähler form $\omega$, and $\Omega$ a holomorphic $(m, 0)$-form on $M$ called the holomorphic volume form, which satisfies

$$\omega^m/m! = (-1)^{m(m-1)/2}(\mathrm{i}/2)^m \Omega \wedge \bar{\Omega} \qquad [1]$$

The constant factor in [1] is chosen to make $\mathrm{Re}\,\Omega$ a calibration. It follows from [1] that $g$ is Ricci-flat, $\Omega$ is constant under the Levi-Civita connection, and the holonomy group of $g$ has $\mathrm{Hol}(g) \subseteq \mathrm{SU}(m)$.

Let $(M, J)$ be a compact, complex manifold, and $g$ a Kähler metric on $M$, with Ricci curvature $R_{ab}$. Define the Ricci form $\rho$ of $g$ by $\rho_{ac} = J_a^b R_{bc}$. Then $\rho$ is a closed real $(1, 1)$-form on $M$, with de Rham cohomology class $[\rho] = 2\pi c_1(M) \in H^2(M, \mathbb{R})$, where $c_1(M)$ is the first Chern class of $M$ in $H^2(M, \mathbb{Z})$. The Calabi conjecture specifies which closed $(1, 1)$-forms can be the Ricci forms of a Kähler metric on $M$.

**The Calabi conjecture** *Let $(M, J)$ be a compact, complex manifold, and $g'$ a Kähler metric on $M$, with Kähler form $\omega'$. Suppose that $\rho$ is a real, closed $(1, 1)$-form on $M$ with $[\rho] = 2\pi c_1(M)$. Then there exists a unique Kähler metric $g$ on $M$ with Kähler form $\omega$, such that $[\omega] = [\omega'] \in H^2(M, \mathbb{R})$, and the Ricci form of $g$ is $\rho$.*

Note that $[\omega] = [\omega']$ says that $g$ and $g'$ are in the same Kähler class. The conjecture was posed by Calabi in 1954, and was eventually proved by Yau in 1976. Its importance to us is that when the canonical bundle $K_M$ is trivial, so that $c_1(M) = 0$, we can take $\rho \equiv 0$, and then $g$ is Ricci-flat. Since $K_M$ is trivial, it has a nonzero holomorphic section, a holomorphic $(m, 0)$-form $\Omega$. As $g$ is Ricci-flat, it follows that $\nabla\Omega = 0$, where $\nabla$ is the Levi-Civita connection of $g$. Rescaling $\Omega$ by a complex constant makes [1] hold, and then $(M, J, g, \Omega)$ is a Calabi–Yau $m$-fold. This proves:

**Theorem 4** *Let $(M, J)$ be a compact complex $m$-manifold with $K_M$ trivial. Then every Kähler class on $M$ contains a unique Ricci-flat Kähler metric $g$. There exists a holomorphic $(m, 0)$-form $\Omega$, unique up to change of phase $\Omega \mapsto \mathrm{e}^{\mathrm{i}\theta}\Omega$, such that $(M, J, g, \Omega)$ is a Calabi–Yau $m$-fold.*

Using algebraic geometry, one can produce many examples of complex $m$-folds $(M, J)$ satisfying these conditions, such as the Fermat $(m + 2)$-tic

$$\{[z_0, \ldots, z_{m+1}] \in \mathbb{CP}^{m+1} : z_0^{m+2} + \cdots + z_{m+1}^{m+2} = 0\} \qquad [2]$$

Therefore, Calabi–Yau $m$-folds are very abundant.

### Special Lagrangian Submanifolds

**Definition 5** Let $(M, J, g, \Omega)$ be a Calabi–Yau $m$-fold. Then $\mathrm{Re}\,\Omega$ is a calibration on the Riemannian manifold $(M, g)$. An oriented real $m$-dimensional submanifold $N$ in $M$ is called a special Lagrangian submanifold (SL $m$-fold) if it is calibrated with respect to $\mathrm{Re}\,\Omega$.

Here is an alternative definition of SL $m$-folds. It is often more useful than Definition 5.

**Proposition 6** *Let $(M, J, g, \Omega)$ be a Calabi–Yau $m$-fold, with Kähler form $\omega$, and $N$ a real $m$-dimensional submanifold in $M$. Then $N$ admits an orientation making it into an SL $m$-fold in $M$ if and only if $\omega|_N \equiv 0$ and $\mathrm{Im}\,\Omega|_N \equiv 0$.*

Regard $N$ as an immersed submanifold, with immersion $\iota : N \to M$. Then $[\omega|_N]$ and $[\mathrm{Im}\,\Omega|_N]$ are unchanged under continuous variations of the immersion $\iota$. Thus, $[\omega|_N] = [\mathrm{Im}\,\Omega|_N] = 0$ is a necessary condition not just for $N$ to be special Lagrangian, but also for any isotopic submanifold $N'$ in $M$ to be special Lagrangian. This proves:

**Corollary 7** *Let $(M, J, g, \Omega)$ be a Calabi–Yau $m$-fold, and $N$ a compact real $m$-submanifold in $M$. Then a necessary condition for $N$ to be isotopic to a special Lagrangian submanifold $N'$ in $M$ is that $[\omega|_N] = 0$ in $H^2(N, \mathbb{R})$ and $[\mathrm{Im}\,\Omega|_N] = 0$ in $H^m(N, \mathbb{R})$.*

### Deformations of Compact SL *m*-Folds

The deformation theory of compact special Lagrangian manifolds was studied by McLean (1998), who proved the following result:

**Theorem 8** *Let $(M, J, g, \Omega)$ be a Calabi–Yau $m$-fold, and $N$ a compact special Lagrangian $m$-fold in $M$. Then the moduli space $\mathcal{M}_N$ of special Lagrangian deformations of $N$ is a smooth manifold of dimension $b^1(N)$, the first Betti number of $N$.*

*Sketch proof*. Suppose for simplicity that $N$ is an embedded submanifold. There is a natural orthogonal decomposition $TM|_N = TN \oplus \nu$, where $\nu \to N$ is the normal bundle of $N$ in $M$. As $N$ is Lagrangian, the complex structure $J : TM \to TM$ gives an isomorphism $J : \nu \to TN$. But the metric $g$ gives an isomorphism $TN \cong T^*N$. Composing these two gives an isomorphism $\nu \cong T^*N$.

Let $T$ be a small tubular neighborhood of $N$ in $M$. Then we can identify $T$ with a neighborhood of the zero section in $\nu$. Using the isomorphism $\nu \cong T^*N$, we have an identification between $T$ and a neighborhood of the zero section in $T^*N$. This can be chosen to identify the Kähler form $\omega$ on $T$ with the natural symplectic

structure on $T^*N$. Let $\pi: T \to N$ be the obvious projection.

Under this identification, submanifolds $N'$ in $T \subset M$ which are $C^1$ close to $N$ are identified with the graphs of small smooth sections $\alpha$ of $T^*N$. That is, submanifolds $N'$ of $M$ close to $N$ are identified with 1-forms $\alpha$ on $N$. We need to know: which 1-forms $\alpha$ are identified with SL $m$-folds $N'$?

Now, $N'$ is special Lagrangian if $\omega|_{N'} \equiv \operatorname{Im}\Omega|_{N'} \equiv 0$. But $\pi|_{N'}: N' \to N$ is a diffeomorphism, so we can push $\omega|_{N'}$ and $\operatorname{Im}\Omega|_{N'}$ down to $N$, and regard them as functions of $\alpha$. Calculation shows that

$$\pi_*(\omega|_{N'}) = \mathrm{d}\alpha \quad \text{and} \quad \pi_*(\operatorname{Im}\Omega|_{N'}) = F(\alpha, \nabla\alpha)$$

where $F$ is a nonlinear function of its arguments. Thus, the moduli space $\mathcal{M}_N$ is locally isomorphic to the set of small 1-forms $\alpha$ on $N$ such that $\mathrm{d}\alpha \equiv 0$ and $F(\alpha, \nabla\alpha) \equiv 0$.

Now it turns out that $F$ satisfies $F(\alpha, \nabla\alpha) \approx \mathrm{d}(*\alpha)$ when $\alpha$ is small. Therefore, $\mathcal{M}_N$ is locally approximately isomorphic to the vector space of 1-forms $\alpha$ with $\mathrm{d}\alpha = \mathrm{d}(*\alpha) = 0$. But by Hodge theory, this is isomorphic to the de Rham cohomology group $H^1(N, \mathbb{R})$, and is a manifold with dimension $b^1(N)$.

To carry out this last step rigorously requires some technical machinery: one must work with certain Banach spaces of sections of $T^*N$, $\Lambda^2 T^*N$ and $\Lambda^m T^*N$, use elliptic regularity results to prove that the map $\alpha \mapsto (\mathrm{d}\alpha,\ F(\alpha, \nabla\alpha))$ has closed image in these Banach spaces, and then use the implicit function theorem for Banach spaces to show that the kernel of the map is what is expected.

### Obstructions to Existence of Compact SL *m*-Folds

Let $\{(M, J_t, g_t, \Omega_t) : t \in (-\epsilon, \epsilon)\}$ be a smooth one-parameter family of Calabi–Yau $m$-folds. Suppose $N_0$ is an SL $m$-fold in $(M, J_0, g_0, \Omega_0)$. When can we extend $N_0$ to a smooth family of SL $m$-folds $N_t$ in $(M, J_t, g_t, \Omega_t)$ for $t \in (-\epsilon, \epsilon)$?

By Corollary 7, a necessary condition is that $[\omega_t|_{N_0}] = [\operatorname{Im}\Omega_t|_{N_0}] = 0$ for all $t$. Our next result shows that locally, this is also a sufficient condition.

**Theorem 9** *Let $\{(M, J_t, g_t, \Omega_t) : t \in (-\epsilon, \epsilon)\}$ be a smooth one-parameter family of Calabi–Yau m-folds, with Kähler forms $\omega_t$. Let $N_0$ be a compact* SL *m-fold in $(M, J_0, g_0, \Omega_0)$, and suppose that $[\omega_t|_{N_0}] = 0$ in $H^2(N_0, \mathbb{R})$ and $[\operatorname{Im}\Omega_t|_{N_0}] = 0$ in $H^m(N_0, \mathbb{R})$ for all $t \in (-\epsilon, \epsilon)$. Then $N_0$ extends to a smooth one-parameter family $\{N_t : \mathrm{t} \in (-\delta, \delta)\}$, where $0 < \delta \le \epsilon$ and $N_t$ is a compact* SL *m-fold in $(M, J_t, g_t, \Omega_t)$.*

This can be proved using similar techniques to Theorem 8. Note that the condition $[\operatorname{Im}\Omega_t|_{N_0}] = 0$ for all $t$ can be satisfied by choosing the phases of the $\Omega_t$ appropriately, and if the image of $H_2(N, \mathbb{Z})$ in $H_2(M, \mathbb{R})$ is zero, then the condition $[\omega|_N] = 0$ holds automatically.

Thus, the obstructions $[\omega_t|_{N_0}] = [\operatorname{Im}\Omega_t|_{N_0}] = 0$ in Theorem 9 are actually fairly mild restrictions, and SL $m$-folds should be considered as pretty stable under small deformations of the Calabi–Yau structure.

**Remark** The deformation and obstruction theory of compact SL $m$-folds are extremely well behaved compared to many other moduli space problems in differential geometry. In other geometric problems (such as the deformations of complex structures on a complex manifold, or pseudoholomorphic curves in an almost-complex manifold, or instantons on a Riemannian 4-manifold), the deformation theory often has the following general structure.

There are vector bundles $E$, $F$ over a compact manifold $M$, and an elliptic operator $P: C^\infty(E) \to C^\infty(F)$, usually first order. The kernel $\operatorname{Ker} P$ is the set of infinitesimal deformations, and the cokernel Coker $P$ the set of obstructions. The actual moduli space $\mathcal{M}$ is locally the zeros of a nonlinear map $\Psi: \operatorname{Ker} P \to \operatorname{Coker} P$.

In a generic case, $\operatorname{Coker} P = 0$, and then the moduli space $\mathcal{M}$ is locally isomorphic to $\operatorname{Ker} P$, and so is locally a manifold with dimension $\operatorname{ind}(P)$. However, in nongeneric situations $\operatorname{Coker} P$ may be nonzero, and then the moduli space $\mathcal{M}$ may be nonsingular, or have an unexpected dimension.

However, SL $m$-folds do not follow this pattern. Instead, the obstructions are topologically determined, and the moduli space is always smooth, with dimension given by a topological formula. This should be regarded as a minor mathematical miracle.

### Mirror Symmetry and the SYZ Conjecture

Mirror symmetry is a mysterious relationship between pairs of Calabi–Yau 3-folds $M, \hat{M}$, arising from a branch of physics known as string theory, and leading to some very strange and exciting conjectures about Calabi–Yau 3-folds, many of which have been proved in special cases.

In the beginning (the 1980s), mirror symmetry seemed mathematically completely mysterious. But there are now two complementary conjectural theories, due to Kontsevich and Strominger–Yau–Zaslow, which explain mirror symmetry in a fairly mathematical way. Probably both are true, at some level. The second proposal, due to Strominger, Yau, and Zaslow (1996), is known as the SYZ conjecture. Here is an attempt to state it.

**The SYZ conjecture** *Suppose $M$ and $\hat{M}$ are mirror Calabi–Yau 3-folds. Then (under some additional conditions), there should exist a compact topological 3-manifold $B$ and surjective, continuous maps $f : M \to B$ and $\hat{f} : \hat{M} \to B$, such that*

(i) *There exists a dense open set $B_0 \subset B$, such that for each $b \in B_0$, the fibers $f^{-1}(b)$ and $\hat{f}^{-1}(b)$ are nonsingular special Lagrangian 3-tori $T^3$ in $M$ and $\hat{M}$. Furthermore, $f^{-1}(b)$ and $\hat{f}^{-1}(b)$ are in some sense dual to one another.*

(ii) *For each $b \in \Delta = B \backslash B_0$, the fibers $f^{-1}(b)$ and $\hat{f}^{-1}(b)$ are expected to be singular special Lagrangian 3-folds in $M$ and $\hat{M}$.*

The fibrations $f$ and $\hat{f}$ are called special Lagrangian fibrations, and the set of singular fibers $\Delta$ is called the discriminant. In part (i), the nonsingular fibers of $f$ and $\hat{f}$ are supposed to be dual tori. What does this mean?

On the topological level, we can define duality between two tori $T, \hat{T}$ to be a choice of isomorphism $H^1(T, \mathbb{Z}) \cong H_1(\hat{T}, \mathbb{Z})$. We can also define duality between tori equipped with flat Riemannian metrics. Write $T = V/\Lambda$, where $V$ is a Euclidean vector space and $\Lambda$ a lattice in $V$. Then the dual torus $\hat{T}$ is defined to be $V^*/\Lambda^*$, where $V^*$ is the dual vector space and $\Lambda^*$ the dual lattice. However, there is no notion of duality between nonflat metrics on dual tori.

Strominger, Yau, and Zaslow argue only that their conjecture holds when $M, \hat{M}$ are close to the "large complex structure limit." In this case, the diameters of the fibers $f^{-1}(b), \hat{f}^{-1}(b)$ are expected to be small compared to the diameter of the base space $B$, and away from singularities of $f, \hat{f}$, the metrics on the nonsingular fibers are expected to be approximately flat. So, part (i) of the SYZ conjecture says that for $b \in B \backslash B_0$, $f^{-1}(b)$ is approximately a flat Riemannian 3-torus, and $\hat{f}^{-1}(b)$ is approximately the dual flat Riemannian torus.

Mathematical research on the SYZ conjecture has followed two broad approaches. The first could be described as symplectic topological. For this, we treat $M, \hat{M}$ just as symplectic manifolds and $f$, $\hat{f}$ just as Lagrangian fibrations. We also suppose $B$ is a smooth 3-manifold and $f, \hat{f}$ are smooth maps. Under these simplifying assumptions, Mark Gross, Wei-Dong Ruan, and others have built up a beautiful, detailed picture of how dual SYZ fibrations work at the global topological level.

The second approach could be described as local geometric. Here, we try to take the special Lagrangian condition seriously from the outset, and focus on the local behavior of special Lagrangian submanifolds, and especially their singularities, rather than on global topological questions. In addition, we are intrested in what fibrations of generic Calabi–Yau 3-folds might look like.

There is now a well-developed theory of SL $m$-folds with isolated singularities modeled on cones (Joyce 2003a). This is applied to SL fibrations and the SYZ conjecture in Joyce (2003a, b), leading to the tentative conclusions that for generic Calabi–Yau 3-folds $M$, special Lagrangian fibrations $f : M \to B$ will be only piecewise smooth, and have discriminants $\Delta$ of real codimension 1 in $B$, in contrast to smooth fibrations which have $\Delta$ of codimension 2. We also argue that for generic mirrors $M, \hat{M}$ and $f, \hat{f}$, the discriminants $\Delta, \hat{\Delta}$ cannot be homeomorphic and so do not coincide. This contradicts part (ii) above.

A better way to formulate the SYZ conjecture may be in terms of families of mirror Calabi–Yau 3-folds $M_t, \hat{M}_t$ and fibrations $f_t : M_t \to B$, $\hat{f}_t : \hat{M}_t \to B$ for $t \in (0, \epsilon)$ which approach the "large complex structure limit" as $t \to 0$. Then we could require the discriminants $\Delta_t$, $\hat{\Delta}_t$ of $f_t, \hat{f}_t$ to converge to some common, codimension 2 limit $\Delta_0$ as $t \to 0$.

It is an important, and difficult, open problem to construct examples of special Lagrangian fibrations of compact, holonomy SU(3) Calabi–Yau 3-folds. None are currently known.

# Calogero–Moser–Sutherland Systems of Nonrelativistic and Relativistic Type

**S N M Ruijsenaars**, Centre for Mathematics and Computer Science, Amsterdam, The Netherlands

## Introduction

Systems of Calogero–Moser–Sutherland (CMS) type form a class of finite-dimensional dynamical systems that are integrable both at the classical and at the quantum level. The CMS systems describe $N$ point particles moving on a line or on a ring, interacting via pair potentials that are specific functions of four types, namely rational (I), hyperbolic (II), trigonometric (III), and elliptic (IV). They occur not only in a nonrelativistic (Galilei-invariant), but also in a relativistic (Poincaré-invariant) setting. Thus, one can distinguish a hierarchy of 16 physically distinct versions (classical/quantum, nonrelativistic/relativistic, type I–IV), the most general one being the quantum relativistic type IV system.

The nonrelativistic systems date back to pioneering work by Calogero, Sutherland, and Moser in the early 1970s. The pair potential structure of the interaction can be encoded in the root system $A_{N-1}$, and there also exist integrable versions for all of the remaining root systems. The classical systems are given by $N$ Poisson commuting Hamiltonians with a polynomial dependence on the particle momenta $p_1, \ldots, p_N$. Accordingly, the quantum versions are described by $N$ commuting Hamiltonians that are partial differential operators.

The relativistic systems were introduced in the mid-1980s, at the classical level by Ruijsenaars and Schneider, and at the quantum level by Ruijsenaars. They converge to the nonrelativistic systems in the limit $c \to \infty$, where $c$ is the speed of light. Again, the systems can be related to the root system $A_{N-1}$, and they admit integrable versions for other root systems. All of the commuting classical Hamiltonians depend exponentially on generalized momenta $p_1, \ldots, p_N$. Hence, the associated commuting quantum Hamiltonians are analytic difference operators.

The above integrable systems can be further generalized by allowing supersymmetry or internal degrees of freedom ("spins"), coupled in quite special ways to retain integrability. In this article, however, the focus is on the 16 versions of the $A_{N-1}$-symmetric CMS systems without internal degrees of freedom. The primary aim is to acquaint the reader with their definition and integrability, and with their most prominent features and interrelationships. Second, we intend to give a rough sketch of the state of the art concerning explicit solutions for the various versions. This involves a concretization of the action-angle maps and eigenfunction transforms that simultaneously diagonalize the commuting dynamics, paying special attention to their remarkable duality properties.

It is beyond the scope of this article to review the hundreds of papers specifically dealing with CMS type systems, let alone the much larger literature where they play some role. Indeed, the systems have been encountered in a great many different contexts and they are related to a host of other integrable systems in various ways. Accordingly, they can be studied from the perspective of various subfields of mathematics and theoretical physics. First some of these perspectives and relations to seemingly quite different topics will be mentioned before embarking on the far more focused survey.

Staying first within the confines of the CMS type systems, some nonobvious limits yielding other familiar finite-dimensional integrable systems will be mentioned. To begin with, all of the $A_{N-1}$ type systems give rise to systems with a Toda type (exponential "nearest neighbor") interaction via a suitable limiting transition (basically a strong-coupling limit). This leads to integrable $N$-particle systems with a classical/quantum, nonrelativistic/relativistic, nonperiodic/periodic version; starting from the quantum relativistic periodic Toda system, the remaining seven versions can be obtained by suitable limits.

Next, we recall that the quantum system of $N$ nonrelativistic bosons on the line or ring interacting via a pair potential of $\delta$-function type is soluble via a Bethe ansatz, with the "line version" exhibiting quantum soliton behavior (factorized scattering). It has been shown that there exist scaling limits of eigenfunctions for suitable CMS systems that give rise to the latter Bethe type eigenfunctions for $N = 2$, while convergence for $N > 2$ is plausible, but has not been demonstrated thus far.

Via suitable analytic continuations preserving reality/formal self-adjointness, one can arrive at CMS systems with more than one species of particle (particles and "antiparticles"). Likewise, analytic continuations and appropriate limits of CMS systems associated with root sytems other than $A_{N-1}$ lead to a further proliferation of $N$-dimensional integrable systems. Typically, such limits refer either

to the commuting Hamiltonians (the Toda limit being a case in point) or to the joint eigenfunctions (as exemplified by the $\delta$-function system limit); it seems difficult to control both sets of quantities at once.

Starting from the spin type CMS systems, another kind of limit can be taken. Specifically, by "freezing" the particles at equilibrium positions, it is possible to arrive at integrable spin chains of Haldane–Shastry and Inozemtsev type.

At this point, it is expedient to insert a brief remark on finite-dimensional integrable systems. As the term suggests, one may expect that, with due effort, such systems can be "integrated," or, equivalently, "solved." But it should be noted that the latter terms (let alone the qualifier "due effort") have no unambiguous mathematical meaning. Certainly, "solving" involves obtaining explicit information on the action-angle map and joint eigenfunction transform at the classical and quantum level, resp., but *a priori* it is not at all clear how far one can proceed.

Focusing again on the CMS systems and their relatives, it should be stressed that, in many cases, one is still far removed from a complete solution, especially for the elliptic CMS systems. In this regard the previous remark serves not only as a caveat, but also to make clear why the various vantage points provided by different subfields in mathematics and physics are crucial: typically, they yield complementary insights and distinct representations for solutions, serving different purposes.

To be sure, in first approximation the mathematics involved at the classical and quantum level is symplectic geometry and Hilbert space theory, resp. In point of fact, however, far more ingredients have turned out to be quite natural and useful. On the classical level, these include the theory of groups, Lie algebras and symmetric spaces, linear algebra and spectral theory, Riemann surface theory, and more generally algebraic geometry.

On the quantum level, the viewpoint of harmonic analysis on symmetric spaces is particularly natural and fruitful for the nonrelativistic CMS systems and their arbitrary root-system versions, whereas quantum groups/algebras/symmetric spaces can be tied in with the relativistic systems and their versions for other root systems. (The $c \to \infty$ limit amounts to the $q \to 1$ limit in the quantum group picture.) As a matter of fact, the whole area of special functions and their $q$-analogs is intimately related to the quantum CMS type systems (cf. also the last section of this article). Finally, the occurrence of commuting analytic difference operators in the relativistic ($q \neq 1$) systems leads to largely uncharted territory in the intersection of the theory of Hilbert space eigenfunction expansions and the theory of linear analytic difference equations.

The study of the thermodynamics ($N \to \infty$ limit with temperature $\geq 0$ and density $\geq 0$ fixed) associated with the trigonometric and elliptic CMS systems and their spin cousins yields its own circle of problems. It was initiated by Sutherland three decades ago, and even though a host of results on partition functions, correlation functions, fractional statistics, strong–weak coupling duality, relations to Yangians, etc., have meanwhile been obtained, many questions are still open. This area also has links with random-matrix theory, but the input from this field is thus far limited to certain discrete couplings.

The above $N$-dimensional integrable systems are related to a great many infinite-dimensional integrable systems, both at the classical and at the quantum level. On the one hand, there are structural analogs that have been used to advantage in the study of CMS systems, including Lax pair and $R$-matrix formulations, zero-curvature representations, bi-Hamiltonian formalism, Bäcklund transformations, time discretizations, and tools such as Baker–Akhiezer functions, Bethe ansatz, separation of variables, and Baxter-type $Q$-operators.

On the other hand, there are striking physical similarities between various soliton field theories (a prominent one being the sine-Gordon field theory) and infinite soliton lattices (in particular several Toda type lattices), and the CMS systems for special parameter values. Particularly conspicuous are the ties between the classical CMS systems and the KP and two-dimensional Toda hierarchies. The latter relations actually extend beyond the solitons, including rational and theta function solutions.

CMS systems are relevant in various other contexts not yet mentioned. A prominent one among these is a class of supersymmetric gauge field theories. In this quantum context, the classical CMS systems have surfaced in the description of moduli spaces encoding the vacuum structure (Seiberg–Witten theory). Equally surprising, certain classical CMS systems (with internal degrees of freedom) have found a second application in a quantum context, namely in the description of quantum chaos (level repulsion).

We conclude this introduction by listing additional disparate subjects where connections with CMS type systems have been found. These include the theory of Sklyanin, affine Hecke, Kac–Moody, Virasoro and $W$-algebras, equations of Knizhnik–Zamolodchikov, Yang–Baxter, Witten–Dijkgraaf–Verlinde–Verlinde, and Painlevé type, Gaudin,

Hitchin, Wess–Zumino, matrix and quasi-exactly solvable models, Dunkl–Cherednik and Polychronakos operators, the quantum Hall effect and quantum transport, two-dimensional Yang–Mills theory, functional equations, integrable mappings, Huygens' principle, and the bispectral problem.

## Classical Nonrelativistic CMS Systems

A system of $N$ nonrelativistic equal-mass $m$ particles on the line interacting via pair potentials can be described by a Hamiltonian

$$H = \frac{1}{2m}\sum_{j=1}^{N} p_j^2 + \sum_{1\le j<k\le N} V(x_j - x_k), \quad m > 0 \quad [1]$$

The CMS systems are defined by four distinct choices of pair potential. The simplest choice reads

$$V(x) = g^2/mx^2, \quad g > 0 \quad (\mathrm{I}) \quad [2]$$

Hence, the coupling constant $g$ has dimension [action] (the product of [position] and [momentum]). This potential is clearly repulsive. Thus, each initial state in the phase space

$$\Omega = \{(x,p) \in \mathbb{R}^{2N} \,|\, x \in G\} \quad [3]$$

where $G$ is the configuration space

$$G = \{x \in \mathbb{R}^N \,|\, x_N < \cdots < x_1\} \quad [4]$$

is a scattering state.

The next level is given by the hyperbolic choice

$$V(x) = g^2\nu^2/m\sinh^2(\nu x), \quad \nu > 0 \quad (\mathrm{II}) \quad [5]$$

Hence, $\nu$ has dimension $[\text{position}]^{-1}$, and the previous system arises by taking $\nu$ to 0. It is clear that [5] yields again a repulsive particle system, so that each state in $\Omega$ given by [3] is a scattering state.

The highest level in the hierarchy is the elliptic level, where

$$V(x) = g^2\wp(x;\omega,\omega')/m, \quad \omega, -\mathrm{i}\omega' > 0 \quad (\mathrm{IV}) \quad [6]$$

and $\wp(x;\omega,\omega')$ denotes the Weierstrass $\wp$-function with periods $2\omega$ and $2\omega'$. It is beyond the scope of this article to elaborate on the elliptic regime, even though it is of considerable interest. It reappears in later sections as the most general regime in which integrability holds true. Indeed, a prominent feature of the elliptic case [6] is that it can be specialized both to the hyperbolic case [5] and to the trigonometric case, given by

$$V(x) = g^2\nu^2/m\sin^2(\nu x) \quad (\mathrm{III}) \quad [7]$$

To obtain the hyperbolic specialization, one should take $\omega' = \mathrm{i}\pi/2\nu$ and send $\omega$ to $\infty$; then [6] reduces to [5] (up to an additive constant). Likewise, [7] results from [6] by choosing $\omega = \pi/2\nu$ and taking $-\mathrm{i}\omega'$ to $\infty$.

The physical picture associated with the trigonometric and elliptic systems is quite different from that of the rational and hyperbolic ones. Of course, the potentials [7] and [6] are again repulsive, but now the internal motion is confined and oscillatory. More specifically, due to energy conservation the phase spaces

$$\Omega_{\mathrm{III}} = G_{\mathrm{III}} \times \mathbb{R}^N, \quad G_{\mathrm{III}} = \{x_N < \cdots < x_1, x_1 - x_N < \pi/\nu\} \quad [8]$$

$$\Omega_{\mathrm{IV}} = G_{\mathrm{IV}} \times \mathbb{R}^N, \quad G_{\mathrm{IV}} = \{x_N < \cdots < x_1, x_1 - x_N < 2\omega\} \quad [9]$$

are left invariant by the flow generated by the trigonometric and elliptic $N$-particle Hamiltonian, resp.

Alternatively, one may interpret the trigonometric Hamiltonian as describing particles constrained to move on a circle and interacting via the inverse square potential [2]. In this picture, the quantities $2\nu x_1, \ldots, 2\nu x_N$ are viewed as angular positions on the circle, and one needs a suitable quotient of the phase space [8] by a discrete group action to describe a state of the system.

Turning to integrability aspects, we begin by noting that the total momentum Hamiltonian

$$P = \sum_{j=1}^{N} p_j \quad [10]$$

obviously Poisson commutes with the above defining Hamiltonians of the systems. For $N = 2$, therefore, integrability is plain. It is possible to write down explicitly the higher commuting Hamiltonians for $N > 2$ as well but, in the nonrelativistic setting, it is more illuminating to characterize them as the power traces or (equivalently) the symmetric functions of a so-called Lax matrix.

The Lax matrix is an $N \times N$ matrix-valued function on the phase space of the system. It plays a pivotal role not only for understanding integrability, but also for setting up an action-angle transformation. The latter issue is discussed again later. Here the more conspicuous features of the Lax matrix will be explained, focusing on the type II system for expository ease. Then one can choose

$$L_{jj} = p_j, \; L_{jk} = \mathrm{i}g\nu/\sinh\nu(x_j - x_k), \quad j,k = 1,\ldots,N, \; j \neq k \quad [11]$$

Thus, $L$ is Hermitean and we have

$$\mathrm{tr}\, L = P, \qquad \mathrm{tr}\, L^2 = 2mH \quad [12]$$

(The rational Lax matrix results from [11] by taking $\nu \to 0$, and the trigonometric one by taking $\nu \to i\nu$. The elliptic Lax matrix has a similar structure, but it involves an extra "spectral" parameter.)

Although not obvious, it is true that all of the power traces

$$H_k = \frac{1}{k}\operatorname{tr} L^k, \quad k = 1, \ldots, N \qquad [13]$$

are in involution (i.e., Poisson commute). One way to understand this involves the so-called Lax pair equation associated with the Hamiltonian flow generated by $H = H_2/m$. This involves a second $N \times N$ matrix function given by

$$\begin{aligned} M_{jj} &= \sum_{l \neq j} \frac{-ig\nu^2}{m \sinh^2 \nu(x_j - x_l)} \\ M_{jk} &= \frac{ig\nu^2 \cosh \nu(x_j - x_k)}{m \sinh^2 \nu(x_j - x_k)} \\ & j \neq k \end{aligned} \qquad [14]$$

When the positions and momenta in $L$ and $M$ evolve according to the $H$-flow, one has

$$\dot{L}_t = [M_t, L_t] \qquad [15]$$

where $[\cdot, \cdot]$ is the matrix commutator. (Indeed, [15] amounts to the Hamilton equations, as is readily checked.) Since $M$ is anti-Hermitean, it is not difficult to derive from this Lax pair equation that the flow is isospectral: $L_t$ is related to $L_0$ by a unitary transformation $L_t = U_t L_0 U_t^*$ obtained from $M_t$, so that the spectrum of $L_t$ is time independent.

This argument already shows the existence of $N$ conserved quantities under the $H$-flow, namely the $N$ eigenvalues of $L$. It is, however, simpler to work with either the power traces $H_k$ given by [13] or with the symmetric functions $S_k$ of $L$, given by

$$\det(\mathbf{1}_N + \lambda L) = \sum_{k=0}^{N} \lambda^k S_k \qquad [16]$$

These Hamiltonians depend only on the eigenvalues of $L$, so they are also conserved under the flow. Note that

$$S_1 = P, \qquad S_2 = P^2 - mH \qquad [17]$$

To see why these Hamiltonians are in involution, one can invoke the long-time asymptotics of the $H$-flow. It reads

$$\begin{aligned} & p(t) \sim \hat{p}, \qquad \hat{p}_N < \cdots < \hat{p}_1, \\ & x_j(t) \sim x_j^+ + t\hat{p}_j/m, \\ & j = 1, \ldots, N, \ t \to \infty \end{aligned} \qquad [18]$$

Accordingly, one gets

$$L_t \sim \operatorname{diag}(\hat{p}_1, \ldots, \hat{p}_N) = L_\infty, \quad t \to \infty \qquad [19]$$

Since the time evolution is a canonical transformation and the Poisson brackets $\{H_k, H_l\}$ are time independent (by the Jacobi identity), it now readily follows from [19] that they vanish. (Indeed, $H_k$ and $H_l$ reduce to power traces of $L_\infty$, and the asymptotic momenta $\hat{p}_1, \ldots, \hat{p}_N$ Poisson commute.)

## Quantum Nonrelativistic CMS Systems

The canonical quantization prescription

$$p_j \to -i\hbar\partial/\partial x_j, \quad j = 1, \ldots, N \qquad [20]$$

($\hbar$ being the Planck constant) gives rise to an unambiguous quantum Hamiltonian

$$H = -\frac{\hbar^2}{2m}\sum_{j=1}^{N} \partial_j^2 + \sum_{1 \le j < k \le N} V(x_j - x_k) \qquad [21]$$

for any classical Hamiltonian [1]. Thus, the defining Hamiltonians of the above systems give rise to well-defined partial differential operators (PDOs), which act on suitable dense subspaces of the Hilbert space $L^2(G_\kappa, dx), \kappa = \mathrm{I}, \ldots, \mathrm{IV}$, with $G_{\mathrm{I}}$ and $G_{\mathrm{II}}$ given by $G$ in [4], and $G_{\mathrm{III}}, G_{\mathrm{IV}}$ by [8] and [9], respectively.

We recall that there is no general result ensuring that a classically integrable system admits an integrable quantum version. More precisely, when one substitutes [20] in $N$ Poisson commuting Hamiltonians, it need not be true that they commute as quantum operators, even when no ordering ambiguities are present. For the power trace Hamiltonians such ambiguities do occur. (For example, [11] gives rise to a term in $H_3$ proportional to $p_1/\sinh^2 \nu(x_1 - x_2)$.) On the other hand, no noncommuting factors occur in the quantization of $S_1, \ldots, S_N$. To verify this, one need only note that $S_k$ equals the sum of all $k \times k$ principal minors of $L$, cf. [16]; choosing a diagonal element $p_j$ in a summand, one therefore has no dependence on $x_j$ in the remaining factors, hence no ordering ambiguity.

As a result, the prescription [20] yields $N$ unambiguous operators $S_k(x, -i\hbar\nabla)$, which are moreover formally self-adjoint on $L^2(G_\kappa, \mathrm{d}x)$ for each of the four cases $\kappa = \mathrm{I}, \ldots, \mathrm{IV}$. Although by no means obvious, it is true that these operators do commute. Thus, integrability is preserved under quantization of the above systems. Now the power traces of a matrix can be expressed as polynomials in the symmetric functions (via the Newton

identities), so this yields an ordering ensuring that the quantized power traces commute as well.

Just as the action-angle transformation for a classically integrable system "diagonalizes" all of the Poisson commuting Hamiltonians at once (in the sense that the transformed Hamiltonians depend only on the action variables), one expects that there exists a unitary operator that transforms all of the commuting Hamiltonians to diagonal form. In the classical setting, the existence of this diagonalizing map follows (under suitable technical restrictions) from the Liouville–Arnold theorem, whereas in the quantum context the existence of such a joint eigenfunction transformation is a far more delicate issue. This problem is briefly discussed later again, noting here that the solutions obtained to date vary considerably in completeness and "explicitness" for the four regimes.

## Classical Relativistic CMS Systems

The nonrelativistic spacetime symmetry group is the Galilei group. Its Lie algebra is represented by the time translation generator $H$ given by [1], space translation generator $P$ given by [10], and the Galilei boost generator

$$B = -m\sum_{j=1}^{N} x_j \qquad [22]$$

More precisely, the Poisson brackets are given by

$$\{H, P\} = 0, \quad \{H, B\} = P, \quad \{P, B\} = Nm \qquad [23]$$

so that the last bracket does not vanish (as is the case for the Galilei Lie algebra). This deviation is inconsequential, however, since the constant $Nm$ (central extension) yields trivial Hamilton equations.

The relativistic spacetime symmetry group (Poincaré group) yields a Lie algebra that differs from [23] only in $Nm$ being replaced by $H/c^2$, where $c$ is the speed of light. Clearly, the functions

$$H = mc^2\sum_{j=1}^{N}\cosh\left(\frac{p_j}{mc}\right)$$
$$P = mc\sum_{j=1}^{N}\sinh\left(\frac{p_j}{mc}\right) \qquad [24]$$

together with $B$ given by [22] give rise to these altered Poisson brackets. Physically, these three generators describe a system of $N$ relativistic free mass-$m$ particles in terms of their rapidities $p_j/mc$.

A natural ansatz to take interaction into account now reads

$$H = mc^2\sum_{j=1}^{N}\cosh\left(\frac{p_j}{mc}\right)V_j(x)$$
$$P = mc\sum_{j=1}^{N}\sinh\left(\frac{p_j}{mc}\right)V_j(x) \qquad [25]$$
$$V_j(x) = \prod_{k\neq j} f(x_j - x_k)$$

Indeed, it is plain that this still entails

$$\{H, B\} = P, \qquad \{P, B\} = H/c^2 \qquad [26]$$

But to obtain a relativistic particle system, the time and space translations must also commute. The corresponding requirement $\{H, P\} = 0$ yields a severe constraint on the "pair potential" function $f(x)$ in [25] whenever $N > 2$. (For $N = 2$, one gets $\{H, P\} = 0$ irrespective of the choice of $f$.)

As it turns out, the vanishing requirement is satisfied when

$$f^2(x) = a + b\wp(x) \qquad [27]$$

where $a$, $b$ are constants and $\wp(x)$ is the Weierstrass function already encountered. Taking, for example, $a, b > 0$, one can take the positive square root of the right-hand side of [27]. This choice of $f(x)$ yields the defining Hamiltonian of the relativistic elliptic system (type IV). In the three degenerate cases, it is convenient to choose

$$f(x) = \begin{cases} (1 + g^2/m^2c^2x^2)^{1/2} & \text{(I)} \\ (1 + \sin^2(\nu g/mc)/\sinh^2(\nu x))^{1/2} & \text{(II)} \\ (1 + \sinh^2(\nu g/mc)/\sin^2(\nu x))^{1/2} & \text{(III)} \end{cases} \qquad [28]$$

It is an elementary exercise to check that this implies

$$\lim_{c\to\infty}(H - Nmc^2) = H_{\text{nr}}, \quad \lim_{c\to\infty} P = P_{\text{nr}} \qquad [29]$$

where $H_{\text{nr}}$ and $P_{\text{nr}}$ are the above nonrelativistic time and space translation generators. Hence, the defining Hamiltonians of the relativistic systems reduce to their nonrelativistic counterparts in the limit $c \to \infty$.

The special character of the function [27] makes itself felt not only in ensuring Poincaré invariance, but also in entailing integrability. To begin with, note that the functions

$$S_{\pm N} = \exp\left(\pm\beta\sum_{j=1}^{N} p_j\right), \quad \beta = 1/mc \qquad [30]$$

commute with $H$ and $P$, so that integrability for $N=3$ is plain. More generally, the Hamiltonians

$$S_{\pm l} = \sum_{\substack{I\subset\{1,\ldots,N\}\\ |I|=l}} \exp\left(\pm\beta\sum_{j\in I} p_j\right)\prod_{\substack{j\in I\\ k\notin I}} f(x_j - x_k), \quad l=1,\ldots,N \qquad [31]$$

can be shown to mutually commute. Clearly, one has

$$S_{-l} = S_{-N}S_{N-l}, \quad l=1,\ldots,N-1 \qquad [32]$$

and

$$H = (S_1 + S_{-1})/2m\beta^2, \quad P = (S_1 - S_{-1})/2\beta \qquad [33]$$

As anticipated by the notation, the functions $S_1,\ldots,S_N$ may be viewed as the symmetric functions of a Lax matrix. More precisely, in the elliptic case this is true up to multiplicative constants that depend on a spectral parameter occurring in the Lax matrix. As before, only the Lax matrix for the type II system is specified here. In this case, one can dispense with the spectral parameter and choose

$$L_{jk} = e_j C_{jk} e_k, \quad j,k=1,\ldots,N \qquad [34]$$

where

$$e_j = \exp(\nu x_j + \beta p_j/2)\prod_{l\neq j} f(x_j - x_l)^{1/2} \qquad [35]$$

$$C_{jk} = \exp(-\nu(x_j + x_k))\frac{\sinh(\mathrm{i}\beta\nu g)}{\sinh \nu(x_j - x_k + \mathrm{i}\beta g)} \qquad [36]$$

In [35], $f(x)$ is the type II function given by [28]. The matrix $C$ arises from Cauchy's matrix $1/(w_j - z_k)$ via a suitable substitution, and Cauchy's identity

$$\det\left(\frac{1}{w_j - z_k}\right)_{j,k=1}^{N} = \prod_{j=1}^{N}\frac{1}{w_j - z_j}\prod_{1\le j<k\le N}\frac{(w_j - w_k)(z_j - z_k)}{(w_j - z_k)(z_j - w_k)} \qquad [37]$$

ensures that [34] yields the Hamiltonians $S_l$ of [31].

To conclude this section, we point out that the relation

$$L = \mathbf{1}_N + \beta L_{\mathrm{nr}} + O(\beta^2), \quad \beta\to 0 \qquad [38]$$

where $L_{\mathrm{nr}}$ denotes the nonrelativistic Lax matrix [11], can be used to deduce the involutivity of the nonrelativistic Hamiltonians from that of their relativistic counterparts.

## Quantum Relativistic CMS Systems

When the canonical quantization prescription [20] is applied to the classical Hamiltonians [31] with $f(x)=1$, one obtains commuting quantum operators whose action is exemplified by

$$\exp\left(-\frac{\hbar}{mc}\mathrm{i}\frac{\mathrm{d}}{\mathrm{d}x}\right)F(x) = F\left(x - \mathrm{i}\frac{\hbar}{mc}\right) \qquad [39]$$

That is, the operators act on functions that have an analytic continuation in $x_1,\ldots,x_N$ from the real line $\mathbb{R}$ to a strip around $\mathbb{R}$ in the complex plane $\mathbb{C}$, whose width is at least $2\hbar/mc$.

Operators of this type are called analytic difference operators (henceforth AΔOs). The choice $f(x)=1$ amounts to the free case $g=0$ in [28]. For $g\neq 0$, however, the canonical quantization exemplified by [39] yields noncommuting AΔOs. Thus, the factor ordering following from [31] would entail that integrability breaks down at the quantum level.

As mentioned before, there is no general result guaranteeing that a different ordering that preserves integrability exists. Even so, this is true in the present case. Specifically, the function $f(x)$ can be factorized as $f_+(x)f_-(x)$, and then the AΔOs

$$S_{\pm l} = \sum_{\substack{I\subset\{1,\ldots,N\}\\ |I|=l}} \prod_{\substack{j\in I\\ k\notin I}} f_{\mp}(x_j - x_k) \times \exp\left(\mp \mathrm{i}\hbar\beta\sum_{j\in I}\partial_j\right)\prod_{\substack{j\in I\\ k\notin I}} f_{\pm}(x_j - x_k) \qquad [40]$$

do commute. In the elliptic case [27], this factorization involves the Weierstrass $\sigma$-function, and commutativity can be encoded in a sequence of functional equations satisfied by the $\sigma$-function. For the type I–III systems the pertinent factorization of [28] is given by

$$f_{\pm}(x) = \begin{cases} (1 \pm \mathrm{i}\beta g/x)^{1/2} & \text{(I)} \\ (\sinh\nu(x\pm \mathrm{i}\beta g)/\sinh\nu x)^{1/2} & \text{(II)} \\ (\sin\nu(x\pm \mathrm{i}\beta g)/\sin\nu x)^{1/2} & \text{(III)} \end{cases} \qquad [41]$$

(Here one has $g > 0$, and the choice of square root is such that $f_{\pm}(x)\to 1$ for $g\downarrow 0$.)

The nonrelativistic limit $c\to\infty$ of the quantum Hamiltonians [33] can be determined by expanding $S_1$ and $S_{-1}$ in a power series in $\beta = 1/mc$. In this way, one obtains once more [29], except for a small, but crucial change in $H_{\mathrm{nr}}$: instead of the coupling constant dependence $g^2$ in the potential energy, one gets $g(g-\hbar)$. The extra term arises from the action of the term linear in $\beta$ in the expansion of the exponential on the term linear in $\beta$ in the expansion of the functions $f_{\pm}(x)$.

From the perspective of the nonrelativistic quantum CMS systems, the change $g^2\to g(g-\hbar)$ appears ad hoc. As it transpires, however, the different

dependence on $g$ ensures that the eigenfunctions of $H_{\mathrm{nr}}$ depend on $g$ in a far simpler way. This will become clear shortly.

## Action-Angle Transforms and Duality

Under certain technical assumptions, any integrable system given by $N$ independent Poisson commuting Hamiltonians $S_1(x,p),\ldots,S_N(x,p)$ on a $2N$-dimensional phase space admits local canonical transformations to action-angle variables. Like the spectral theorem on the quantum level, this structural result is of limited practical value. Indeed, just as the spectral theorem yields no concrete information concerning eigenfunctions, bound-state energies, scattering, etc., associated with a given self-adjoint Hamiltonian, the Liouville–Arnold theorem only yields general insight in the type of motion that can occur and the geometric character of the local maps (in terms of invariant tori).

To fully comprehend ("solve") a given integrable system, one should render the associated action-angle map as concrete as possible. For the CMS type systems, a complete solution to this problem has only been achieved for the systems of type I–III. The motion in the trigonometric systems is oscillatory, so that a closeup via the action-angle transform involves extensive geometric constructions. By contrast, the type I and II systems are scattering systems, and here the action-angle map can be tied in with the classical wave maps (Møller transformations).

We now sketch some salient features of the action-angle maps for systems of type I and II. In all cases the map (denoted $\Phi$) is a canonical transformation from the phase space $\Omega$ (eqn [3]) with 2-form $\mathrm{d}x \wedge \mathrm{d}p$ to the phase space

$$\hat{\Omega} = \{(\hat{x},\hat{p}) \in \mathbb{R}^{2N} \mid \hat{p} \in G\} \qquad [42]$$

with 2-form $\mathrm{d}\hat{x} \wedge \mathrm{d}\hat{p}$. Thus, the actions $\hat{p}_1,\ldots,\hat{p}_N$ vary over $G$ given by [4] and the "angles" $\hat{x}_1,\ldots,\hat{x}_N$ over $\mathbb{R}$. Consequently, $\hat{\Omega}$ amounts to $\Omega$ with $x$ and $p$ interchanged.

As should be the case, the transformed commuting Hamiltonians

$$\hat{S}_k = S_k \cdot \Phi^{-1}, \quad k = 1,\ldots,N \qquad [43]$$

depend only on the action vector $\hat{p}$. To be specific, they arise from $S_k(x,p)$ by taking $g=0$ (no interaction, hence no $x$ dependence) and substituting $p \to \hat{p}$. Indeed, the actions $\hat{p}_k$ are the $t \to \infty$ limits of the momenta $p_k(t)$, where the $t$ dependence refers to the defining Hamiltonian of the system.

As it happens, the Lax matrix $L$ is of decisive importance to concretize the action-angle map $\Phi$, and in particular to reveal its hidden duality properties. The starting point is a commutation relation of $L(x,p)$ with a diagonal matrix $A(x)$ given by

$$A(x) = \mathrm{diag}(\mathrm{d}(x_1),\ldots,\mathrm{d}(x_N))$$
$$\mathrm{d}(y) = \begin{cases} y & \text{(I)} \\ \exp(2\nu y) & \text{(II)} \end{cases} \qquad [44]$$

Obviously, the symmetric functions $\check{D}_k(x)$ of $A(x)$ yield an integrable system on $\Omega$, so the Hamiltonians

$$D_k(\hat{x},\hat{p}) = (\check{D}_k \circ \Phi^{-1})(\hat{x},\hat{p}), \quad k = 1,\ldots,N \qquad [45]$$

yield an integrable system on the action-angle phase space $\hat{\Omega}$. The crux of the matter is now that these systems are familiar: they are also systems of type I and II!

To be specific, let us denote the dual systems just described by a caret, and the nonrelativistic/relativistic systems by a suffix nr/rel, resp. Then the duality properties alluded to are given by

$$\hat{\mathrm{I}}_{\mathrm{nr}} \simeq \mathrm{I}_{\mathrm{nr}}, \qquad \hat{\mathrm{I}}_{\mathrm{rel}} \simeq \mathrm{II}_{\mathrm{nr}}$$
$$\hat{\mathrm{II}}_{\mathrm{nr}} \simeq \mathrm{I}_{\mathrm{rel}}, \qquad \hat{\mathrm{II}}_{\mathrm{rel}} \simeq \mathrm{II}_{\mathrm{rel}} \qquad [46]$$

and $\Phi^{-1}$ serves as the action-angle map for the dual systems.

In order to sketch why this state of affairs holds true for the $\mathrm{II}_{\mathrm{rel}}$ system, recall that its Lax matrix is given by [34]. From this, one readily checks the commutation relation

$$\coth(\mathrm{i}\beta\nu g)[A,L] = 2e \otimes e - (AL + LA) \qquad [47]$$

Since $L$ is Hermitean, there exists a unitary $U$ diagonalizing $L$. It can now be shown that the spectrum of $L$ is positive and nondegenerate, and that $U^*e$ has nonzero components. The gauge ambiguity in $U$ (given by a permutation matrix and diagonal phase matrix) can, therefore, be fixed by requiring

$$U^*LU = \mathrm{diag}(\exp(\beta\hat{p}_1),\ldots,\exp(\beta\hat{p}_N)),$$
$$\hat{p}_N < \cdots < \hat{p}_1 \qquad [48]$$

$$(U^*e)_j > 0, \quad j = 1,\ldots,N \qquad [49]$$

A suitable reparametrization of $U^*e$ then yields the "angle" vector $\hat{x}$.

As a consequence, $U^*AU$ becomes a function of $\hat{x}$ and $\hat{p}$. In detail, one finds

$$(U^*AU)(\hat{x},\hat{p}) = L(\beta/2, 2\nu; \hat{p},\hat{x})^{\mathrm{T}} \qquad [50]$$

where $L(\nu,\beta;x,p)$ is given by [34] and $T$ denotes the transpose. Therefore, the "dual Lax matrix" $\hat{A} = U^*AU$ is essentially equal to $L$, explaining the self-duality $\hat{\mathrm{II}}_{\mathrm{rel}} \simeq \mathrm{II}_{\mathrm{rel}}$ announced above.

With the action-angle transform under explicit control, much more can be said about the solutions to Hamilton's equations for each of the commuting Hamiltonians, both as regards finite times and as regards long-time asymptotics (scattering). It is beyond the scope of this article to enlarge on this, but it is worth mentioning that the scattering reveals the solitonic character of the particles. Indeed, the set of asymptotic momenta $\hat{p}_1, \ldots, \hat{p}_N$ is conserved under the scattering and the asymptotic position shifts are factorized in terms of pair shifts. A quite remarkable feature of the type I systems is that the shifts actually vanish ("billiard ball" scattering).

## Eigenfunction Transforms and Duality

Both at the relativistic and at the nonrelativistic level the commuting quantum Hamiltonians $S_1, \ldots, S_N$ are formally self-adjoint on the Hilbert space $L^2(G_\kappa, \mathrm{d}x), \kappa = \mathrm{I}, \ldots, \mathrm{IV}$. Thus, it may be expected that it is possible to construct a unitary eigenfunction transform

$$\Phi_\kappa : L^2(G_\kappa, \mathrm{d}x) \to L^2(\hat{G}_\kappa, \mathrm{d}\mu_\kappa(p)), \quad \kappa = \mathrm{I}, \ldots, \mathrm{IV} \qquad [51]$$

diagonalizing $S_k$ as multiplication by a real-valued function $M_k(p)$. Here $\hat{G}_\kappa$ encodes the joint spectrum and $\mathrm{d}\mu_\kappa(p)$ is a suitable measure on $\hat{G}_\kappa$.

Obviously, this expectation is borne out in the free case $g = 0$. Then, $\Phi_\kappa$ is basically Fourier transformation, its kernel consisting of a sum of joint eigenfunctions

$$\exp(-\mathrm{i}x \cdot \sigma(p)/\hbar), \quad \sigma \in S_N \qquad [52]$$

with $\sigma$ ranging over the permutation group $S_N$. For $\kappa = \mathrm{I}, \mathrm{II}$, one can take $G_\kappa = \hat{G}_\kappa = G$ (eqn [4]) and $\mathrm{d}\mu_\kappa(p) = \mathrm{d}p$. Here one gets

$$M_k(p) = \sum_{1 \le i_1 < \cdots < i_k \le N} \begin{cases} p_{i_1} \cdots p_{i_k} \\ \exp(\beta p_{i_1}) \cdots \exp(\beta p_{i_k}) \end{cases} \qquad [53]$$

in the nonrelativistic and relativistic case, resp. For $\kappa = \mathrm{III}, \mathrm{IV}$, one needs to take into account periodic boundary conditions on the walls of $G_\kappa$, yielding a discrete joint spectrum after the center-of-mass motion is omitted. (With the above choices of $G_{\mathrm{III}}$ and $G_{\mathrm{IV}}$, cf. [8] and [9], the center-of-mass motion is a free motion along the line, so the total momentum still varies continuously.) Of course, the diagonalized $S_k$ are once more given by [53], since the kernel of $\Phi_\kappa$ consists of free boson states.

Taking next $g > 0$, the above expectation has not been confirmed for all of the eight regimes involved. This is not only because in some cases not even the existence of joint eigenfunctions has been shown, but also because in the relativistic case the unitarity of $\Phi_{\mathrm{II}}$ and $\Phi_{\mathrm{IV}}$ already breaks down for $N = 2$ when $g$ increases beyond a critical value, cf. [57] below. It is quite likely that this happens for $N > 2$ as well, but this is not readily apparent from the current fragmentary knowledge on joint eigenfunctions for $N > 2$.

The only two cases where the $g > 0$ joint eigenfunction transform is of an elementary nature are the $\mathrm{III}_{\mathrm{nr}}$ and $\mathrm{III}_{\mathrm{rel}}$ cases. Indeed, the joint eigenfunctions describing the internal motion are of the form

$$\psi_n(x) = W(x)^{1/2} P_n(x), \quad n \in \mathbb{N}^{N-1} \qquad [54]$$

Here,

$$W(x) = \prod_{1 \le j < k \le N} w(x_j - x_k) \qquad [55]$$

is a positive weight function on $G_{\mathrm{III}}$ and the $P_n(x)$ are multivariable orthogonal polynomials. Thus, $P_n(x)$ is a finite linear combination of the above free boson states, with $p$ in [52] a linear function of $n$. For the $\mathrm{III}_{\mathrm{nr}}$ case, these eigenfunctions were already found by Sutherland. (Here, the functions $P_n(x)$ amount to polynomials, often called the Jack polynomials, which arose in a statistics context.) The $\mathrm{III}_{\mathrm{rel}}$ polynomials may be viewed as the special $A_{N-1}$ case of Macdonald's orthogonal $q$-polynomials for arbitrary root systems, with

$$q = \exp(-2\hbar\beta\nu) \qquad [56]$$

(Note that $q$ converges to 1 both in the nonrelativistic limit $c \to \infty$ and in the classical limit $\hbar \to 0$.)

For the $\mathrm{II}_{\mathrm{nr}}$ case, the joint eigenfunctions were found and studied a couple of decades ago by Heckman and Opdam, yielding a multivariable hypergeometric transform. Indeed, for $N = 2$, the eigenfunctions can be expressed in terms of the hypergeometric function ${}_2F_1$, as has been known since the early days of quantum mechanics. Likewise, the arbitrary-$N$ $\mathrm{I}_{\mathrm{nr}}$ joint eigenfunction transform (studied in detail by de Jeu) can be viewed as a multivariable Hankel transform, the $N = 2$ kernel being essentially a Hankel function.

Much less is known concerning $\mathrm{IV}_{\mathrm{nr}}$ eigenfunctions, and *a fortiori* for the associated transform $\Phi_{\mathrm{IV}}$. For $N = 2$ the time-independent Schrödinger equation amounts to the Lamé equation. Hence, solutions are Lamé functions that can be studied in particular via Fuchs theory (regular singularities). A far more explicit form of the eigenfunctions dates back to work by Hermite in the nineteenth century. More precisely, provided the $g$ dependence of the

defining Hamiltonian is changed from $g^2$ to $g(g-\hbar)$ (a change already encountered above), Hermite's results apply to couplings $g=l\hbar$, $l=2,3,4,\ldots$ His eigenfunctions have a structure that is nowadays referred to as the Bethe ansatz. For the same $g$ values and arbitrary $N$, $H_{\mathrm{nr}}$ eigenfunctions of Bethe ansatz type were found and studied by Felder and Varchenko, but even for these $g$ values much remains to be done to achieve a complete understanding of the $\Phi_{\mathrm{IV}}$ transform.

A quite different approach, due to Komori and Takemura, does yield rather detailed information on $\Phi_{\mathrm{IV}}$ for arbitrary $g>0$. The key feature of their strategy is to view the $\mathrm{IV}_{\mathrm{nr}}$ case as a perturbation of the $\mathrm{III}_{\mathrm{nr}}$ case. This entails, however, that the validity of their results is restricted to large imaginary period of the $\wp$-function.

For the $\mathrm{IV}_{\mathrm{rel}}$ system, there are only rather complete results on $\Phi_{\mathrm{IV}}$ for $N=2$. More specifically, the eigenfunction transform is known to be unitary for

$$g \in [0, \hbar + \pi/\beta\nu] \qquad [57]$$

and a dense set in a corresponding parameter space. (For $g$ outside this interval, unitarity is violated.) The kernel of $\Phi_{\mathrm{IV}}$ involves eigenfunctions of Bethe ansatz structure. For $g=l\hbar$, $l=2,3,\ldots$ and arbitrary $N$, Bethe ansatz type $H_{\mathrm{rel}}$ eigenfunctions were found by Billey, generalizing the Felder–Varchenko results mentioned above.

It remains to discuss the $\mathrm{I}_{\mathrm{rel}}$ and $\mathrm{II}_{\mathrm{rel}}$ systems. To this end, we first recall the classical dualities [46]. It is natural to expect that these dualities are still present at the quantum level. For the $\mathrm{I}_{\mathrm{nr}}$ case, this is readily confirmed: the transform is indeed invariant under interchange of $x$ and $p$. In fact, the $N=2$ center-of-mass Hankel transform even depends only on $(x_1-x_2)(p_1-p_2)$, so that self-duality is manifest in this case.

More generally, for $N=2$ the expected dualities [46] are indeed present. The $\mathrm{II}_{\mathrm{nr}}$ ${}_2F_1$ transform satisfies the $\mathrm{I}_{\mathrm{rel}}$ analytic difference equation in $p_1-p_2$ due to the contiguous relations obeyed by ${}_2F_1$. The $\mathrm{II}_{\mathrm{rel}}$ transform is only unitary when $g$ is restricted by [57], and it is indeed self-dual in the same sense as the action-angle map (Ruijsenaars).

Turning finally to the case $N>2$, the multi-variable hypergeometric transform $\Phi_{\mathrm{II}}$ does have the expected duality property. More specifically, its inverse diagonalizes the commuting $\mathrm{I}_{\mathrm{rel}}$ A$\Delta$Os (Chalykh). For $\mathrm{II}_{\mathrm{rel}}$ with $N>2$ and $g=l\hbar$, $l=2,3,\ldots$, Chalykh also finds elementary joint eigenfunctions with the expected self-duality. To date, no Hilbert space results for the $N>2$ $\mathrm{II}_{\mathrm{rel}}$ case have been obtained.

To conclude, we mention that the soliton scattering behavior at the classical level is preserved under quantization in all cases where this can be checked. That is, no new momenta are created in the scattering process and the $S$-matrix is factorized as a product of pair $S$-matrices. Moreover, for the type I cases, the $S$-matrix is a momentum-independent (but $g$-dependent) phase, as a quantum analog of the classical billiard ball scattering.

# Canonical General Relativity

**C Rovelli**, Université de la Méditerranée et Centre de Physique Théorique, Marseilles, France

## Introduction

Lagrangian formulations of general relativity (GR) were found by Hilbert and by Einstein himself, almost immediately after the discovery of the theory. The construction of Hamiltonian formulations of GR, on the other hand, has taken much longer, and has required decades of theoretical research.

The first such formulations were developed by Dirac and by Bergmann and his collaborators, in the 1950s. Their cumbersome formalism was simplified by the introduction of new variables: first by Arnowit, Deser, and Misner in the 1960s and then by Ashtekar in the 1980s. A large number of variants and improvements of these formalisms have been developed by many other authors. Most likely the process is not over, and there is still much to learn about the canonical formulation of GR.

A number of reasons motivate the study of canonical GR. In general, the canonical formalism can be an important step towards quantum theory; it allows the identification of the physical degrees of freedom, and the gauge-invariant states and observables of theory; and it is an important tool for analyzing formal aspects of the theory such as its Cauchy problem. All these issues are highly nontrivial, and present open problems, in GR.

In turn, the structural peculiarity and the conceptual novelty of GR have motivated re-analyses and extensions of the canonical formalism itself.

The following sections discuss the source of the peculiar difficulty of canonical GR, and summarize the formulations of the theory that are most commonly used.

## The Origin of the Difficulties

The reason for the complexity of the Hamiltonian formulation of GR is not so much in the intricacy of its nonlinear field equations; rather, it must be found in the conceptual novelty introduced by GR at the very foundation of the structure of mechanics.

The dynamical systems considered before GR can be formulated in terms of states evolving in time. One assumes that a time variable $t$ can be measured by a physical clock, and that certain observable quantities $A$ of the system can be measured at every instant of time. If we know the state $s$ of the system at some initial time, the theory predicts the value $A(t)$ of these quantities for any given later instant of time $t$. The space of the possible initial states $s$ is the phase space $\Gamma_0$. Observables are real functions on $\Gamma_0$. Infinitesimal time evolution can be represented as a vector field in $\Gamma_0$. This vector field is determined by the Hamiltonian, which is also a function on $\Gamma_0$. The integral lines $s(t)$ of this vector field determine the time evolution $A(t) = A(s(t))$ of the observables.

This conceptual structure is very general. It can be easily adapted to special-relativistic systems. However, it is not general enough for general-relativistic systems. GR is *not* formulated as the evolution of states and observables in a preferred time variable which can be measured by a physical clock. Rather, it is formulated as the *relative* (common) evolution of many observable quantities. Accordingly, in GR there is no quantity playing the same role as the conventional Hamiltonian. In fact, the canonical Hamiltonian density that one obtains from a Legendre transformation from a Lagrangian vanishes identically in GR.

The origin of this peculiar behavior of the theory is the following. The field equations are written as evolution equations in a time coordinate $t$. However, they are invariant under arbitrary changes of $t$. That is, if we replace $t$ with an arbitrary function $t' = t'(t)$ in a solution of the field equations, we obtain another solution. This underdetermination does not lead to a lack of predictivity in GR, because we do not interpret the variable $t$ as the measurable reading of a physical clock, as we do in non-general-relativistic theories. Rather, we interpret $t$ as a nonobservable mathematical parameter, void of physical significance. Accordingly, the notions of "state at a given time" and "value of an observable at a given time" are very unnatural in GR.

A Hamiltonian formulation of GR requires a version of the canonical formalism sufficiently general to deal with this broader notion of evolution. Generalizations of the Hamiltonian formalism have been developed by many authors, such as Dirac (see below), Souriau, Arnold, Witten, and many others. The first step in this direction was taken by Lagrange himself: Lagrange gave a time-independent interpretation of the phase space as the space $\Gamma$ of the solutions of the equations of motion (modulo gauges). As we shall see, however, consensus is still lacking on a fully satisfactory formalism.

## Dirac Theory of Constrained Systems

Dirac has developed a Hamiltonian theory for mechanical systems with constraints, precisely in

view of its application to GR. Dirac's theory is beautiful, finds vast applications, and it is still commonly taken as the basis to discuss Hamiltonian GR, although GR does not fit very naturally into Dirac's scheme. In the following, only the part of Dirac's theory relevant for GR is summarized.

Consider a Lagrangian system with Lagrangian variables $q^i$, with $i = 1, \ldots, n$. Call $v^i$ the corresponding velocities. Let the system be defined by the Lagrangian $L(q^i, v^i)$. The momenta are defined as functions of $q^i$ and $v^i$ by $p_i(q^i, v^i) = \partial L(q^i, v^i)/\partial v^i$. The canonical Hamiltonian $H(q^i, p_i) = v^i(q^i, p_i)p_i - L(q^i, v^i(q^i, p_i))$ (summation over repeated indices is understood) is obtained by inverting the function $p_i(q^i, v^i)$ and expressing the velocities as functions of the momenta $v^i(q^i, p_i)$. The phase space $\Gamma_0$ is the space of the variables $(q^i, p_i)$. Infinitesimal time evolution is given by the vector field $V = v^i(q^i, p_i)\partial/\partial q^i + f_i(q^i, p_i)\partial/\partial p_i$, where velocities and forces are given by the Hamilton equations $v^i = \partial H/\partial p_i$ and $f_i = -\partial H/\partial q^i$.

More formally, the 2-form $\omega = \mathrm{d}p_i \wedge \mathrm{d}q^i$ endows $\Gamma_0$ with a symplectic structure. In the presence of such a structure, every function $A$ determines a vector field $V_A$, defined by $i_{V_A}\omega = -\mathrm{d}A$. By integrating this field, we have a flow in $\Gamma_0$, called the flow generated by $A$. Time evolution is the flow generated by the Hamiltonian. Given two functions $A$ and $B$, their Poisson brackets are defined by the function $\{A, B\} = -V_A(B) = V_B(A)$. Therefore, the time evolution of an observable $A$ satisfies $\mathrm{d}A/\mathrm{d}t = \{A, H\}$. A dynamical system is completely characterized by the set $(\Gamma_0, \omega, \mathcal{A}, H)$, where $\mathcal{A} = (A_1, \ldots, A_N)$ is the ensemble of the observables.

A constrained system, in the sense of Dirac, is a system for which the image of the function $v^i \rightarrow p_i(q^i, v^i)$ is smaller than $R^n$. We can characterize the image $\mathcal{I}$ of the map $(q^i, v^i) \rightarrow (q^i, p_i)$ with a set of equations on $\Gamma_0$

$$C_\alpha(q^i, p_i) = 0 \qquad [1]$$

where $\alpha = 1, \ldots, m'$. These are called the primary constraints.

The "constraint surface" $C$ is the largest subspace of $\mathcal{I}$ which is preserved by time evolution. It can be characterized by adding additional constraints, still of the form (1), with $\alpha = m' + 1, \ldots, m$. These additional constraints, called secondary constraints, can be computed as the Poisson brackets of the primary constraints with the Hamiltonian (plus the Poisson brackets of these secondary constraints with the Hamiltonian, and so on, until the Poisson brackets of all the constraints with the Hamiltonian vanish on in $C$). We say that an equation holds weakly if it holds on $C$.

A constrained system is "first class" if the Poisson brackets of the constraints among themselves vanishes weakly. Maxwell theory and GR are first-class constrained systems. In a first-class constrained system, the constraints generate flows that preserve $C$ and foliate it into "orbits." The space of these orbits is called the physical phase space (see Figure 1).

This flow is interpreted as a "gauge" transformation, namely as a change of mathematical description of the same physical state. As first observed by Dirac, such interpretation is necessary if we demand a deterministic physical evolution, for the following reason. A first-class constrained system is a system in which the time evolution $q^i(t)$ of the Lagrangian variables is not completely determined by the equations of motion. (The relation between constraints and underdetermination of the evolution is simple to understand. In a Lagrangian system, the number of equations of motion is equal to the number of Lagrangian variables. If one of these equations is a constraint (between the initial velocities and initial coordinates), then one evolution equation is missing.) To recover a deterministic physical evolution, we must interpret two "mathematical" states that can evolve from the same initial data, as describing the same "physical" state. As shown by Dirac, the transformations generated by the constraints are precisely the ones that implement such an identification.

It follows that the physical states must be identified with the equivalence classes of the points of $C$ under the gauge transformations generated by the constraints, namely with the orbits of their flow. It is easy to show that (locally) there is a unique symplectic 2-form $\omega_{\mathrm{ph}}$ on $\Gamma_{\mathrm{ph}}$ such that its pullback to $C$ is equal to the pullback of $\omega$ to $C$ ($i_*\omega = \pi_*\omega_{\mathrm{ph}}$, see Figure 1). Physical observables $A_{\mathrm{ph}}$ are functions on $C$ that are gauge invariant, namely constant on

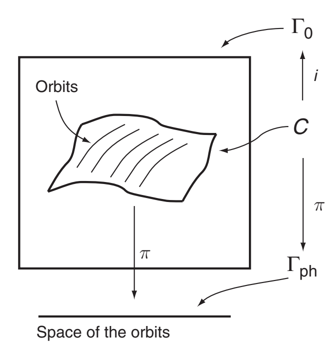

**Figure 1** The structure of a first-class constrained system. $\Gamma_0$: phase space, $C$: constraint surface, $\Gamma_{\mathrm{ph}}$: physical phase space; $i$: imbedding of $C$ in $\Gamma$; $\pi$ projection to orbit space (sending each point into its orbit).

the orbits. That is, they are functions on $\Gamma_{\mathrm{ph}}$. The Hamiltonian is a physical observable. The dynamical system $(\Gamma_{\mathrm{ph}}, \omega_{\mathrm{ph}}, \mathcal{A}_{\mathrm{ph}}, H)$, where $\mathcal{A}_{\mathrm{ph}}$ is the ensemble of the physical observables, is a complete description of the physical system, called the gauge-invariant formulation, with no more constraints or gauges.

For instance, the phase space of Maxwell theory is coordinatized by the Maxwell potential $A_\mu(\boldsymbol{x}), \mu = 0, 1, 2, 3$, and its conjugate momentum $E^\mu(\boldsymbol{x})$. Since the time derivative of $A_0$ does not appear in the Maxwell action, the primary constraint is

$$E^0(\boldsymbol{x}) = 0 \qquad [2]$$

The secondary constraint turns out to be the Gauss law,

$$\partial_a E^a(\boldsymbol{x}) = 0 \qquad [3]$$

where $a = 1, 2, 3$. The first generates arbitrary transformations of $A_0$, while the second generates the time-independent gauge transformations $\delta A_a(\boldsymbol{x}) = \partial_a \lambda(\boldsymbol{x})$. The pair $(A_0, \pi^0)$ can be dropped altogether, since it is formed by a pure gauge variable and a variable constrained to vanish. The (gauge-invariant) Hamiltonian is $H = 1/8\pi \int \mathrm{d}^3\boldsymbol{x}\,(E^a E_a + B^a B_a)$, where $B^a = \epsilon^{abc}\partial_b A_c$ is the magnetic field and $E^a$ is easily recognized as the electric field. $E^a$ and $B_a$ are the physical observables.

## General Structure of GR Constraints

GR fits into Dirac theory with a certain difficulty. Since the constraints are the generators of the gauge invariances, it is easy to determine their structure in GR. The gauge invariances of GR are given by the coordinate transformations $x^\mu \to x'^\mu = f^\mu(x)$, where $x = (\boldsymbol{x}, t)$. Accordingly, we have four primary constraints $\pi^\mu = 0$, analogous to [2], and four secondary constraints $C_\mu(\boldsymbol{x}) = 0$, analogous to [3]. These are usually separated into the three "momentum" constraints

$$C_a(\boldsymbol{x}) = 0 \qquad [4]$$

which generate fixed-time spatial coordinate transformations and the "Hamiltonian" constraint

$$C(\boldsymbol{x}) = 0 \qquad [5]$$

which generates changes in the $t$ coordinate.

The metric $g_{\mu\nu}(x)$ that represents the gravitational field in Einstein's original formulation has ten independent components per point. Each first-class constraint indicates that one Lagrangian variable is a gauge degree of freedom. The physical degrees of freedom of GR are therefore $(10 - 4 - 4) = 2$ per point. In the linearized theory, these are the two degrees of freedom that describe the two polarizations of a gravitational wave of given momentum. Formulations of GR in which there are additional gauge invariances (such as Cartan's tetrad formulation, see below) have, accordingly, more constraints.

Since the Hamiltonian generates evolution in the Lagrangian evolution parameter $t$, and since such evolution can be obtained as a gauge transformation, it follows that the Hamiltonian is a constraint in GR. The vanishing of the Hamiltonian is a characteristic feature of general-relativistic systems. The Hamiltonian structure of GR is therefore determined by its phase space and its constraints. The gauge-invariant formulation of the theory is given just by the set $(\Gamma_{\mathrm{ph}}, \omega_{\mathrm{ph}}, \mathcal{A}_{\mathrm{ph}})$ and no Hamiltonian. The physical interpretation of this structure is discussed in the last section.

## ADM Formalism

In Einstein's formulation, the Lagrangian variable of GR is the metric field $g_{\mu\nu}(\boldsymbol{x}, t)$ (here we use the signature $[-,+,+,+]$). Arnowit, Deser, and Misner have introduced the following change of variables:

$$q_{ab} = g_{ab}, \quad N = 1/\sqrt{-g^{00}}, \quad N^a = q^{ab} g_{a0} \qquad [6]$$

where $q^{ab}$ is the inverse of the three-dimensional metric $q_{ab}$, used henceforth to raise and lower space indices $a, b = 1, 2, 3$. This is equivalent to writing the invariant interval in the form

$$\mathrm{d}s^2 = -N^2\,\mathrm{d}t^2 + q_{ab}(\mathrm{d}x^a + N^a\,\mathrm{d}t)(\mathrm{d}x^b + N^b\,\mathrm{d}t)$$

These variables have an interesting geometric interpretation. Consider a family of spacelike ("ADM") surfaces $\Sigma_t$ defined by $t = \text{constant}$. $q_{ab}$ is the 3-metric induced on the surface. $N$ is called the "lapse" function and $N^a$ is called the "shift" function. Their geometrical interpretation is illustrated in Figure 2.

When written in terms of these variables, the action of GR takes the form

$$S[q_{ab}, N, N^a] = \int \mathrm{d}^4x \sqrt{q} N[R + k_{ab}k^{ab} - k^2]$$

where $q = \det q_{ab}$ and $R$ are the determinant and the Ricci scalar of the metric $q_{ab}$;

$$k_{ab} = \frac{1}{2N}(\partial_t q_{ab} - D_a N_b - D_b N_a)$$

is the extrinsic curvature of the constant time surface; and $D_a$ is the covariant derivative of $q_{ab}$. This action is independent of the time derivatives of

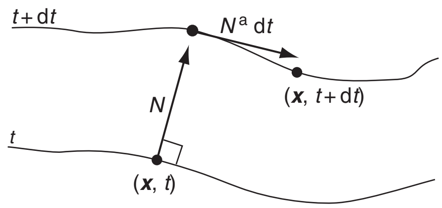

**Figure 2** The geometrical interpretation of the lapse $N(\boldsymbol{x}, t)$ and shift $N^a(\boldsymbol{x}, t)$ fields. Two ADM surfaces, defined by the values $t$ and $t + dt$, are displayed. $N(\boldsymbol{x}, t)dt$ is the proper length of the vector joining the two surfaces, normal to the first surface at $(\boldsymbol{x}, t)$. This is the proper time lapsed between the two surfaces for an observer at rest on the first surface at $(\boldsymbol{x}, t)$. The quantity $dx^a = N^a(\boldsymbol{x}, t)dt$ is the shift (the displacement) between the endpoint of this vector and the point $(\boldsymbol{x}, t + dt)$ having the same spacial coordinates as $(\boldsymbol{x}, t)$.

$N$ and $N^a$. The conjugate momenta $\pi$ and $\pi_a$ of these quantities are therefore the primary constraints and the pairs $(\pi, N)$ and $(\pi_a, N^a)$ can be taken out of the phase space as for the pair $(E^0, A_0)$ in the Maxwell example. We can therefore take the 3-metric $q_{ab}(\boldsymbol{x})$ and its conjugate momentum $p^{ab}(\boldsymbol{x})$ as the canonical variables of GR. The momentum is related to the "velocity" $\partial_t q_{ab}$, by

$$p^{ab} = \sqrt{q}(k^{ab} - kq^{ab})$$

where $k = k_{ab}q^{ab}$.

The secondary constraints [4] and [5] turn out to be

$$C_a = \sqrt{q}D_b\left(\frac{1}{\sqrt{q}}p^b{}_a\right) = 0 \qquad [7]$$

and

$$C = \frac{1}{\sqrt{q}}\left(p^{ab}p_{ab} - \frac{1}{2}p^2\right) - \sqrt{q}R = 0 \qquad [8]$$

where $p = p^{ab}q_{ab}$

If the two fields $q_{ab}(\boldsymbol{x}, t)$ and $p^{ab}(\boldsymbol{x}, t)$ satisfy the Hamilton equations

$$\frac{\partial q_{ab}(\boldsymbol{x}, t)}{\partial t} = \{q_{ab}(\boldsymbol{x}, t), H(t)\} \qquad [9]$$

$$\frac{\partial p^{ab}(\boldsymbol{x}, t)}{\partial t} = \{p^{ab}(\boldsymbol{x}, t), H(t)\} \qquad [10]$$

where

$$H(t) = \int d^3x\, N(\boldsymbol{x}, t)C[q_{ab}(\boldsymbol{x}, t),\, p^{ab}(\boldsymbol{x}, t)] + N^a(\boldsymbol{x}, t)C_a[q_{ab}(\boldsymbol{x}, t),\, p^{ab}(\boldsymbol{x}, t)]$$

with arbitrary functions $N(\boldsymbol{x}, t), N^a(\boldsymbol{x}, t)$, then the metric $g_{\mu\nu}(\boldsymbol{x}, t)$, defined from $q_{ab}, N, N^a$ by eqn [6], is the general solution of the vacuum Einstein equation $\text{Ricci}[g] = 0$. Therefore, these equations provide a Hamiltonian form of the Einstein field equation.

## Tetrad Formalism

The tetrad formalism, developed by Cartan, Weyl, and Schwinger, has definite advantages with respect to the metric formalism. It allows the coupling of fermion fields to GR and is, therefore, needed to couple the standard model to GR. In the tetrad formalism, the gravitational field is represented by four covariant fields $e^I_\mu(x)$, where $I, J, \ldots = 0, 1, 2, 3$ are flat Lorentz indices raised and lowered with the Minkowski metric $\eta_{IJ} = \text{diag}[-1, +1, +1, +1]$. The relation with the metric formalism is given by

$$g_{\mu\nu} = \eta_{IJ}e^I_\mu e^J_\nu$$

In this formulation, GR has an additional local SO(3,1) gauge invariance, given by local Lorentz transformations on the $I$ indices. The corresponding canonical formalism is usually defined in a gauge in which $e^i_0 = 0$, where $i, j, \ldots = 1, 2, 3$ are flat three-dimensional indices raised and lowered with the $\delta_{ij} = \text{diag}[+1, +1, +1]$. In this gauge, the Lorentz group is reduced to the local SO(3) group of spatial transformations, and the ADM variable are defined by

$$e^I_\mu = \begin{pmatrix} N & N^i \\ 0 & e^i_a \end{pmatrix} \qquad [11]$$

where $N^i = e^i_a N^a$. This is equivalent to writing the invariant interval in the form

$$ds^2 = -N^2\, dt^2 + (e_{ai}\, dx^a + N_i\, dt)\left(e^i_b\, dx^b + N^i\, dt\right)$$

The reduced canonical variables can be taken to be the field $e^i_a(\boldsymbol{x})$ that represents the "triad" of the ADM surface, and its conjugate momentum $p^a_i(\boldsymbol{x})$. Their relation with the three-dimensional metric variables is given by transforming internal indices into tangent indices with the triad field $e^i_a$ and its inverse $e^a_i$. In particular,

$$q_{ab} = \delta_{ij}e^i_a e^j_b \qquad [12]$$

$$p^{ab} = e^{bi}p^a_i \qquad [13]$$

Also, for later reference,

$$k^i_a \equiv e^{ib}k_{ab} = \frac{2}{\det e}\left(p^i_a - \tfrac{1}{2}e^i_a p\right) \qquad [14]$$

where $p = e^i_a p^a_i$.

The momentum and Hamiltonian constraints are the same as in the ADM formulation, with $q_{ab}$ and $p^{ab}$ expressed in terms of the triad variables. The additional constraint that generates the internal rotations is

$$G_i = \epsilon_{ijk}e^j_a\, p^{ak} = 0 \qquad [15]$$

## Ashtekar Formalism

The Ashtekar formalism simplifies the form of the constraints and casts GR in a form having the same kinematics as Yang–Mills theory. With its variants, it is widely used in nonperturbative quantum gravity, in particular in the loop formulation (*see* Loop Quantum Gravity). It can be obtained from the tetrad canonical formalism by the canonical transformation

$$A^i_a = \tfrac{1}{2}\epsilon^i_{jk}\omega^{jk}_a + \mathrm{i}k^i_a \qquad [16]$$

$$E^a_i = \det e\, e^a_i \qquad [17]$$

where $\omega^{ij} = \omega^{ij}_a\, \mathrm{d}x^a$ is the (torsion-free) spin connection of the triad 1-form field $e^i = e^i_a\, \mathrm{d}x^a$, determined by the Cartan equation

$$\mathrm{d}e^i + \omega^i_k \wedge e^k = 0$$

The "electric" field $E$ is real, while the Sen–Ashtekar connection $A^i = A^i_a\, \mathrm{d}x^a$ is complex and satisfies the reality condition

$$A^i + \overline{A^i} = 2\Gamma^i[e] \qquad [18]$$

The connection $A^i$ has a simple geometrical interpretation. It is the pullback $A_{ai} = \omega^{(+)}_{a0i}$ on the $t = 0$ ADM surface of the self-dual part

$$\omega^{(+)}_{IJ} = \frac{1}{2}\left(\omega_{IJ} - \frac{\mathrm{i}}{2}\,\epsilon_{IJ}{}^{KL}\omega_{KL}\right)$$

of the four-dimensional torsion free spin connection $\omega^{IJ}_\mu$ determined by the tetrad field $e^I_\mu$.

In terms of these fields, the constraint equations can be written in the form

$$G_i = D_a E^a_i = 0 \qquad [19]$$

$$C_a = F^i_{ab} E^a_i = 0 \qquad [20]$$

$$C = \epsilon_{ijk} F^i_{ab} E^{ja} E^{kb} = 0 \qquad [21]$$

where $D_a$ is the covariant derivative and $F_{ab}$ is the curvature defined by the connection $A$. The first of these constraints is the nonabelian version of the Gauss law [3]: it is the gauge constraint of Yang–Mills theory. The constraints are polynomial in the canonical variables.

These equations are often written using a basis $\tau_i$ in the su(2) Lie algebra, and defining the su(2) connection $A = A^i\tau_i$ and the su(2)-valued vector field $E^a = E^{ai}\tau_i$. In terms of these fields the constraints can be written in the form

$$G = D_a E^a = 0$$

$$C_a = \mathrm{tr}[F_{ab}E^a] = 0$$

$$C = \mathrm{tr}[F_{ab}E^a E^b] = 0$$

where the trace is on su(2).

A variant of this formalism commonly used in quantum gravity is obtained by replacing [16] with the Barbero connection

$$A^i_a = \tfrac{1}{2}\,\epsilon^i_{jk}\,\omega^{jk}_a + \gamma\, k^i_a \qquad [22]$$

where $\gamma$ is an arbitrary complex number, called the Immirzi parameter. In terms of this connection, [21] is replaced by

$$C = \epsilon_{ijk} F^i_{ab} E^{ja} E^{kb} + \frac{1+\gamma^2}{4}\det e(k_{ab}k^{ab} - k^2) = 0$$

where $e^i_a$ and $k_{ab}$ are given as function of $E$ and $A$ by [22] and [17]. The choice $\gamma = 1$, with the constraint [19]–[21], gives the canonical formulation of Euclidean GR.

All the formulations described extend readily to matter couplings. The structure of the constraints remains the same – with additional constraints corresponding to matter gauge invariances, if any. The GR constraints are modified by the addition of matter terms. In particular, the Hamiltonian constraint $C$ and the momentum constraint $C_a$ are modified by the addition of terms determined by the energy density and the momentum density of the matter, respectively. In the Ashtekar formulation, a fermion field modifies the Gauss law constraint by the addition of a torsion term.

## Evolution

In the gauge-invariant canonical structure of GR, there is no explicit time flow generated by a Hamiltonian. If the formalism is utilized just in order to express the Einstein equation in first-order canonical form, this is not a difficulty, because evolution in the coordinate time is generated by the constraints. On the other hand, if we are interested in understanding the structure of states, observables, and evolution of GR, the situation appears to be puzzling. An additional complication arises from the fact that virtually no gauge-invariant observable $A_{\mathrm{ph}}$ is known explicitly as a function on the phase space. These issues become especially relevant when the canonical formalism is taken as a starting point for quantization. How is physical evolution represented in canonical GR?

The first relevant observation is that the gauge-invariant phase space $\Gamma_{\mathrm{ph}}$ is better understood as a phase space in the sense of Lagrange: namely as the space $\Gamma$ of the solutions of the equations of motion modulo gauges, rather than a space of instantaneous states. Recall that in GR the notion of "instantaneous state" is rather unnatural.

In the ADM formulation, for instance, an orbit on the constraint surface of GR can be understood as the ensemble of all possible values that the variables

$(q_{ab}(\boldsymbol{x}), p^{ab}(\boldsymbol{x}))$ can take on arbitrary spacelike ADM surfaces embedded in a given solution of the Einstein equation. Motion along the orbit (which has dimension $4 \times \infty^3$) corresponds to arbitrary deformations of the surface.

Physical applications of classical GR deal with relations between "partial observables." A partial observable is any variable physical quantity that can be measured, even if its value cannot be determined from the knowledge of the physical state. An example of partial observable in nonrelativistic mechanics is given precisely by the nonrelativistic time $t$. Partial observables are represented in GR as functions on $\Gamma_0$. A physical state in $\Gamma_{\text{ph}}$ determines an orbit in $C$, and therefore a set of relations between partial observables (see Figure 1). That is, it determines the possible values that the partial observables can take "when" and "where" other partial observables have given values. All physical predictions of classical GR can be expressed in this form.

One of the partial observables can be selected to play the role of a physical clock time, and evolution can be expressed in terms of such clock time. In general, it is difficult – if not impossible – to find a clock time observable in terms of which evolution is a proper conventional Hamiltonian evolution. Matter couplings partially simplify the task. For instance, if the motion of planet Earth is coupled to GR, then proper time along this motion from a significative event on Earth, which is a partial observable, can be a convenient clock time. In pure gravity, the "York time" defined as the trace of the extrinsic curvature $T_{\text{Y}} = k$, on ADM surfaces where $k$ is spatially constant, has been extensively and effectively used as a clock time in formal analysis of the theory. A Hamiltonian that generates evolution in a given clock time $T$ can be formally obtained by solving the Hamiltonian constraint with respect to a momentum $P_T$ conjugate to $T$. Such "reparametrizations" of the relative evolution of the partial observables can be useful to analyze equations and to help intuition, but they are by no means necessary to have a well-defined interpretation of the theory.

Another possibility to introduce a preferred time flow is to consider asymptotically flat solutions of the field equations. In this case, one can define a nonvanishing Hamiltonian, given by a boundary integral at spacial infinity. This Hamiltonian generates evolution in an asymptotic Minkowski time. This choice is convenient for describing observations performed from a large distance on isolated gravitational systems. Many general-relativistic physical observations do not belong to this category.

Various other techniques to define a fully generally covariant canonical formalism have been explored. Among these: definitions of the physical symplectic structure directly on the space of the solutions of the field equations; generalization of the initial and final surfaces to boundaries of compact spacetime regions; construction of "evolving constants of motion," namely families of gauge-invariant observables depending on a clock time parameter; multisymplectic formalisms that treats space and time derivatives on a more equal footing; and others. Many of these techniques are attempts to overcome the unequal way in which time and space dependence are treated in the conventional Hamiltonian formalism.

GR has deeply modified our understanding of space and time. An extension of the canonical formalism of mechanics, compatible with such a modification, is needed, but consensus on the way (or even the possibility) of formulating a fully satisfactory general-relativistic extension of Hamiltonian mechanics is still lacking.

# Capacities Enhanced by Entanglement

**P Hayden**, McGill University, Montreal, QC, Canada

## Introduction

Shared entanglement between a sender and receiver can significantly improve the usefulness of a quantum channel for the communication of either classical or quantum data. Superdense coding and teleportation provide the most well-known examples of this improvement; free entanglement doubles the classical capacity of a noiseless quantum channel and makes it possible for a noiseless classical channel to send quantum data. In fact, the entanglement-assisted classical and quantum capacities of a quantum channel are in many senses simpler and better behaved than their unassisted counterparts (Holevo 1998, Schumacher and Westmoreland 1997, Devetak 2005). Most importantly, these capacities can be calculated using simple formulas and finite optimization procedures (Bennett *et al.* 1999, 2002). No such finite procedure is known for either of the unassisted capacities. Moreover, the entanglement-assisted classical and quantum capacities are related by a simple factor of 2. The unassisted capacities, in contrast, have completely different formulas. In fact, the simple factor of 2 generalizes to a statement known as the quantum reverse Shannon theorem, which governs the rate at which one quantum channel can simulate another (Bennett *et al.* 2005). The answer is given by the ratio of the entanglement-assisted capacities.

### Notation

Quantum systems will be denoted by $A$, $B$, and so on as well as their variants such as $A'$ and $\hat{A}$. The choice of letter will generally indicate which party holds a given system, with $A$ reserved for the sender, Alice, and $B$ for the receiver, Bob. Given a quantum system $C$, $C^{\otimes n}$ will often be written as $C^n$. These symbols will be used to denote both the Hilbert space of the quantum system and the set of density operators on that system. Thus, a quantum channel $\mathcal{N}: A' \to B$ refers to a trace-preserving, completely positive (TPCP) map from the operators on the Hilbert space of $A'$ to those of $B$. $\mathrm{id}^C$ refers to the identity channel on $C$. The map $\mathcal{N} \otimes \mathrm{id}^C$ will frequently be abbreviated to $\mathcal{N}$ in order to simplify long expressions. Likewise, the density operator $|\varphi\rangle\langle\varphi|$ of a pure quantum state $|\varphi\rangle$ will be abbreviated to $\varphi$. $\pi^C$ will refer to the maximally mixed state on $C$ and $\pi_d$ to the maximally mixed state on a specified $d$-dimensional quantum system.

For a given quantum state $\varphi^{AB}$ on the composite system $AB$, $\varphi^A = \mathrm{tr}_B\, \varphi^{AB}$ and

$$H(A)_\varphi = H(\varphi^A) = -\mathrm{tr}(\varphi^A \log_2 \varphi^A) \qquad [1]$$

is the von Neumann entropy of $\varphi^A$, while

$$H(A|B)_\varphi = -I_c(A\rangle B) = H(AB)_\varphi - H(B)_\varphi \qquad [2]$$

is its conditional entropy and

$$I(A;B)_\varphi = H(A)_\varphi + H(B)_\varphi - H(AB)_\varphi \qquad [3]$$

its mutual information.

## Entanglement-Assisted Classical and Quantum Capacities

The entanglement-assisted classical capacity of a quantum channel $\mathcal{N}: A' \to B$ is the optimal rate at which classical information can be communicated through the channel while in addition making use of an unlimited number of maximally entangled states.

The formal definition proceeds as follows. Alice and Bob are assumed to share $nS$ ebits in the form of a maximally entangled state $|\Phi\rangle^{\tilde{A}\tilde{B}}$ of Schmidt rank $2^{nS}$. Conditioned on her message $m \in \{1, 2, \ldots, 2^{nR}\}$, Alice will apply an encoding operation $\mathcal{E}_m : \tilde{A} \to A'^n$. Bob's decoding is given by a POVM $\{\Lambda_m\}_{m=1}^{2^{nR}}$ on the composite system $\tilde{B}B^n$. The procedure is said to have maximum probability of error $\epsilon$ if

$$\max_m \mathrm{tr}\left[\Lambda_m(\mathcal{N}^{\otimes n} \circ \mathcal{E}_m)(\Phi)\right] \geq 1 - \epsilon \qquad [4]$$

These elements, illustrated in Figure 1, consisting of the shared entanglement, as well as the encoding and decoding operations meeting the criterion of eqn [4], are called a $(2^{nR}, 2^{nS}, n, \epsilon)$ entanglement-assisted classical code for the channel $\mathcal{N}$. A rate $R$ is said to be achievable if there exists a choice of $S \geq 0$ and a sequence of entanglement-assisted classical codes $(2^{nR}, 2^{nS}, n, \epsilon_n)$ with $\epsilon_n \to 0$. The entanglement-assisted

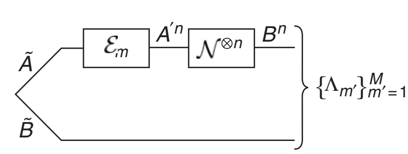

**Figure 1** Circuit representation of the elements of an entanglement-assisted classical code for the channel $\mathcal{N}$. Alice encodes message $m$ by applying the operation $\mathcal{E}_m$ to her half of the shared entanglement. Bob decodes by applying the POVM $\{\Lambda_{m'}\}$ on the output of the channel and his half of the shared entanglement.

classical capacity $C_E(\mathcal{N})$ of $\mathcal{N}$ is defined to be the supremum over all achievable rates.

**Theorem 1** (Bennett *et al.* 1999, 2002). *The entanglement-assisted classical capacity $C_E$ of a quantum channel $\mathcal{N}: A' \to B$ is given by*

$$C_E(\mathcal{N}) = \max_{\sigma} I(A;B)_\sigma \qquad [5]$$

*where the maximization is over states $\sigma^{AB} = \mathcal{N}(\varphi^{AA'})$ arising from the channel by acting on the $A'$ half of any pure state $|\varphi\rangle^{AA'}$.*

The theorem bears a strong formal resemblance to Shannon's noisy coding theorem for the classical capacity of a classical noisy channel. There the capacity formula is also given by an optimization of the mutual information, but over joint distributions between the input and output alphabets arising from the action of the channel. Such a joint distribution cannot exist in general for a quantum channel because the no-cloning theorem excludes the possibility of the input and output existing simultaneously. Equation [5] instead refers to a natural substitute for the joint input–output distribution: a quantum state arising from the quantum channel acting on half of an entangled pure state.

Another point worth stressing is that, unlike the known formulas for the unassisted classical and quantum capacities of a quantum channel, eqn [5] refers to only a single use of $\mathcal{N}$ instead of the limit of many uses, $\mathcal{N}^{\otimes n}$. The formula can therefore readily be used to evaluate $C_E$ for any channel of interest.

Consider, for example, the $d$-dimensional depolarizing channel

$$\mathcal{D}_p(\rho) = (1-p)\rho + p\pi_d \qquad [6]$$

that with probability $p$ completely randomizes the input but otherwise leaves the input invariant. For such channels, the maximum is achieved by choosing a maximally entangled state for $|\varphi\rangle^{AA'}$, yielding

$$C_E(\mathcal{D}_p) = 2\log_2 d - h_{d^2}\left(1 - p\frac{d^2-1}{d^2}\right) \qquad [7]$$

where for any $0 \leq q \leq 1$ and integer $r \geq 1$,

$$h_r(q) = -q\log_2 q - (1-q) \times \log_2\left(\frac{1-q}{r-1}\right) \qquad [8]$$

is the Shannon entropy of the distribution $(q, (1-q)/(r-1), \ldots, (1-q)/(r-1))$.

Entanglement assistance also simplifies the relationship between the classical and quantum capacities of a channel. Proceeding as before to formally define the quantum capacity, Alice and Bob are again assumed to share a maximally entangled state $|\Phi\rangle^{\tilde{A}\tilde{B}}$ of Schmidt rank $2^{nS}$. Alice's encoding operation will be a TPCP map $\mathcal{E}: \hat{A}\tilde{A} \to A'^n$ acting on an input system $\hat{A}$ and her half of the shared entanglement, $\tilde{A}$. Bob's decoding will likewise be a TPCP map $\mathcal{D}: \tilde{B}B^n \to \hat{B}$ acting on the output of the channel, $B^n$, and his half of the shared entanglement, $\tilde{B}$. $\hat{A}$ and $\hat{B}$ are assumed to be isomorphic quantum systems of some fixed dimension $2^{nQ}$. The procedure is said to have subspace fidelity $1-\epsilon$ if

$$^{\hat{B}}\langle\varphi|\left(\mathcal{D}\circ\mathcal{N}^{\otimes n}\circ\mathcal{E}\right)\left(\Phi^{\tilde{A}\tilde{B}}\otimes\varphi^{\hat{A}}\right)|\varphi\rangle^{\hat{B}} \geq 1-\epsilon \qquad [9]$$

for all $|\varphi\rangle^{\hat{A}} \in \hat{A}$. These elements, illustrated in Figure 2, are together called a $(2^{nQ}, 2^{nS}, n, \epsilon)$ entanglement-assisted quantum code for the channel $\mathcal{N}$. A rate $Q$ is said to be achievable if there exists a choice of $S \geq 0$ and a sequence of entanglement-assisted quantum codes $(2^{nR}, 2^{nS}, n, \epsilon_n)$ with $\epsilon_n \to 0$. The entanglement-assisted quantum capacity $Q_E(\mathcal{N})$ of $\mathcal{N}$ is defined to be the supremum over all achievable rates.

There is considerable freedom in the definition of the entanglement-assisted quantum capacity. It could, for example, be defined as the largest amount of maximal entanglement that can be generated using the channel, minus the entanglement consumed during the protocol itself. Alternatively, the fidelity criterion eqn [9] could be strengthened to require that $\mathcal{D}\circ\mathcal{N}^{\otimes n}\circ\mathcal{E}$ preserve not only pure states on $\hat{A}$ but any entanglement between $\hat{A}$ and a reference system. All of these variants yield the same capacity formula:

$$Q_E(\mathcal{N}) = \tfrac{1}{2}C_E(\mathcal{N}) \qquad [10]$$

This equivalence is a direct consequence of the existence of the teleportation and superdense coding protocols. When maximal entanglement is available, teleportation converts the ability to send classical data into the ability to send quantum data at half the classical rate. Conversely, by consuming

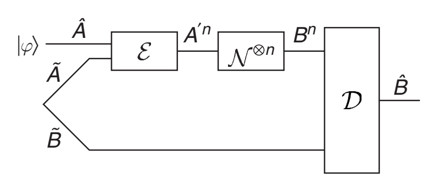

**Figure 2** Circuit representation of the elements of an entanglement-assisted quantum code for the channel $\mathcal{N}$. $\mathcal{E}$ is Alice's encoding operation, which acts on both her input state and her half of the shared entanglement. Bob decodes using a quantum operation $\mathcal{D}$ acting on the output of the channel and his half of the shared entanglement.

maximal entanglement, superdense coding converts the ability to send quantum data into the ability to send classical data at double the quantum rate.

## Sketch of Proof

The proof of a capacity theorem can usually be broken into two parts, achievability and optimality. The achievability part demonstrates the existence of a sequence of codes reaching the prescribed rate while the optimality part shows that it is impossible to do better.

The main idea in the achievability proof can be understood by studying the special case where $\varphi^{A'} = \pi^{A'}$. Let $d_{A'} = \dim A'$ and $\{U_j\}_{j=1}^{d_{A'}^{2n}}$ be a set of Weyl operators for $A'^n$. The relevant property of these operators is that averaging over them implements the constant map: for all density operators $\rho$,

$$\frac{1}{d_{A'}^{2n}} \sum_{j=1}^{d_{A'}^{2n}} U_j \rho U_j^\dagger = \pi^{A'^n} \qquad [11]$$

Consider the state $\sigma_j$ that arises if Alice acts with $U_j$ on the $A'^n$ half of a rank-$d_{A'}^n$ maximally entangled state $|\varphi\rangle^{AA'^n}$ and then sends the $A'^n$ half of the resulting state through $\mathcal{N}$. (Note that here $A'^n$ also plays the role of $\tilde{A}$.) The entropy of the resulting state is

$$H(\sigma_j) = H\Big(\mathcal{N}((U_j \otimes I_{\tilde{B}})\varphi(U_j^\dagger \otimes I_{\tilde{B}}))\Big) \qquad [12]$$

$$= H(\mathcal{N}(\varphi)) \qquad [13]$$

since $U_j$ does not change the local density operator on $A'^n$.

On the other hand, if Alice selects a value of $j$ from the uniform distribution, then the resulting average input state to the channel will be

$$\pi^{A'^n} \otimes \pi^A = \varphi^{A'^n} \otimes \varphi^A \qquad [14]$$

and the corresponding average output state will be $\mathcal{N}(\varphi^{A'^n}) \otimes \varphi^A$, which has entropy

$$H(\mathcal{N}(\varphi^{A'^n})) + H(\varphi^A) \qquad [15]$$

Therefore, the Holevo quantity of the ensemble of output states, defined as the entropy of the average state minus the average of the entropies of the individual output states, will be equal to

$$H(\varphi^A) + H\Big(\mathcal{N}(\varphi^{A'^n})\Big) - H\Big(\mathcal{N}(\varphi^{AA'^n})\Big) \qquad [16]$$

This is precisely the quantity $I(A;B)_\sigma$ for the state $\mathcal{N}(\varphi^{AA'^n})$ since the channel $\mathcal{N}$ transforms the $A'^n$ system into $B$. Moreover, if Bob is given the $A$ part of the maximally entangled state, then this is the Holevo quantity of an ensemble of states that can be produced by Alice acting on half of a shared entangled state and then sending her half through the channel. Invoking the Holevo–Schumacher–Westmoreland (HSW) theorem for the classical capacity (Holevo 1998, Schumacher and Westmoreland 1997) therefore completes the proof; using coding, the Holevo quantity is an achievable communication rate.

The proof that eqn [5] is optimal involves a series of entropy manipulations similar to the optimality proofs for the unassisted classical and quantum capacities. From the point of view of quantum information, the truly unusual part of the proof is the demonstration that it is unnecessary to consider multiple copies of $\mathcal{N}$ (Cerf and Adami 1997). Specifically, let

$$f(\mathcal{N}) = \max_\sigma I(A;B)_\sigma \qquad [17]$$

where the maximization is defined as in Theorem 1. Techniques analogous to those used for the unassisted capacities yield the upper bound

$$C_E(\mathcal{N}) \le \lim_{n\to\infty} \frac{1}{n} f(\mathcal{N}^{\otimes n}) \qquad [18]$$

Unlike the unassisted case, however, a relatively easy argument shows that

$$f(\mathcal{N}_1 \otimes \mathcal{N}_2) = f(\mathcal{N}_1) + f(\mathcal{N}_2) \qquad [19]$$

(The analogous statement is an important conjecture for the classical capacity and is known to be false for the quantum capacity (DiVincenzo *et al.* 1998).) As a result, $C_E(\mathcal{N}) \le f(\mathcal{N})$, which is the optimality part of Theorem 1.

To see the origin of eqn [19], it will be helpful to invoke Stinespring's theorem to write $\mathcal{N}_j = \mathrm{tr}_{E_j} \mathcal{U}_j^{B_j E_j}$, where $\mathcal{U}_j : A'_j \to B_j E_j$ is an isometry. Fix a state $|\varphi\rangle^{AA'_1A'_2}$ and let $\sigma = (\mathcal{U}_1 \otimes \mathcal{U}_2)(\varphi)$. Equation [19] follows from the fact that

$$\begin{aligned} I(A;B_1B_2)_\sigma &\le I(AB_2E_2;B_1)_\sigma \\ &\quad + I(AB_1E_1;B_2)_\sigma \end{aligned} \qquad [20]$$

Simply redefining $A$ to be $AB_2E_2$ shows that the first term of the right-hand side is upper bounded by $f(\mathcal{N}_1)$. The second term, likewise, is upper bounded by $f(\mathcal{N}_2)$. Equation [20] is itself equivalent to the inequality

$$\begin{aligned} H(B_1B_2|E_1E_2)_\sigma &+ H(B_1B_2)_\sigma \\ &\le H(B_1|E_1)_\sigma + H(B_2|E_2)_\sigma \\ &\quad + H(B_1)_\sigma + H(B_2)_\sigma \end{aligned} \qquad [21]$$

The inequality $H(B_1B_2)_\sigma \le H(B_1)_\sigma + H(B_2)_\sigma$ holds by the subadditivity of the von Neumann entropy.

Repeated applications of the strong subadditivity inequality, moreover, lead to the inequality

$$H(B_1B_2|E_1E_2)_\sigma \leq H(B_1|E_1)_\sigma + H(B_2|E_2)_\sigma \qquad [22]$$

Together, they prove eqn [20] and, thence, eqn [19]. The intuitive meaning of this "single-letterization" is unclear, but regardless, it is interesting to note that the proof involved invoking a pair of purifying environment systems, $E_1$ and $E_2$, and studying the entropy relationships between the true outputs of the channel and the environment's share.

## The Quantum Reverse Shannon Theorem

A strong argument can be made that the entanglement-assisted capacity of a quantum channel is the most important capacity of that channel and that all the other capacities are, in some sense, of less significance. The fact that it is unnecessary to distinguish between the classical and quantum entanglement-assisted capacities because they are related by a factor of 2 is a hint in that direction, as is the simple, single-letter formula for $C_E(\mathcal{N})$.

A more general argument can be made by considering the problem of having one channel simulate another. Indeed, the quantum capacity of a quantum channel is simply the optimal rate at which that channel can simulate the noiseless channel $\mathrm{id}_2$ on a single qubit. Likewise, the classical capacity of a quantum channel is its optimal rate for simulation of a qubit dephasing channel

$$\rho \mapsto |0\rangle\langle 0|\rho|0\rangle\langle 0| + |1\rangle\langle 1|\rho|1\rangle\langle 1| \qquad [23]$$

In this spirit, the fact that $C_E(\mathcal{N}) = 2Q_E(\mathcal{N})$ can be re-expressed in the form

$$Q_E(\mathcal{N}) = \frac{C_E(\mathcal{N})}{C_E(\mathrm{id}_2)} \qquad [24]$$

Equivalently, when entanglement is free, the optimal rate at which $\mathcal{N}$ can simulate a noiseless qubit channel is given by the ratio between the entanglement-assisted classical capacities of $\mathcal{N}$ and $\mathrm{id}_2$. The quantum reverse Shannon theorem generalizes this statement to the simulation of arbitrary channels in the presence of free entanglement.

Suppose that Alice and Bob would like to use $\mathcal{N}_1 : A' \to B$ to simulate another channel $\mathcal{N}_2 : A' \to B$. Fix an input state $\varphi^{A'}$ and let $|\varphi\rangle^{AA'^n}$ be a purification of $(\varphi^{A'})^{\otimes n}$. As always, assume that Alice and Bob share a maximally entangled state $|\Phi\rangle^{\tilde{A}\tilde{B}}$ of Schmidt rank $2^{nS}$. Alice's encoding operation will be a TPCP map $\mathcal{E} : \tilde{A}A'^n \to A'^m$ acting on $n$ copies of the input system $A'$ and her half of the shared entanglement, $\tilde{A}$. Bob's decoding will likewise be a TPCP map $\mathcal{D} : B^m\tilde{B} \to B^n$ acting on $m$ copies of the output of the channel, and his half of the shared entanglement, $\tilde{B}$. This procedure is said to $\epsilon$-simulate $\mathcal{N}_2^{\otimes n}$ on $(\varphi^{A'})^{\otimes n}$ if

$$F\Big(\mathcal{N}_2^{\otimes n}(\varphi^{AA'^n}), (\mathcal{D} \circ \mathcal{N}_1^{\otimes m} \circ \mathcal{E})(\Phi^{\tilde{A}\tilde{B}} \otimes \varphi^{AA'^n})\Big) \geq 1 - \epsilon \qquad [25]$$

where $F$ is the mixed state fidelity $F(\rho, \sigma) = (\mathrm{tr}\sqrt{\rho^{1/2}\sigma\rho^{1/2}})^2$. The entire procedure, illustrated in Figure 3, is said to be a $(2^{nS}, m, n, \epsilon)$ entanglement-assisted simulation of $\mathcal{N}_2$ by $\mathcal{N}_1$. A rate $R$, measured in copies of $\mathcal{N}_2$ per copy of $\mathcal{N}_1$, is said to be achievable for $\varphi^{A'}$ if there exists a choice of $S \geq 0$ and a sequence of $(2^{nS}, m_n, n, \epsilon_n)$ entanglement-assisted simulations with $n/m_n \to R$ while $\epsilon_n \to 0$.

The quantum reverse Shannon theorem states that the entanglement-assisted capacity completely governs the achievable simulation rates.

**Theorem 2** (Winter 2004, Bennett *et al.*). *Given two channels $\mathcal{N}_1 : A' \to B$ and $\mathcal{N}_2 : A' \to B$, $R$ is an achievable simulation rate for $\mathcal{N}_2$ by $\mathcal{N}_1$ and all input states $\varphi^{A'}$ if and only if*

$$R \leq \frac{C_E(\mathcal{N}_1)}{C_E(\mathcal{N}_2)} \qquad [26]$$

Note that the form of eqn [26] ensures that the simulation is asymptotically reversible: if a channel $\mathcal{N}_1$ is used to simulate $\mathcal{N}_2$ and the simulation is then used to simulate $\mathcal{N}_1$ again, then the overall rate becomes

$$\frac{C_E(\mathcal{N}_1)}{C_E(\mathcal{N}_2)}\frac{C_E(\mathcal{N}_2)}{C_E(\mathcal{N}_1)} = 1 \qquad [27]$$

Thus, in the presence of free entanglement and for a known input density operator of the form $(\varphi^{A'})^{\otimes n}$, a single parameter, the entanglement-assisted classical capacity, suffices to completely characterize the asymptotic properties of a quantum channel.

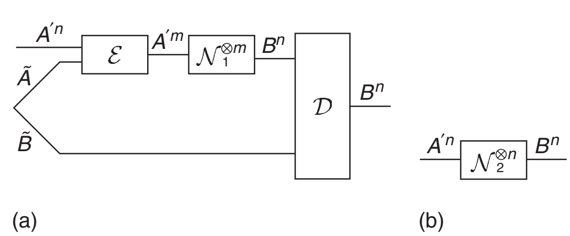

**Figure 3** Circuit representation of an entanglement-assisted simulation of $\mathcal{N}_2$ by $\mathcal{N}_1$. (a) The simulation circuit, with Alice's encoding operation $\mathcal{E}$ acting on $n$ copies of $A'$ and Bob's decoding operation producing $n$ copies of $B$. (b) The circuit that the protocol is intended to simulate. As stated, the quantum reverse Shannon theorem allows the simulation circuit to depend on the density operator of the input state restricted to $A'^n$.

Moreover, since two channels that are asymptotically equivalent without free entanglement will surely remain equivalent if free entanglement is permitted, eqn [26] gives essentially the only possible nontrivial, single-parameter asymptotic characterization of quantum channels. This is the sense in which the entanglement-assisted capacity should be regarded as the most important capacity of a quantum channel.

The proof of the quantum reverse Shannon theorem is quite involved, but some of its features can be understood without much work. First, note that by the optimality statement of the entanglement-assisted classical capacity, the desired simulation can exist only if eqn [26] holds. Otherwise, composing the simulation of $\mathcal{N}_2$ by $\mathcal{N}_1$ with a sequence of codes achieving $C_E(\mathcal{N}_2)$ would result in a sequence of codes beating the capacity formula for $\mathcal{N}_1$.

Similarly, note that one method to simulate a channel $\mathcal{N}_1$ using $\mathcal{N}_2$ is to first use $\mathcal{N}_2$ to simulate the noiseless channel and then use the simulated noiseless channel to simulate $\mathcal{N}_1$. Since the achievable rates for the first step are characterized by the entanglement-assisted capacity theorem, proving the achievability part of Theorem 2 reduces to finding protocols for simulating a general noisy quantum channel $\mathcal{N}_2$ by a noiseless one. That perhaps sounds like a strange goal, but nonetheless is the difficult part of the quantum reverse Shannon theorem.

It is likely that the quantum reverse Shannon theorem can be extended to cover other types of inputs than the known tensor power states $(\varphi^{A'})^{\otimes n}$. The most desirable form of the theorem would be one valid for all possible input density operators on $A'^{\otimes n}$, providing a single simulation procedure dependent only on the channels and not the input state. It is known that without modifying the form of the free entanglement, this most ambitious form of the theorem fails, but it is conjectured that the full-strength theorem does hold provided very large amounts of entanglement are supplied in the form of the so-called embezzling states (van Dam and Hayden 2003).

## Relationships between Protocols

There is another sense in which the entanglement-assisted capacity can be viewed as the fundamental capacity of a quantum channel: an efficient protocol for achieving the entanglement-assisted capacity can be converted into protocols achieving the unassisted quantum and classical capacities, or at least very close variants thereof.

An efficient protocol in this case refers to one that does not waste entanglement. Suppose that $\mathcal{N}: A' \to B$ can be written $\mathrm{tr}_E \mathcal{U}^{BE}$ for some isometry $\mathcal{U}^{BE}$. Let $|\varphi\rangle^{AA'}$ be a pure state and $|\sigma\rangle^{ABE} = \mathcal{U}^{BE}|\varphi\rangle^{AA'}$ the corresponding purified channel output state. Careful analysis of the entanglement-assisted classical communication protocol achieving the rate $I(A;B)_\sigma$ leads to an entanglement-assisted quantum communication protocol consuming entanglement at the rate $(1/2)I(A;E)_\sigma$ ebits per use of $\mathcal{N}$ and yielding communication at the rate of $(1/2)I(A;B)_\sigma$ qubits per use $\mathcal{N}$. The protocol achieving this goal is known as the "father" (Devetak *et al.* 2004).

If the entanglement consumed in the father were actually supplied by quantum communication from Alice to Bob, then the net rate of quantum communication produced by the resulting protocol would be $(1/2)I(A;B)_\sigma - (1/2)I(A;E)_\sigma$ qubits from Alice to Bob, that is, the total produced minus the total consumed.

This quantity, how much more information $B$ has about $A$ than $E$ does, can be simplified using an interesting identity. Since $|\sigma\rangle^{ABE}$ is pure,

$$I(A;E)_\sigma = H(A)_\sigma + H(E)_\sigma - H(AE)_\sigma \qquad [28]$$

$$= H(A)_\sigma + H(AB)_\sigma - H(B)_\sigma \qquad [29]$$

Expanding $I(A;B)_\sigma$ and canceling terms then reveals that

$$\begin{aligned}\tfrac{1}{2}I(A;B) - \tfrac{1}{2}I(A;E) &= -H(A|B)_\sigma \\ &= I_c(A\rangle B)_\sigma \qquad [30]\end{aligned}$$

where the function $I_c$ is known as the coherent information. After optimizing over input states and multiple channel uses, this is precisely the formula for the unassisted quantum capacity of a quantum channel (Devetak 2005). Thus, the net rate of qubit communication for the protocol derived from the father exactly matches the rates necessary to achieve the unassisted quantum capacity. The only caveat is that the protocol derived from the father uses quantum communication catalytically, meaning that some communication needs to be invested in order to get a gain of $I_c(A\rangle B)$. For the unassisted quantum capacity, no investment is necessary. Nonetheless, detailed analysis of the situation reveals that the amount of catalytic communication required can be reduced to an amount sublinear in the number of channel uses, meaning the rate of required investment can be made arbitrarily small. In this sense, the father protocol essentially generates the optimal protocols for the unassisted quantum capacity.

Protocols achieving the unassisted classical capacity can be constructed in a similar way. In this case, one starts from an ensemble $\mathcal{E} = \{p_j, \mathcal{N}(\psi_j^{A'})\}$ of states generated by the channel. Achievability of

the unassisted classical capacity formula follows from achievability of rates of the form

$$\chi(\mathcal{E}) = H\Big(\sum_j p_j \mathcal{N}(\psi_j^{A'})\Big) - \sum_j p_j H\Big(\mathcal{N}(\psi_j^{A'})\Big) \qquad [31]$$

for arbitrary ensembles of output states. Consider the channel

$$\widetilde{\mathcal{N}}(\rho) = \sum_j \langle j|\rho|j\rangle \cdot \mathcal{N}(\psi_j) \qquad [32]$$

and input state $|\varphi\rangle^{AA'} = \sum_j \sqrt{p_j}|j\rangle^A|j\rangle^{A'}$. If $\sigma = \widetilde{\mathcal{N}}(\varphi)$, then $I(A;B)_\sigma$ is equal to $\chi(\mathcal{E})$. Thus, there are protocols consuming entanglement that achieve the classical communications rate $\chi(\mathcal{E})$ for the modified channel $\widetilde{\mathcal{N}}$. Because the channel $\widetilde{\mathcal{N}}$ includes an orthonormal measurement which destroys all entanglement between $A$ and $B$, however, it can be argued that any entanglement used in such a protocol could be replaced by shared randomness, which could then in turn be eliminated by a standard derandomization argument. The net result is a procedure for choosing rate $\chi(\mathcal{E})$ codes for the channel $\mathcal{N}$ consisting of states of the form $\psi_{j_1} \otimes \cdots \otimes \psi_{j_n}$, which is the essence of the achievability proof for the unassisted classical capacity.

This may seem like an unnecessarily cumbersome and even circular approach to the unassisted classical capacity given that the proof sketched above for the entanglement-assisted classical capacity itself invokes the unassisted result in the form of the HSW theorem. The approach becomes more satisfying when one learns that simple and direct proofs of the father protocol exist that completely bypass the HSW theorem (Abeyesinghe *et al.* 2005).

Thus, the entanglement-assisted communication protocols can be easily transformed into their unassisted analogs, confirming the central place of entanglement-assisted communication in quantum information theory.

## Acknowledgmnts

The author is grateful to the inventors of the quantum reverse Shannon theorem for letting him discuss their results prior to their publication and to Jon Yard for a careful reading of the manuscript. This work has been supported by the Canadian Institute for Advanced Research, the Canada Research Chairs program, and Canada's NSERC.

# Capacity for Quantum Information

**D Kretschmann**, Technische Universität Braunschweig, Braunschweig, Germany

## Introduction

Any processing of quantum information, be it storage or transfer, can be represented as a quantum channel: a completely positive and trace-preserving map that transforms states (density matrices) on the sender's end of the channel into states on the receiver's end. Very often, the channel $S$ that sender and receiver (conventionally called Alice and Bob, respectively) would like to implement is not readily available, typically due to detrimental noise effects, limited technology, or insufficient funding. They may then try to simulate $S$ with some other channel $T$, which they happen to have at their disposal. The quantum channel capacity $Q(T,S)$ of $T$ with respect to $S$ quantifies how well this simulation can be performed, in the limit of long input strings, so that Alice and Bob can take advantage of collective pre- and post-processing (cf. Figure 1). Higher capacities may result if Alice and Bob are allowed to use additional resources in the process, such as classical side channels or a bunch of maximally entangled pairs shared between them.

Quantum capacity thus gives the ultimate benchmarks for the simulation of one quantum channel by another and for the optimal use of auxiliary resources. Together with the compression rate of a quantum source (*see* Source Coding in Quantum Information Theory), it lies at the heart of quantum information theory.

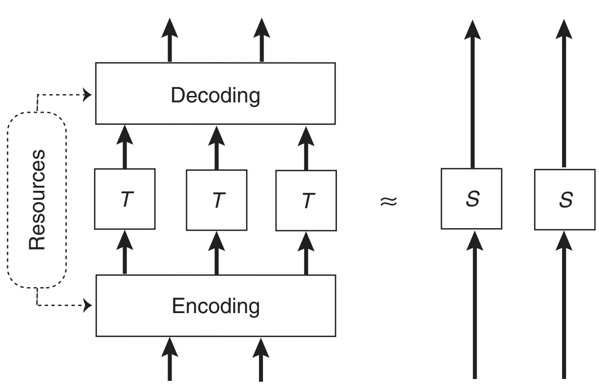

**Figure 1** Equipped with collective encoding and decoding operations (and perhaps some auxiliary resources), $n=3$ instances of the channel $T$ simulate $m=2$ instances of the channel $S$. The transmission rate of the above scheme is 2/3. Capacity is the largest such rate, in the limit of long messages and optimal encoding and decoding.

In a very typical scenario, Alice and Bob would like to implement the ideal (noiseless) quantum channel $S = \mathrm{id}$: they are interested in sending quantum states undistorted over some distance, or want to store them safely for some period of time, so that all the precious quantum correlations are preserved. The capacity $Q(T) \equiv Q(T, \mathrm{id})$ is then the maximal number of qubit transmissions per use of the channel, taken in the limit of long messages and using collective encoding and decoding schemes asymptotically eliminating all transmission errors. This is what is generally called the *quantum capacity* of the channel $T$, and it is our main focus in this article. Little is known so far about the quantum capacity for the simulation of other (nonideal) channels (cf. the section "Related capacities").

In remarkable contrast to the classical setting, quantum channel capacities are very much affected by additional resources. This leads to unexpected and fascinating applications such as teleportation and dense coding. But it also results in a bewildering variety of inequivalent channel capacities, which still hold many challenges for future research.

### Notation

A quantum channel which transforms input systems on a Hilbert space $\mathcal{H}_\mathcal{A}$ into output systems on a (possibly different) Hilbert space $\mathcal{H}_\mathcal{B}$ is represented (in Schrödinger picture) by a completely positive and trace-preserving linear map $T : \mathcal{B}_*(\mathcal{H}_\mathcal{A}) \to \mathcal{B}_*(\mathcal{H}_\mathcal{B})$, where $\mathcal{B}_*(\mathcal{H})$ denotes the space of trace class operators on the Hilbert space $\mathcal{H}$ (*see* Channels in Quantum Information Theory). We write $\mathcal{A}$ instead of $\mathcal{B}_*(\mathcal{H}_\mathcal{A})$ to streamline the presentation, and $\mathcal{A}^n$ for the $n$-fold tensor product $\mathcal{B}_*(\mathcal{H}_\mathcal{A})^{\otimes n}$.

It is evident that the definition of channel capacity requires the comparison of different quantum channels. A suitable distance measure is the *norm of complete boundedness* (or cb-norm, for short), denoted by $\| \cdot \|_{\mathrm{cb}}$. For two channels $T$ and $S$, the distance $(1/2)\|T - S\|_{\mathrm{cb}}$ can be defined as the largest difference between the overall probabilities in two statistical quantum experiments differing only by exchanging one use of $S$ by one use of $T$. These experiments may involve entangling the systems on which the channels act with arbitrary further systems; hence the cb-norm remains a valid distance-measure if the given channel is only part of a larger system. Equivalently, we may set $\|T\|_{\mathrm{cb}} := \sup_n \|T \otimes \mathrm{id}_n\|$, where $\|R\| := \sup_{\|\varrho\|_1 \le 1} \|R(\varrho)\|_1$

denotes the norm of linear operators, and $\|\varrho\|_1 := \mathrm{tr}\sqrt{\varrho^*\varrho}$ is the trace norm on the space of trace-class operators $\mathcal{B}_*(\mathcal{H})$.

We use base two logarithms throughout, and we write $\mathrm{ld}\, x := \log_2 x$ and $\exp_2 x := 2^x$.

## Quantum Channel Capacity

The intuitive concept underlying quantum channel capacity is made rigorous in the following definition:

**Definition 1** A positive number $R$ is called *achievable rate* for the quantum channel $T: \mathcal{A} \to \mathcal{B}$ with respect to the quantum channel $S: \mathcal{A}' \to \mathcal{B}'$ iff for any pair of integer sequences $(n_\nu)_{\nu\in\mathbb{N}}$ and $(m_\nu)_{\nu\in\mathbb{N}}$ with $\lim_{\nu\to\infty} n_\nu = \infty$ and $\overline{\lim}_{\nu\to\infty} \frac{m_\nu}{n_\nu} \leq R$ we have

$$\lim_{\nu\to\infty} \inf_{D,E} \|DT^{\otimes n_\nu}E - S^{\otimes m_\nu}\|_{\mathrm{cb}} = 0 \qquad [1]$$

the infimum taken over all encoding channels $E$ and decoding channels $D$ with suitable domain and range. The *channel capacity* $Q(T,S)$ of $T$ with respect to $S$ is defined to be the supremum of all achievable rates. The *quantum capacity* is the special case $Q(T) := Q(T, \mathrm{id}_2)$, with $\mathrm{id}_2$ being the ideal qubit channel.

In this article, we mainly concentrate on channels between finite-dimensional systems. This is enough to bring out the basic ideas. Many of the concepts and results discussed here can be generalized to *Gaussian channels*, which play a central role as building blocks for quantum optical communication lines (Holevo and Werner 2001, Eisert and Wolf).

There is considerable freedom in the definition of quantum channel capacity, at least for ideal reference channels (Kretschmann and Werner 2004). In particular, the encoding channels $E$ in eqn [1] may always be restricted to isometric embeddings.

In addition, it is not necessary to check an infinite number of pairs of sequences $(n_\nu)_{\nu\in\mathbb{N}}$ and $(m_\nu)_{\nu\in\mathbb{N}}$ when testing a given rate $R$, as Definition 1 would suggest. Instead, it is enough to find one such pair which achieves the rate $R$ infinitely often, $\overline{\lim}_{\nu\to\infty} m_\nu/n_\nu = R$.

Without affecting the capacity, the cb-norm $\|T\|_{\mathrm{cb}}$ may be replaced by the unstabilized operator norm $\|T\|$ or by fidelity measures, which are in general much easier to compute. In particular, one might choose the *minimum fidelity*,

$$F(T) := \min_{\|\psi\|=1} \langle\psi|T(|\psi\rangle\langle\psi|)|\psi\rangle \qquad [2]$$

or even the *average fidelity*,

$$\bar{F}(T) := \int \langle\psi|T(|\psi\rangle\langle\psi|)|\psi\rangle \, \mathrm{d}\psi \qquad [3]$$

Unfortunately, this equivalence is restricted to capacities with noiseless reference channel $S = \mathrm{id}$. In the vicinity of other (nonideal) channels, equivalence of the stabilized and unstabilized error criteria may be lost. Of course, the comparison of channels is ultimately based on the comparison of a state to its image, and here the pure states are the worst case. Hence, the remarkable insensitivity of the quantum capacity to the choice of the error criterion stems from the observation that the comparison between an arbitrary state and a pure state is rather insensitive to the criterion used.

Instead of requiring the error quantity in eqn [1] to approach zero in the large block limit $\nu \to \infty$, one might feel tempted to impose that the errors vanish completely for some sufficiently large block length, since this is the standard setup in the theory of quantum error correction (*see* Quantum Error Correction and Fault Tolerance). While it is true that errors can always be assumed to vanish exponentially in eqn [1], requiring perfect correction may completely change the picture: if a channel has some small positive probability for depolarization, the same also holds for its tensor powers, and no such channel allows the perfect transmission of even one qubit. Hence, the capacity for perfect correction will vanish for such channels, while the standard capacity (in accordance with Definition 1) will be close to maximal, $Q(T) \approx 1$. The existence of perfect error-correcting codes thus gives lower bounds on the channel capacity, but is not required for a positive transfer rate.

In the other extreme, one might sometimes feel inclined to tolerate (small) finite errors in the transmission. For some $\varepsilon > 0$, we define $Q_\varepsilon(T)$ exactly like the quantum capacity in Definition 1, but require only that the error quantity in eqn [1] falls below $\varepsilon$ for some sufficiently large $\nu$. Obviously, $Q_\varepsilon(T) \geq Q(T)$ for any quantum channel $T$. We also have $\lim_{\varepsilon\to 0} Q_\varepsilon(T) = Q(T)$ (Kretschmann and Werner 2004). In the classical setting, even a *strong converse* is known: if $\varepsilon > 0$ is small enough, one cannot achieve bigger rates by allowing small errors, that is, $C_\varepsilon(T) = C(T)$. It is still undecided whether an analogous property holds for the quantum capacity $Q(T)$.

## Related Capacities

This article is chiefly concerned with the quantum capacity of a quantum channel. A variety of other

capacities have been derived from Definition 1 by either amending the channel $S$ to be simulated, or allowing Alice and Bob to make use of additional resources. Their interrelations are reviewed in Bennett *et al.* (2004)

Much interest has been devoted to the hybrid problem of transmitting classical information undistorted over noisy quantum channels. The classical capacity $C(T)$ of a quantum channel $T$ is discussed in the article Quantum Channels: Classical Capacity of this Encyclopedia. It is obtained by choosing the ideal one-bit channel rather than the one-qubit channel as the standard of reference in Definition 1. Encoding channels $E$ and decoding channels $D$ are then restricted to preparations and measurements, respectively. Since a quantum channel can also be employed to send classical information, we have $C(T) \geq Q(T)$. There are, obviously, examples in which this inequality is strict: the *entanglement-breaking* channel $T(\varrho) = \sum_j \langle j|\varrho|j\rangle\, |j\rangle\langle j|$ is composed of a measurement in the orthonormal basis $\{|j\rangle\}_j$, followed by a preparation of the corresponding basis states. It destroys all the entanglement between the sender and a reference system, implying $Q(T) = 0$. Yet all the basis states $|j\rangle$ are transmitted undistorted, which is enough to guarantee that $C(T) = 1$.

Definition 1 also applies to purely classical channels, and thus to the setting of Shannon's information theory. A classical channel $T$ between two $d$-level systems is completely specified by the $d \times d$ matrix $(T_{xy})_{x,y=1}^{d}$ of transition probabilities. For these channels the cb-norm difference is just (twice) the maximal error probability:

$$\|\mathrm{id} - T\|_{\mathrm{cb}} = 2\sup_x\{1 - T_{xx}\}$$

which is the standard error criterium for classical information transfer.

Dense coding and teleportation suggest that entanglement is a powerful resource for information transfer. It doubles the classical channel capacity of a noiseless channel, and it allows to send quantum information over purely classical channels. Surprisingly, the *entanglement-assisted capacities* are often simpler and better behaved than their unassisted counterparts. Unlike the classical and quantum capacities proper, they are relatively easy to calculate using finite optimization procedures, and there has recently been significant progress in understanding the simulation rates for nonideal channels in this scenario (*see* Capacities Enhanced by Entanglement).

The quantum channel capacity is unaffected by entanglement-breaking side channels. In particular, classical forward communication alone cannot enhance it. However, unlike in the purely classical case, both the quantum and classical channel capacity (but not the entanglement-assisted capacity) may increase under classical feedback.

## Elementary Properties

The capacity of a composite channel $T_1 \circ T_2$ cannot be bigger than the capacity of the channel with the smallest bandwidth. This in turn suggests that simulating a concatenated channel is in general easier than simulating any of the individual channels. These relations are known as *bottleneck inequalities*:

$$Q(T_1 \circ T_2, S) \leq \min\{Q(T_1, S), Q(T_2, S)\} \qquad [4]$$

$$Q(T, S_1 \circ S_2) \geq \max\{Q(T, S_1), Q(T, S_2)\} \qquad [5]$$

Instead of running $T_1$ and $T_2$ in succession, we may also run them in parallel. In this case, the capacity can be shown to be *superadditive*,

$$Q(T_1 \otimes T_2, S) \geq Q(T_1, S) + Q(T_2, S) \qquad [6]$$

For the standard ideal channels, we even have additivity. The same holds true if both $S$ and one of the channels $T_1, T_2$ are noiseless, the third channel being arbitrary. However, results on the activation of bound-entangled states seem to suggest that the inequality in eqn [6] may be strict for some channels (*see* Entanglement).

Finally, the *two-step coding inequality* tells us that by using an intermediate channel in the coding process we cannot increase the transmission rate:

$$Q(T_1, T_2) \geq Q(T_1, T_3)\, Q(T_3, T_2) \qquad [7]$$

Applying eqn [7] twice with $T_2 = \mathrm{id}$ and $T_3 = \mathrm{id}$ immediately yields upper and lower bounds on the channel capacity with nonideal reference channel,

$$\frac{Q(T_1)}{Q(T_2)} \geq Q(T_1, T_2) \geq Q(T_1)\, Q(\mathrm{id}, T_2) \qquad [8]$$

The evaluation of the lower bound in eqn [8] then requires efficient protocols for simulating a noisy channel $T_2$ with a noiseless resource.

There are special cases in which the quantum channel capacity can be evaluated relatively easily, the most relevant one being the noiseless channel $\mathrm{id}_n$, where by the subscript $n$ we denote the dimension of the underlying Hilbert space. In this case, we have

$$Q(\mathrm{id}_n, \mathrm{id}_m) = \frac{\mathrm{ld}\, n}{\mathrm{ld}\, m} \qquad [9]$$

The lower bound $Q(\mathrm{id}_n, \mathrm{id}_m) \geq \mathrm{ld}n/\mathrm{ld}m$ is immediate from counting dimensions. To establish the upper bound, we use the fact that a noiseless quantum channel cannot simulate itself with a rate

exceeding unity: $Q(\mathrm{id}_m, \mathrm{id}_m) \leq 1$. This is just the upper bound we want to prove for the special case $n = m$, and it can be extended to the general case with the help of the two-step coding inequality [7]: $Q(\mathrm{id}_m, \mathrm{id}_n)\, Q(\mathrm{id}_n, \mathrm{id}_m) \leq Q(\mathrm{id}_m, \mathrm{id}_m) \leq 1$, implying $Q(\mathrm{id}_n, \mathrm{id}_m) \leq 1/Q(\mathrm{id}_m, \mathrm{id}_n) \leq \mathrm{ld}\, n/\mathrm{ld}\, m$, where in the last step we have applied the lower bound with the roles of $n$ and $m$ interchanged.

Combining eqn [9] with the two-step coding inequality [7], we see that for any channel $T$

$$Q(T, \mathrm{id}_n) = \frac{\mathrm{ld}\, m}{\mathrm{ld}\, n} Q(T, \mathrm{id}_m) \qquad [10]$$

which shows that quantum channel capacities relative to noiseless channels of different dimensionality only differ by a constant factor. Fixing the dimensionality of the reference channel then only corresponds to a choice of units. Conventionally, the ideal qubit channel $\mathrm{id}_2$ is chosen as a standard of reference, as in Definition 1 above, thereby fixing the unit "bit."

The upper bound on the capacity of ideal channels can also be obtained from a general upper bound on quantum capacities (Holevo and Werner 2001), which has the virtue of being easily calculated in many situations. It involves the *transposition map*, which we denote by $\Theta$, defined as matrix transposition with respect to some fixed orthonormal basis. The transposition is positive but not completely positive, and thus does not describe a physical channel (*see* Channels in Quantum Information Theory). We have $\|\Theta\|_{\mathrm{cb}} = d$ for a $d$-level system. For any channel $T$ and small $\varepsilon > 0$,

$$Q(T) \leq Q_\varepsilon(T) \leq \mathrm{ld}\ \|T\Theta\|_{\mathrm{cb}} =: Q_\Theta(T) \qquad [11]$$

where $Q_\varepsilon$ is the finite error capacity introduced in the section "Quantum channel capacity."

The upper bound $Q_\Theta(T)$ has some remarkable properties, which make it a capacity-like quantity in its own right. For example, it is exactly additive,

$$Q_\Theta(S \otimes T) = Q_\Theta(S) + Q_\Theta(T) \qquad [12]$$

for any pair $S, T$ of channels, and it satisfies the bottleneck inequality:

$$Q_\Theta(ST) \leq \min\{Q_\Theta(S),\ Q_\Theta(T)\}$$

Moreover, it coincides with the quantum capacity on ideal channels, $Q_\Theta(\mathrm{id}_n) = Q(\mathrm{id}_n) = \mathrm{ld}\, n$, and it vanishes whenever $T\Theta$ is completely positive. In particular, if $\mathrm{id} \otimes T$ maps any entangled state to a state with positive partial transpose, we have $Q_\Theta(T) = 0$.

## State–Channel Duality

Quantum capacity is closely related to the *distillable entanglement*, which is the optimal rate $m/n$ at which $n$ copies of a given bipartite quantum state $\varrho$ shared between Alice and Bob can be asymptotically converted into $m$ maximally entangled qubit pairs (*see* Entanglement). Similar to the quantum capacity, the definition involves the large block limit $n, m \to \infty$ and an optimization over all conceivable distillation protocols. These may consist of several rounds of local quantum operations and (forward or two-way) classical communication. The one-way and two-way distillable entanglement of $\varrho$ will be denoted by $D_1(\varrho)$ and $D_2(\varrho)$, respectively.

Suppose that Alice and Bob are connected by a quantum channel $T$ and run such a one-way distillation protocol on (many copies of) the state $\varrho_T := (T \otimes \mathrm{id})|\Omega\rangle\langle\Omega|$, where $|\Omega\rangle := (1/\sqrt{d_{\mathcal{A}}}) \sum_i |i, i\rangle$ is maximally entangled on $\mathcal{H}_{\mathcal{A}} \otimes \mathcal{H}_{\mathcal{A}'}$. If the distillation yields maximally entangled qubits at positive rate $R$, Alice may apply the standard teleportation scheme to send arbitrary quantum states to Bob undistorted at that same rate $R$. Like the distillation protocol itself, teleportation requires classical forward communication, which however does not affect the channel capacity (cf. the section "Related capacities"). Thus, $Q(T) \geq D_1(\varrho_T)$. If two-way distillation is allowed, we have $Q_2(T) \geq D_2(\varrho_T)$ for the capacity $Q_2(T)$ assisted by two-way classical side communication.

Conversely, if Alice and Bob use a bipartite quantum state $\varrho$ shared between them as a substitute for the maximally entangled state $|\Omega\rangle$ in the standard teleportation protocol, they will implement some noisy quantum channel $T_\varrho$. If this channel allows to transfer quantum information at nonvanishing rate $R$, Alice may share maximally entangled states with Bob at that same rate $R$. Consequently, $D_1(\varrho) \geq Q(T_\varrho)$ and $D_2(\varrho) \geq Q_2(T_\varrho)$.

These relations (Bennett *et al.* 1996) allow to bound channel capacities in terms of distillable entanglement and vice versa. If the two maps $T \mapsto \varrho_T$ and $\varrho \mapsto T_\varrho$ are mutually inverse, we even have $D_1(\varrho) = Q(T_\varrho)$ and $D_2(\varrho) = Q_2(T_\varrho)$. In this case, the duality $\varrho \rightleftharpoons T_\varrho$ is the physical implementation of Jamiolkowski's isomorphism between bipartite states and channels (*see* Channels in Quantum Information Theory). This has been shown (Horodecki *et al.* 1999) to hold for *isotropic states*, which are invariant under the group of all $\overline{U} \otimes U$ transformations, where $\overline{U}$ is the complex conjugate of the unitary $U$. The corresponding channels are partly depolarizing.

In general, $T_{\varrho_T} \neq T$. However, the so-called *conclusive teleportation* allows us to implement $T$ at least probabilistically, resulting in the relation

$$\frac{1}{d_{\mathcal{A}}^2} Q(T) \leq D_1(\varrho_T) \leq Q(T) \qquad [13]$$

The duality [13] can be applied to show that both the unassisted and the two-way quantum capacities are continuous in any open set of channels having nonvanishing capacities (Horodecki and Nowakowski 2005).

## Coding Theorems

Computing channel capacities straight from Definition 1 is a tricky business. It involves optimization in systems of asymptotically many tensor factors, and can only be performed in special cases, like the noiseless channels in the section "Elementary properties." *Coding theorems* aspire to reduce this problem to an optimization over a low-dimensional space. They usually come in two parts: the *converse* provides an upper bound on the channel capacity (typically in terms of some entropic expression), while the *direct* part consists of a coding scheme that attains this bound. By Shannon's celebrated coding theorem, the classical capacity of a classical noisy channel can be obtained from a maximization of the *mutual information* over all joint input–output distributions.

For the quantum channel capacity, the relevant entropic quantity is the *coherent information*,

$$I_c(T, \varrho) := H(T(\varrho)) - H\big(T \otimes \mathrm{id}(|\psi_\varrho\rangle\langle\psi_\varrho|)\big) \qquad [14]$$

where $H$ denotes the von Neumann entropy: $H(\varrho) = -\mathrm{tr}\,\varrho\,\mathrm{ld}\varrho$, and $\psi_\varrho \in \mathcal{H}_A \otimes \mathcal{H}_{A'}$ is a purification of the density operator $\varrho \in \mathcal{A}$. The coherent information does not increase under quantum operations, $I_c(S \circ T, \varrho) \le I_c(T, \varrho)$ for any quantum channel $S$ and state $\varrho \in \mathcal{A}$. This is the *data processing inequality* (Barnum *et al.* 1998), which shows that the regularized coherent information provides an upper bound on the quantum channel capacity: if Alice and Bob have a coding scheme for the channel $T$ with capacity $Q(T)$, $n$ channel uses allow them to share a maximally entangled state of size $\sim \exp_2 n\,Q(T)$. The coherent information of this state equals $\sim n\,Q(T)$, and was no larger prior to Bob's decoding.

Recently, Devetak (2005) developed a coding scheme to show that this bound is in fact attainable. Different proofs were outlined by Lloyd and Shor.

**Theorem 1** *For every quantum channel $T$,*

$$Q(T) = \lim_{n\to\infty} \frac{1}{n} \max_{\varrho} I_c(T^{\otimes n}, \varrho) \qquad [15]$$

Unlike the classical or quantum mutual information, coherent information is strictly superadditive for some channels (DiVincenzo *et al.* 1998). Hence, taking the limit $n \to \infty$ in eqn [15] is indeed required, and in general the evaluation of the capacity formula [15] still demands the solution of asymptotically large variational problems. This should be contrasted with the entanglement-assisted capacities $C_E(T) = 2Q_E(T)$ (where a simple nonregularized coding theorem is known to hold, *see* Capacities Enhanced by Entanglement) and the capacity for classical information $C(T)$ (where additivity is conjectured but not proved, *see* Quantum Channels: Classical Capacity). Even a maximization of the single-shot coherent information $I_c(T, \varrho)$ appears to be a difficult optimization problem, since this quantity is neither convex nor concave and may have multiple local maxima (Shor 2003). Thus, even for simple-looking systems like the qubit depolarizing channel, so far we only have upper and lower bounds on the quantum channel capacity, but do not yet know how to compute its exact value.

We now sketch Devetak's proof of Theorem 1, assuming only some familiarity with Holevo–Schumacher–Westmoreland (HSW) random codes for the classical channel capacity (*see* Quantum Channels: Classical Capacity). It is easily seen from Stinespring's dilation theorem (*see* Channels in Quantum Information Theory) that a noiseless quantum channel provides perfect security against eavesdropping. This is one of the characteristic traits of quantum mechanics and lies at the heart of quantum cryptography. In his proof, Devetak showed a way to turn this around and upgrade coding schemes for private classical information to quantum channel codes.

The relation between quantum information transfer over a channel $T : \mathcal{A} \to \mathcal{B}$ and privacy against eavesdropping is best understood in terms of the *companion channel* $T_\mathcal{E} : \mathcal{A} \to \mathcal{E}$. $T_\mathcal{E}$ arises from a given Stinespring isometry $V : \mathcal{H}_\mathcal{A} \to \mathcal{H}_\mathcal{B} \otimes \mathcal{H}_\mathcal{E}$ of $T \equiv T_\mathcal{B}$ by interchanging the roles of the output system $\mathcal{B}$ and the environment $\mathcal{E}$:

$$T_\mathcal{B}(\varrho) = \mathrm{tr}_\mathcal{E} V \varrho V^* \rightleftharpoons T_\mathcal{E}(\varrho) = \mathrm{tr}_\mathcal{B} V \varrho V^* \qquad [16]$$

The channel $T_\mathcal{E}$ describes the information flow into the environment $\mathcal{E}$, a system we assume to be under complete control of a potential eavesdropper, Eve say. The setup for private classical information transfer (including the definition of rates and capacity) is then exactly the same as for the classical channel capacity (*see* Quantum Channels: Classical Capacity), but the protocols now have to satisfy the additional requirement that $T_\mathcal{E}$ releases (almost) no information to the environment. This can be achieved by randomizing over $\nu_\mathcal{E} \sim \exp_2 n\,\chi(T_\mathcal{E}, \{p_i, \varrho_i\})$ code words of a standard HSW code of total size $\sim \exp_2 n\,\chi(T_\mathcal{B}, \{p_i, \varrho_i\})$, where $\{p_i, \varrho_i\}$ is the quantum ensemble from which a set of random code words

$\{\sigma_{k,l}\}_{k=1,l=1}^{\nu_\mathcal{B},\nu_\mathcal{E}}$ is generated. The appearance of the *Holevo bound*

$$\chi(T,\{p_i,\varrho_i\}) := H\left(\sum_i p_i T(\varrho_i)\right) - \sum_i p_i H(T(\varrho_i)) \quad [17]$$

in the dimension of both these code spaces can be understood from the size of the relevant typical subspaces (Devetak and Winter 2004).

The randomization guarantees that the remaining $\nu_\mathcal{B} \sim \exp_2 n(\chi(T_\mathcal{B}) - \chi(T_\mathcal{E}))$ code words are almost indistinguishable to Eve:

$$\left\| \frac{1}{\nu_\mathcal{E}} \sum_{l=1}^{\nu_\mathcal{E}} T_\mathcal{E}^{\otimes n}(\sigma_{kl} - \sigma_{jl}) \right\|_1 \leq \varepsilon, \quad \forall j,k = 1,\ldots,\nu_\mathcal{B} \quad [18]$$

The net transfer rate for private classical information is then $R \sim \chi(T_\mathcal{B}) - \chi(T_\mathcal{E})$, which is just the total transfer rate for the channel Alice $\to$ Bob reduced by the transfer rate Alice $\to$ Eve.

Remarkably, if $\varrho = \sum_i p_i |\psi_i\rangle\langle\psi_i|$ is a decomposition of $\varrho \in \mathcal{A}$ into pure states, the private transfer rate exactly equals the coherent information,

$$\begin{aligned} I_c(T_\mathcal{B},\varrho) &= H(T_\mathcal{B}(\varrho)) - H(T_\mathcal{E}(\varrho)) \\ &= \chi(T_\mathcal{B}) - \chi(T_\mathcal{E}) \end{aligned} \quad [19]$$

The so-called *entropy exchange*

$$H(T_\mathcal{E}(\varrho)) = H\big(T_\mathcal{B} \otimes \mathrm{id}(|\psi_\varrho\rangle\langle\psi_\varrho|)\big)$$

quantifies the extent to which a formerly pure ancilla state becomes mixed via interaction with the signal states. Equation[19] then nicely reflects the intuition that for high-rate quantum information transfer the signal states should not entangle too much with the environment. In fact, for an almost noiseless channel the entropy exchange nearly vanishes, and the optimized coherent information almost attains the maximal value 1, while for nearly depolarizing channels we have $I_c(T_\mathcal{B},\varrho) \approx -H(\varrho) \leq 0$.

So far, we have sketched a protocol for private classical information transfer. Devetak's *coherentification* allows to pass from the transmission of classical messages to the transmission of coherent superpositions. This technique has also been applied to obtain entanglement distillation protocols from secret key distillation, and offers a unified view on the secret classical resources and their quantum counterparts (Devetak and Winter 2004, Devetak *et al.* 2004).

In order to transfer quantum information, Alice will only need to send one half of a maximally entangled state of dimensionality $\sim \exp_2 n I_c(T_\mathcal{B},\varrho)$. As described in the previous section, teleportation then allows her to transfer arbitrary quantum states from a subspace of that size.

Given a set of pure state code words $\{|\varphi_{kl}\rangle\}_{k=1,l=1}^{\nu_\mathcal{B},\nu_\mathcal{E}}$ of a private classical information protocol, for entanglement transfer Alice prepares the input state

$$|\Phi\rangle_{\mathcal{A}'\mathcal{A}} = \frac{1}{\sqrt{\nu_\mathcal{B}}} \sum_{k=1}^{\nu_\mathcal{B}} |k\rangle_{\mathcal{A}'} \otimes \frac{1}{\sqrt{\nu_\mathcal{E}}} \sum_{l=1}^{\nu_\mathcal{E}} |\varphi_{kl}\rangle_\mathcal{A} \quad [20]$$

where $\mathcal{A}'$ denotes a reference system that Alice keeps in her lab. On his share of the resulting output state $|\Phi'\rangle_{\mathcal{A}'\mathcal{B}\mathcal{E}}$ Bob will then employ the corresponding measurement operators $\{M_{kl}\}_{k,l=1}^{\nu_\mathcal{B},\nu_\mathcal{E}}$ to implement the coherent measurement

$$V_M\,|\varphi\rangle_\mathcal{B} := \sum\nolimits_{kl} \sqrt{M_{kl}}|\varphi\rangle_\mathcal{B} \otimes |kl\rangle_{\mathcal{B}_1\mathcal{B}_2}$$

which places the measurement outcomes into some reference system $\mathcal{B}_1 \otimes \mathcal{B}_2$. Any measurement which identifies the output with high probability only slightly disturbs the output state, and thus Bob's coherent measurement leaves the total system in an approximation of the state

$$|\Phi''\rangle = \frac{1}{\sqrt{\nu_\mathcal{B}\nu_\mathcal{E}}} \sum_{k=1,l=1}^{\nu_\mathcal{B},\nu_\mathcal{E}} |k\rangle_{\mathcal{A}'}|k\rangle_{\mathcal{B}_1}|l\rangle_{\mathcal{B}_2}|\varphi'_{kl}\rangle_{\mathcal{B}\mathcal{E}} \quad [21]$$

in which Eve and Bob are still entangled. A completely depolarizing channel $T_\mathcal{E}$ would directly yield a factorized output state $\mathcal{B} \otimes \mathcal{E}$ here. Although the randomization in eqn [18] does not necessarily result in complete depolarization, there is a controlled unitary operation which Bob may apply to effectively decouple Eve's system, resulting in the output state $\sim (1/\sqrt{\nu_\mathcal{B}}) \sum_k |kk\rangle_{\mathcal{A}'\mathcal{B}_1} \otimes \mathcal{E}$, which is the maximally entangled state of size $\nu_\mathcal{B} \sim \exp_2 n I_c(T_\mathcal{B},\varrho)$ required for teleportation. The direct part of the capacity theorem then follows by applying the above coding scheme to large blocks and maximizing over (pure) input ensembles, concluding the proof.

Devetak's proof of the coding theorem seems to indicate that the private classical capacity $C_p(T)$ equals the quantum capacity $Q(T)$ for every quantum channel $T$. However, for the coherentification protocol, we have restricted the private coding schemes to pure state input ensembles, and thus we can only conclude that $Q(T) \leq C_p(T)$. The existence of bound-entangled states with positive one-way distillable secret key rate (Horodecki *et al.* 2005) implies that this inequality can be strict. A general procedure does exist to retrieve (almost) all the information from the output of a noisy quantum channel that releases (almost) no information to the environment. But this requires a stronger form of privacy than eqn [18].

## Quantum Channels with Memory

This article has so far been restricted to *memoryless* quantum channels, in which successive channel inputs are acted on independently. Messages of $n$ symbols are then processed by the tensor product channel $T^{\otimes n}$, as in Definition 1 and illustrated in **Figure 1**. In many real-world applications, the assumption of having uncorrelated noise cannot be justified, and memory effects need to be taken into account. For a quantum channel $T$ with register input $\mathcal{A}$ and register output $\mathcal{B}$, such effects are conveniently modeled (Bowen and Mancini 2004) by introducing an additional memory system $\mathcal{M}$, so that now $T:\mathcal{M}\otimes\mathcal{A}\rightarrow\mathcal{B}\otimes\mathcal{M}$ is a completely positive and trace-preserving map with two input systems and two output systems. Long messages with $n$ signal states will then be processed by the concatenated channel $T_n:\mathcal{M}\otimes\mathcal{A}^n\rightarrow\mathcal{B}^n\otimes\mathcal{M}$. In such a concatenation, the memory system is passed on from one channel application to the next, and thus introduces (classical or quantum) correlations between consecutive register inputs.

Remarkably, this relatively simple model can be shown (Kretschmann and Werner 2005) to encompass every reasonable physical process: every stationary channel $S:\mathcal{A}^\infty\rightarrow\mathcal{B}^\infty$ which turns an infinite string of input states (on the quasilocal algebra $\mathcal{A}^\infty$) into an infinite string of output states on $\mathcal{B}^\infty$ and satisfies the *causality* constraint is in fact a concatenated memory channel. Causality here means that the outputs of the stationary channel $S$ at given time $t_0$ do not depend on inputs at times $t > t_0$. **Figure 2** illustrates the *structure theorem* for causal stationary quantum channels. In general, it produces not only the memory channel $T$ with memory algebra $\mathcal{M}$, but also a map $R$ describing the influence of input states in the remote past. Intuitively, such a map is often not needed, because memory effects decrease in time: the memory channel $T$ is called *forgetful* if outputs at a large time $t$ depend only weakly on the memory initialization at time zero. In fact, memory effects can be shown to die out even exponentially. The set of these channels is open and dense in the set of quantum memory channels. Hence, generic memory channels are forgetful.

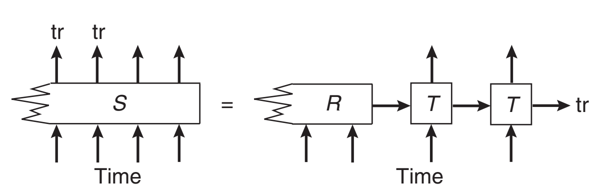

**Figure 2** By the structure theorem, a causal automaton $S$ can be decomposed into a chain of concatenated memory channels $T$ plus some input initializer $R$. Evaluation with the partial trace tr means that the corresponding output is ignored.

The capacity of memory channels is defined in complete analogy to the memoryless case, replacing the $n$-fold tensor product $T^{\otimes n}$ in Definition 1 by the $n$-fold concatenation $T_n$. The coding theorems for (private) classical and quantum information can then be extended from the memoryless case to the very important class of forgetful channels (Kretschmann and Werner 2005).

Nonforgetful channels call for universal coding schemes, which apply irrespective of the initialization of the input memory. Such schemes are presently known only for very special cases.

## Acknowledgmnts

The author thanks the members of the quantum information group at TU Braunschweig for their careful reading of the manuscript and many helpful suggestions. He also gratefully acknowledges the funding from Deutsche Forschungsgemeinschaft (DFG).

# Capillary Surfaces

**R Finn**, Stanford University, Stanford, CA, USA

## Historical and Conceptual Background

A capillary surface is the interface separating two fluids that lie adjacent to each other and do not mix. Examples of such surfaces are the upper surface of liquid partially filling a vertical cylinder (capillary tube), the surface of a liquid drop resting in equilibrium on a tabletop (sessile drop) and the surface of a liquid drop hanging from a ceiling (pendent drop); further instances are the surface of a falling raindrop, the bounding surface of the liquid in the fuel tank of a spaceship, and the interface formed by a fluid mass rotating within another fluid. This last example extends to the problem of rotating stars.

Interfaces separating fluids and solids share some of the physical attributes of capillary surfaces, and the study of wetted portions of rigid "support surfaces" becomes essential for describing global behavior of capillary configurations. However, some significant distinctions appear that change the formal structure of the problems, and must be accounted for in the theory.

Phenomena governed by capillarity pervade all of daily life, and most are so familiar as to escape special notice. By contrast, throughout the eighteenth century and presumably earlier, great attention centered on the rise of liquid in a narrow glass circular-cylindrical tube dipped vertically into a liquid reservoir (Figure 1); this striking event had a dramatic impact that confounded intuition. Clarification of the behavior became one of the major problems challenging the scientific world of the time, and was not achieved during that period. The term "capillary," adapted from the Latin "capillus" for hair, was applied to the phenomenon since it was observed only for tubes with very fine openings; the

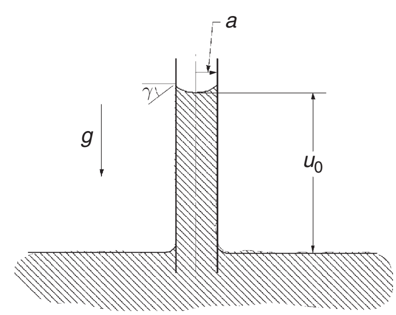

**Figure 1** Capillary tube in infinite reservoir, in downward gravity field.

more general usage adopted in the definition above derives from the recognition of a class of phenomena with a common physical basis.

The first recorded observations concerning capillarity seem due to Aristoteles *c.* 350 BC. He wrote that "a broad flat body, even of heavy material, will float on water, however a narrow thin one such as a needle will always sink." Any reader with access to a needle and a glass of water will have little difficulty refuting the assertion. Remarkably, the error in reasoning seems not to have been pointed out for almost 2000 years, when Galileo addressed the problem in his *Discorsi*, about 1600. The only substantive studies till that time are apparently those of Leonardo da Vinci a hundred years earlier. Leonardo introduced reasoning close in spirit to that of current literature; however, the Calculus was not available to him, and he was not in a position to develop his ideas in quantitative ways.

### Young's Contribution

The later discovery of the Calculus provided a driving impetus guiding many new studies during the eighteenth century. But despite the enormity of that weapon, it did not on its own suffice, and initial quantitative success had to await two initiatives

taken by Thomas Young in 1805. Young based his studies on the concept of surface tension that had been introduced by von Segner half a century earlier. Segner hypothesized that every curve on a fluid/fluid interface $S$ experiences on both its sides an orthogonal force $\sigma$ per unit length, which (for given temperature) depends only on the materials and is directed into the tangent planes on the respective sides. The presence of such forces can be indicated by simple experiments. They become clearly evident in the case of thin (soap) films spanning a frame, in which case there is an easily observed orthogonal pull on the frame, see the section "Dual interpretation of $\sigma$: distinction between fluids and solids." Young made two basic conceptual contributions (Y1, Y2):

Y1. *Relation of pressure jump across a free interface to mean curvature and surface tension.*

Consider a piece of surface $S$ in the shape of a spherical bowl of radius $R$, separating two immiscible fluid media, as in Figure 2. In equilibrium, any pressure difference $\delta p$ across $S$ must be balanced by a tension $\sigma$ on its rim $\Gamma$. If $S$ projects to a disk of (small) radius $r$ on the plane tangent to $S$ at the symmetry point, we are led to

$$\pi r^2 \delta p \simeq 2\pi r \sigma \sin\vartheta \qquad [1]$$

where $\vartheta$ is inclination of $S$ at the rim, relative to the plane. We thus find at the base point

$$\delta p = 2\sigma \frac{d \sin\vartheta}{dr} = 2\sigma \frac{1}{R} \qquad [2]$$

Young then went on to consider a general $S$, without symmetry hypothesis. Letting $1/R_1, 1/R_2$ denote the planar curvatures at a point in $S$ of two normal sections in orthogonal directions, he asserted that

$$\delta p = 2\sigma \frac{1}{2}\left(\frac{1}{R_1} + \frac{1}{R_2}\right) \equiv 2\sigma H \qquad [3]$$

where $H$ is the mean curvature of $S$ at the point. Although Young provided no formal justification for this step, we can establish it with the aid of a general formula from differential geometry that was not known in his lifetime:

$$\int_S 2H\mathbf{N}\, dS = \oint_\Gamma \mathbf{n}\, ds \qquad [4]$$

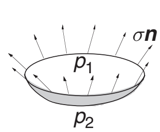

**Figure 2** Pressure change across fluid element, balanced by surface tension.

where $\mathbf{N}$ is a unit normal on $S$, and $\mathbf{n}$ is unit conormal (as indicated in Figure 2) on $\Gamma$. Multiplying both sides of [4] by $\sigma$, the right-hand side becomes the net surface tension force on $S$. Since that must equal the net balancing pressure force, we obtain

$$\int_S (\delta p - 2\sigma H)\mathbf{N}\, dS = 0 \qquad [5]$$

Letting the diameter of $S$ tend to zero, the assertion follows.

We emphasize here the implicit assumption above, that $\sigma$ is a constant depending only on the particular materials, and not on the shape of $S$. This author knows of no source in which that is clearly established, although experiments and experience provide some *a posteriori* justification. See the further comments under Y2, and later in sections "Gauss' contribution: the energy method" and "Dual interpretation of $\sigma$: distinction between fluids and solids."

Y2. *The capillary contact angle.*

Young asserted that there are surface tensions for solid/fluid interfaces analogous to those just introduced, and again depending only on the materials. This assertion is erroneous, as was suggested in writings of Bikerman and of others, and more recently established in a definitive example by Finn. Using his premise, Young attempted to characterize the *contact angle* $\gamma$ made by the fluid surface with a rigid boundary, by requiring that the net tangential component of the three surface tension vectors vanish at the triple interface; this leads to the often employed but incorrect "Young diagram," see Figure 3, and the relation

$$\cos\gamma = \frac{\sigma_1 - \sigma_2}{\sigma_0} \qquad [6]$$

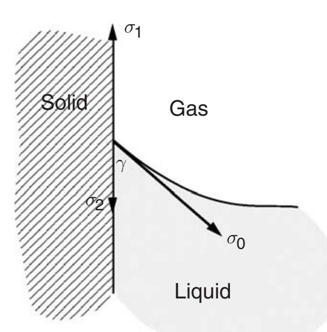

**Figure 3** Young diagram; balance of tangential forces. Residual normal force remains.

for $\cos\gamma$ in terms of the magnitudes of the three "surface tensions.'' Young concluded that the contact angle depends only on the materials, and in no other way on the conditions of the problem. This basic assertion is by a fortuitous accident correct, as follows from the contribution by Gauss described below; it underlies all modern theory.

Using Y1 and Y2, Young produced the first verifiable prediction for the rise height $u_0$ in the circular capillary tube of Figure 1. He assumed the interface to be spherical, so that $H$ is constant and $a = \cos\gamma/H$. He assumed vanishing outside pressure. According to classic laws of hydrostatics, $\delta p = \rho g u_0 = 2\sigma H$ by Y1, where $\rho$ is fluid density; there follows the celebrated relation, presented entirely in words in his 1805 article:

$$u_0 \approx \frac{2\cos\gamma}{\kappa a}, \qquad \kappa = \frac{\rho g}{\sigma} \qquad [7]$$

Young scorned the mathematical method, and made a point of deriving and publishing his results on capillarity without use of any mathematical symbols. This personal idiosyncrasy causes his publications to be something of a challenge to read.

### The Laplace Contribution

In 1806, Laplace published the first analytical expression for the mean curvature of a surface $u(x, y)$, and showed that the expression can be written as a divergence. He obtained the equation

$$\operatorname{div} Tu \equiv 2H, \quad Tu \equiv \frac{\nabla u}{\sqrt{1 + |\nabla u|^2}} \qquad [8]$$

Thus, if $H$ is known from geometrical or physical considerations, as it is for the capillary tube in the example just considered, one finds a second-order (nonlinear) equation for the surface height of any solution as a graph. The equation is elliptic for any function $u(x, y)$ inserted into the coefficients, however not uniformly so; the particular nonuniformity leads to some striking and unusual behavior of its solutions, as we shall see. With the aid of [8], Laplace improved the Young estimate [7] to

$$u_0 \approx \frac{2\cos\gamma}{\kappa a} - \left[\frac{1}{\cos\gamma} - \frac{2}{3}\left(\frac{1 - \sin^3\gamma}{\cos^3\gamma}\right)\right] a \qquad [9]$$

Both Young and Laplace proposed their formulas for "narrow tubes", but neither gave any quantitative indication of what "narrow" should signify. Note that whenever $0 \le \gamma < \pi/2$, [9] becomes negative when the nondimensional *Bond Number* $B = \kappa a^2$ exceeds 8; since $u$ is known to be positive in the indicated range for $\gamma$, [9] provides no information in that case, whereas [7] is still of some value. Nevertheless, [9] is asymptotically exact and consists of the first two terms of the formal expansion in powers of $a$; that was first proved by D Siegel in 1980, almost 200 years following the discovery of the formulas. In 1968, P Concus extended the formal expansion for the height to the entire traverse $0 < r < a$. F Brulois (1981) and independently E Miersemann (1994) proved the expansion to be asymptotic to every order. Explicit bounds for the rise height above and below, making quantitative the notion of "narrow," were obtained by Finn.

Laplace supplied the first detailed mathematical investigations into the behavior of capillary surfaces, applying his ideas to many specific examples. His underlying motivation apparently derived at least partly from astronomical problems, and he published his contributions in two "Suppléments" to the tenth volume of his *Mécanique Céleste*.

### Gauss' Contribution: The Energy Method

Young and Laplace both based their reasonings on force-balance arguments, which at best were unclear and at worst conceptually wrong. In 1830, Gauss took up the problem anew from a variational point of view, using the Johann Bernoulli principle of virtual work. To do so, he attempted to characterize both surface energies and bulk fluid energies in terms of postulated particle attractions and repulsions. In an astonishing 30 pages, he essentially introduced foundations of modern potential theory, of measure theory, and of thermodynamics. He ended up with elaborate expressions that could not readily be applied, and which at least to some extent he did not use. He asserted, for example, that the bulk internal energy would be proportional to volume, which for an incompressible fluid is constant under admissible deformations, and on that basis he ignored the bulk energy term completely. His procedures then led him, in an independent and more convincing way, to the identical equation and boundary condition that had been produced by his predecessors. It must, of course, be remarked that his justification for ignoring the bulk energy term would not be correct for a compressible liquid (see the section "Compressibility"), and it is open to some

question for the central motivating problem of a capillary tube dipped into an infinite liquid bath, in which event there is no volume constraint.

The material that follows is guided by the ideas of Gauss; however, I have found it advantageous to replace his elaborate hypotheses on particle attractions and repulsions by a simpler phenomenological reasoning as to the nature of the energy terms to be expected.

To fix ideas, we consider a semi-infinite cylinder of general section $\Omega$ and of homogeneous material, closed at the bottom, situated vertically in a downward gravity field $g$ per unit mass, and partly filled with an incompressible liquid of density $\rho$ covering the bottom (a more exact discussion, taking account of compressibility, is indicated below in the section "Compressibility"). We assume an equilibrium fluid configuration with the liquid bounded above by an ideally thin interface $S: u(x, y)$ (see Figure 4). We distinguish the energy terms that occur:

1. *Surface energy*. This is the energy required to create the surface interface $S$. We can characterize it by noting that fluid particles within or exterior to the liquid are attracted equally to neighboring particles in all directions; however, at the surface $S$ there is a differential attraction, to particles of the exterior medium (such as air) above, or to the liquid below (see Figure 5). Thus, particles in the interface are pulled orthogonally to $S$. In general, for a liquid–gas interface, significant work will be done only on the liquid and those particles will be pulled toward the liquid; otherwise, the liquid would evaporate across the interface and disappear. The work done in that (infinitesimal) motion is proportional to the area of $S$, so that for the surface energy $E_S$ we obtain

$$E_S = \sigma \int_\Omega \sqrt{1 + |\nabla u|^2} \mathrm{d}x \qquad [10]$$

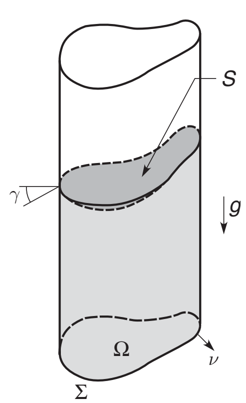

**Figure 4** Liquid in cylindrical capillary tube, of general section $\Omega$. Reproduced with permission from the American Institute of Aeronautics and Astronautics.

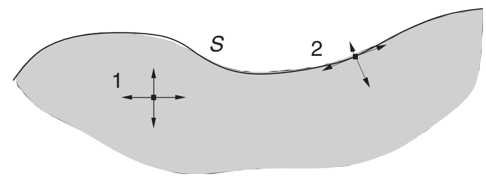

**Figure 5** Attractions on a fluid element: (1) interior to the fluid; (2) on the surface interface.

The constant $\sigma$ has the dimensions of force per unit length, and turns out to be the surface tension of the interface. We note from [10] its dual interpretation as areal energy density on $S$, arising from formation of that surface. This alternative interpretation lends conceptual support to the supposition that $\sigma$ is constant on $S$. See the section "Dual interpretation of $\sigma$: distinction between fluids and solids."

Implicit in the above discussion are deep premises about the nature of the forces acting within the fluid. Essentially these forces must be perceptible only at infinitesimal distances, and grow rapidly with decreasing distance. Forces both of attraction and of repulsion must be present. The recognition of the need for such forces can be traced back to Newton. Quantitative postulates as to their precise nature were introduced by van der Waals in the late nineteenth century, and the topic remains still in active study. Since these forces appear at molecular distance levels, their introduction leads inevitably to questions of statistical mechanics. Additionally, our discussion of work done in forming the surface implicitly assumes a compressible transition layer there, in conflict with our treatment of $S$ as an ideally thin interface bounding an incompressible fluid. In these senses, it is striking that [10] – which is in accord with classical constructions – could be obtained via global qualitative postulates concerning a continuum in static equilibrium, in which the specific nature of the forces is not introduced.

Rayleigh measured the thickness of the surface interface between water and air to be of molecular size, thus providing experimental justification for the procedure adopted.

2. *Wetting energy*. A similar discussion applies at the interface separating the liquid and solid at the cylinder walls; however, this time the net attraction can be in either direction, as particles from neither medium can migrate significantly into the other. For the wetting energy $E_W$, we write, with $\Sigma$ the boundary of $\Omega$,

$$E_W = -\beta\sigma \oint_\Sigma u \, \mathrm{d}s \qquad [11]$$

We designate $\beta$ as the *relative adhesion coefficient* of the liquid–gas–solid configuration. We assume that the cylinder walls are of homogeneous material, so that $\beta$ will be constant. In general, $\beta$ is a difference of factors that apply on the walls at the two interfaces, with the liquid and with the external medium.

3. *Gravitational energy*. The work done in lifting an amount of liquid $\rho\delta h\delta\Omega$ against the gravity field from the base level to a height $h$ in a vertical tube of small section $\delta\Omega$ is $\rho gh\delta h\delta\Omega$. Thus, the work done in filling that tube up to the surface height $u$ is $(\rho gu^2/2)\delta\Omega$, and the total gravitational energy is

$$E_G = \frac{\rho g}{2}\int_\Omega u^2\,\mathrm{d}x \qquad [12]$$

4. *Volume constraint*. In the configuration considered the volume is to be unvaried during admissible deformations; we take account of the constraint by introducing a Lagrange parameter $\lambda$, and an additional "energy" term

$$E_V = \lambda\sigma\int_\Omega u\,\mathrm{d}x \qquad [13]$$

According to the principle of virtual work, the sum $E$ of the above energies must remain unvaried in any deformation that respects all mechanical constraints other than the volume constraint. We choose a deformation $u \to u + \varepsilon\eta$, with $\eta$ smooth in the closure of $\Omega$, which determines a functional $E(\varepsilon)$. From $E'(0) = 0$ follows

$$\int_\Omega\left\{\nabla\eta\cdot\frac{\nabla u}{\sqrt{1+|\nabla u|^2}} + \eta(\kappa u+\lambda)\right\}\mathrm{d}x - \beta\oint_\Sigma \eta\,\mathrm{d}s = 0 \qquad [14]$$

from which

$$\int_\Omega \eta\{-\operatorname{div}Tu + (\kappa u+\lambda)\}\mathrm{d}x + \oint_\Sigma \eta(\nu\cdot Tu - \beta)\mathrm{d}s = 0 \qquad [15]$$

with $Tu \equiv \nabla u/\sqrt{1+|\nabla u|^2}$, and with $\nu$ the unit exterior normal on $\Sigma$. Choosing first $\eta$ to have compact support in $\Omega$, the boundary term vanishes, and the "fundamental lemma" of the calculus of variations yields

$$\operatorname{div}Tu = \kappa u + \lambda, \qquad \kappa = \rho g/\sigma \qquad [16]$$

throughout $\Omega$. Thus, the area integral in [15] vanishes for any $\eta$. We are therefore free to choose $\eta$ as we wish on the boundary, and the fundamental lemma now yields $\nu\cdot Tu = \beta$ on $\Sigma$. We now note that for any liquid surface $u(x,y)$ there holds

$$\nu\cdot Tu = \cos\gamma \qquad [17]$$

on $\Sigma$, where $\gamma$ is the angle between the cylinder wall and the surface $S$, measured within the liquid. Since $\beta$ is assumed to be constant, that is so also for $\gamma$. It is a physical constant: the contact angle, that must be measured in an independent experiment, and cannot be prescribed in advance or calculated within the scope of the theory.

The constant $\beta$, originally introduced as a general proportionality constant, is now characterized as $\beta = \cos\gamma$. We thus see that a physical surface of the form envisaged is possible only if $-1 \le \beta \le 1$. Physically, one expects that if $\beta < -1$ the liquid will separate from the walls, while, if $\beta > 1$, the liquid will spread over the walls as a thin film.

Equation [16] and boundary condition [17] provide a nonlinear second-order equation that is elliptic for any function $u(x,y)$, and also a nonlinear transversality condition on the boundary, for determining the surface interface $S$. The expression $\operatorname{div}Tu$ is exactly twice the mean curvature of the surface $S$. If $\kappa \neq 0$ then $\lambda$ can be eliminated by addition of a constant to $u$. The problem [16]–[17] for the fluid in a vertical cylindrical capillary tube of general section becomes thus a geometrical one: to find a surface whose mean curvature is a prescribed function of position in space, and which meets the cylindrical boundary walls in a prescribed angle $\gamma$.

In the absence of gravity, [16] takes the form

$$\operatorname{div}Tu = 2H \qquad [18]$$

for a surface of constant mean curvature $H$. The constant $H$ is determined by integrating [18] over $\Omega$, and using [17]:

$$2H = \frac{|\Sigma|\cos\gamma}{|\Omega|} \qquad [19]$$

where $|\Sigma|$ and $|\Omega|$ denote the respective perimeter and area, and thus $H$ is independent of volume. From the known uniqueness up to an additive constant of the solutions of [18], [17] it follows that the shape of the solution surface is independent of volume. That result holds also for [16], [17] in view of the possibility to eliminate $\lambda$ from the equation by addition of a constant, and the uniqueness of the solutions of the resulting equation.

Equations [16]–[17] or [18]–[17] are appropriate for determining capillary surfaces that are graphs

$u(x, y)$ over a base domain $\Omega$. More generally, any surface $S$ in 3-space satisfies the equation

$$\Delta x = 2HN \quad [20]$$

where $H$ is its scalar mean curvature and $N$ is a unit normal vector on $S$. Here $\Delta$ is the "intrinsic Laplacian" in the metric of $S$. This is the appropriate relation to be applied in situations for which the physical surface folds over itself and cannot be expressed globally as a graph. The formal simplicity of [20] is deceptive; the challenges arising from the nonlinearity in the equation can be formidable, and very little general theory is as yet available.

### Dual Interpretation of $\sigma$: Distinction between Fluids and Solids

We have already remarked the duality in connection with eqn [10] above. It can be made explicit with a simple experiment proposed by Dupré. One makes a rigid frame with a sliding bar of length $l$, as in Figure 6, and dips the frame into soap solution. On lifting the frame from the solution the opening will be filled with a soap film, and one finds a force $F = 2\sigma l$ on the bar, directed orthogonal to the bar (the factor 2 appears since the film has two sides). The work done in sliding the bar a distance $\delta x$ is $\delta F = 2\sigma l \delta x$, which can also be written $\delta F = 2\sigma \delta A$ with $\delta A$ an element of area. In this sense, the two interpretations of $\sigma$ are formally equivalent, for fluid/fluid interfaces.

The equivalence cannot be extended to solid/fluid interfaces. Consider a rigid spherical ball of generic material and radius $R$, freely floating in an infinite liquid bath in a gravity-free environment, see Figure 7a. It can be shown that the unique symmetric solution to the problem is a horizontal surface, as in the figure. A variational procedure as above shows that if $e_0, e_1, e_2$ are the interfacial energy densities associated with the three interfaces, then

$$\cos \gamma = \frac{e_1 - e_2}{e_0} \quad [21]$$

in formal analogy with the Young relation [6]. But $e_1, e_2$ cannot be interpreted as interfacial forces whose net tangential component cancels that of $e_0$.

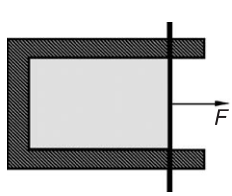

**Figure 6** Dupré apparatus for exhibiting surface tension.

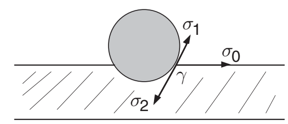

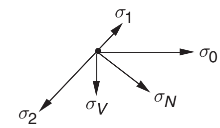

**Figure 7** (a) Floating spherical ball; presumed "Young" forces. (b) Normal and vertical components of Young forces; contradiction to presumed equilibrium.

To do so would lead to a net downward force $\sigma_v$ on the ball (see Figure 7b), contradicting the supposed equilibrium state.

## Mathematical and Physical Predictions: Experiments

In the following sections, we study the kinds of behavior imposed on a surface $S$ by the requirement that it appear as solution of one of the indicated equations and boundary conditions. Some of these properties are quite surprising in the context of classically expected behavior of solutions of equations of mathematical physics. The mathematical predictions were, however, corroborated in certain cases experimentally, as we discuss below.

### Uniqueness and Nonuniqueness

We begin by considering uniqueness questions. We start with a semi-infinite capillary tube, closed at the bottom, to be partially filled with a prescribed volume of (incompressible) liquid making contact angle $\gamma$ on the container walls (Figure 8a). If $\kappa \geq 0$, any solution is uniquely determined. That is a quite general theorem, valid for a wide class of domains $\Omega$ including all piecewise smooth domains (at the corners of which data of the form [17] cannot be prescribed); formally, data can be omitted on any boundary set of linear Hausdorff measure zero. In this result, no growth conditions need be imposed near the boundary (note that such a statement would be false for solutions of the Laplace equation under Dirichlet boundary conditions).

Next we consider a sessile liquid drop on a horizontal plate (Figure 8b). Again the solution is uniquely determined by the volume and by $\gamma$, although the known proof differs greatly from that of the other case.

We now consider a smooth deformation of the base plane, depending on a parameter $t$, which carries it into the cylinder; that can be done in such a way that the supporting surface is at all times "bowl-shaped," as in Figure 8c. Since the bowl formation tends to restrict the possible deformations

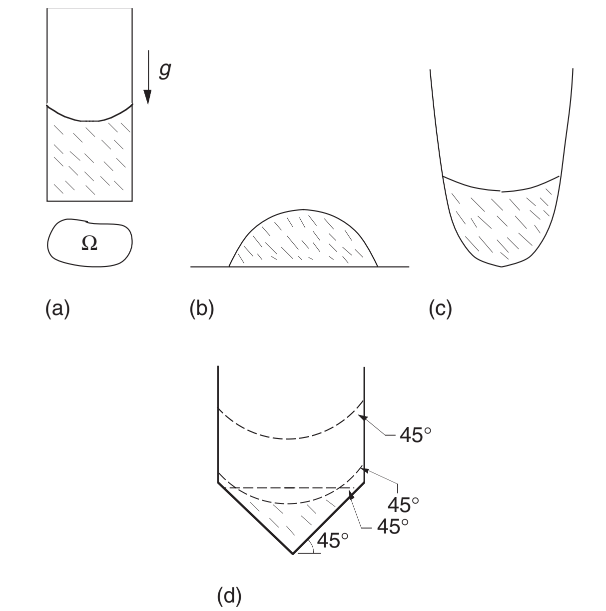

**Figure 8** Support configurations: (a) capillary tube, general section; (b) horizontal plate; (c) convex surface appearing during deformation of horizontal plate to capillary tube; and (d) Nonuniqueness of configuration appearing during convex deformation. Reproduced from *Mathematics Intelligencer* 24(3) 2002 21–33 with permission from Springer-Verlag Heidelberg.

of the fluid consistent with smooth contact with the supporting rigid surface, one might expect that the corresponding capillary surface $S(t)$, arising from the identical fluid mass, will for each $t$ be uniquely determined.

That is however not true, even for symmetric configurations. We can see that from the configuration of Figure 8d, consisting of a vertical circular cylinder whose base is a 45° cone. We assume a contact angle $\gamma = 45°$ and adjust the radius so that a horizontal surface lying just below the cylinder/cone juncture provides the prescribed volume. This is a formal solution surface. Now fill the configuration with a larger volume, so that the contact line will lie above the juncture. The upper surface will no longer be flat, in view of the 45° contact angle, and takes an appearance as indicated in the figure. Finally, we decrease the fluid volume, keeping all other parameters unchanged. As noted above, the upper surface moves rigidly downward, and it is clear that if the original surface is close enough to the juncture line, then the prescribed volume will be attained before the contact line reaches the juncture. Thus, uniqueness fails.

In this construction as just described, the bounding surface is not smooth; however, one sees easily that the procedure continues to work if the edge and vertex are smoothed locally. In fact, one can carry the procedure to a striking conclusion; by appropriate smoothing, one can construct a bounding surface admitting an entire continuum of distinct solution interfaces, all with the same contact angle and enclosing the same fluid volume (Gulliver and Hildebrandt; Finn). This can be done for any gravity field. Figure 9 illustrates seven members of the family of interfaces, in the particular case $\kappa = 0$.

The question immediately arises as to which if any of the continuum of surfaces will be seen in an experiment. In fact, it can be proved that none of the indicated surfaces is mechanically stable (Finn, Concus and Finn, Wente). Since the indicated family includes all symmetric surfaces that are stationary for the energy functional, we find that any stable stationary configuration must be asymmetric. Thus, we have obtained an example of symmetry breaking, in which all conditions of the problem are symmetric, but for which all physically acceptable solutions are asymmetric.

These results were subjected to computational test by M Callahan using the Surface Evolver software, to experimental test by M Weislogel in a drop tower, and to experimental test by S Lucid in the Mir Space Station. The results of the latter experiment are compared in Figure 10 with the computer calculations. In both cases, both a local minimizer (potato chip) and a presumed global minimizer (spoon) were observed.

The seven surface interfaces indicated in Figure 9 all provide the same sum of surface and wetting energy, and bound the same volume of fluid. They all satisfy an eqn [18] with constant $H$, in accordance with hypotheses of incompressibility and vanishing gravity. Thus, formally, all configurations have identical mechanical energy. The surfaces

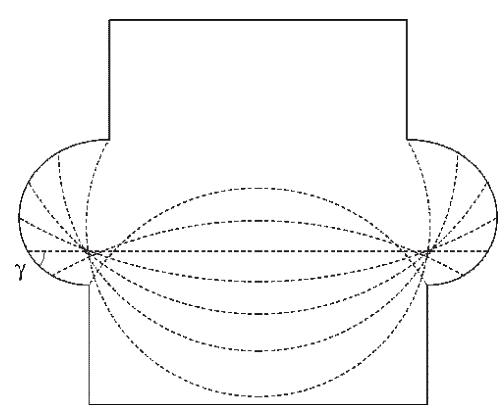

**Figure 9** Seven spherical capillary interfaces in an "exotic" container of homogeneous material in zero gravity. All interfaces bound the same volume and have the same sum of free surface and wetting energies. If all pressures above the interfaces are the same, then the pressures below them successively increase as the curvature vectors of the vertical sections change from upwardly to downwardly directed. are all spherical caps; however, the radii $R$ of the caps vary considerably. According to Y1 above, the pressure change across each interface is $\Delta p = 2\sigma/R$. Since one may assume the outer region to be a vacuum with zero pressure for all caps, we find that the pressures within the fluids vary greatly among the configurations. One would thus expect that work is done within the fluid in passing from one configuration to another, a circumstance we have excluded by hypothesis when determining the family. From this point of view, the (customary) hypothesis of incompressibility that was used in determining the family is put into significant question; we examine this point in some detail in the section "Compressibility."

#### Discontinuous Dependence I

Capillary surfaces can exhibit striking discontinuous dependence on the defining data. As initial example, we consider the behavior of a solution of [18]–[17] at a protruding corner point $P$ of the domain $\Omega$ of definition. For simplicity, we assume the corner bounded locally by straight segments, meeting in an opening angle $2\alpha < \pi$, thus forming locally a wedge domain. In anticipation of material to follow, we assume contact angles $\gamma_1$ and $\gamma_2$ on the respective sides, $0 \leq \gamma_1, \gamma_2 \leq \pi$. One can show that a necessary condition for a solution surface over a domain $\Omega_\delta$ as in Figure 11 to have a continuous normal vector up to $P$ is that the data point $(\gamma_1, \gamma_2)$ lie in the closure of the rectangle $R$ of Figure 12. (This figure includes also additional material anticipating the section "Drops in wedges").

For data points interior to $R$, this criterion also suffices for the existence of at least one such solution surface, for any prescribed $H$; such surfaces can in fact be produced explicitly as spherical caps (planes if $H = 0$). It remains to discuss what can occur with data arising from the remaining four subregions of the square.

If $(\gamma_1, \gamma_2) \in D_1^{\pm}$, then there is no solution to [18]–[17] in any neighborhood of the corner point $P$. On the other hand, an explicit solution for any $H > 0$ can be found as a lower spherical cap on the segment $\gamma_1 + \gamma_2 = \pi - 2\alpha$ that separates $D_1^+$ from $R$ (see Figure 13, which indicates the equatorial circle). Correspondingly, if $H < 0$ then an explicit solution can be found on the separation line between $D_1^-$ and $R$. Thus, there is a

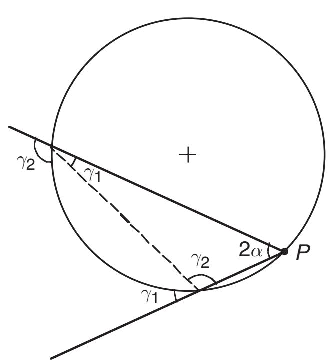

**Figure 13** Construction of solution as lower hemisphere; $\gamma_1 + \gamma_2 = \pi - 2\alpha, H > 0$. Reproduced from "Capillary Wedges Revisited" in *SIAM J. Math. Anal.* 27 No.1 (1996) 56–69 with permission from SIAM.

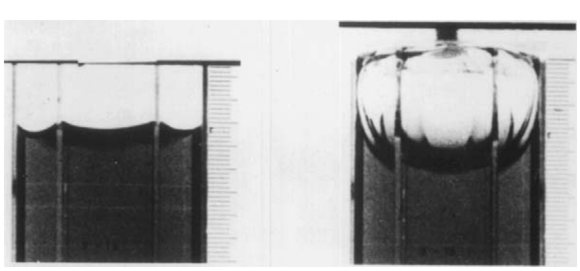
discontinuous change in behavior in crossing from $R$ to either of the $D_1$ regions.

This behavior was put to experimental test by W Masica, who considered the case $0 < \gamma_1 = \gamma_2 = \gamma < \pi/2$ near the crossing point $\gamma = \gamma_{cr}$ with $D_1^+$, for which $\alpha + \gamma_{cr} = \pi/2$. He partially filled a regular hexagonal cylinder of acrylic plastic, successively with two different liquids, making respective contact angles greater or less than $\gamma_{cr}$ with the plastic. For each liquid, Masica then allowed the cylinder to fall in a 132 m drop tower. Figure 14 compares the two configurations after about 5 s of free fall. In the case $\gamma > \gamma_{cr}$ he obtained the spherical-cap solution, which in this case covers the entire base domain $\Omega$ and appears as an explicit solution of [18]–[17]. When $\gamma < \gamma_{cr}$, the liquid rose to the top of the cylinder near the edges, filling out the edges over the corner points. The surface interface $S$ does not cover $\Omega$, but instead folds back over itself, doubly covering a portion of $\Omega$. Thus, a physical surface appears as it must, but it is not a solution of [18] over $\Omega$.

### Discontinuous Dependence II

About 1970, M Miranda raised informally the question, whether a capillary tube $Z_0$, whose section



(a) (b)

**Figure 14** Liquid in hexagonal cylinder, during free fall in drop tower: (a) $\alpha + \gamma > \pi/2$; (b) $\alpha + \gamma < \pi/2$.

$\Omega_0$ lies strictly interior to a section $\Omega_1$ of a tube $Z_1$, will raise liquid from an infinite reservoir in a downward directed gravity field to a higher level over $\Omega_0$ than will $Z_1$ over that subdomain of its section. That is true if both cylinders are circular, and in the intervening years its correctness was established in a number of other cases of particular interest.

Finn and Kosmodem'yanskii, Jr. showed, however, by example that the assertion fails in a large range of cases, and in fact can fail with arbitrarily large height differences, uniformly over $\Omega_0$. Beyond that, the construction exhibits a strikingly discontinuous change of behavior, under perturbations of a disk as inner domain. Perhaps more remarkably, the assertion can hold with the inner domain a disk, but with discontinuous reversal of behavior as the disk is perturbed to neighboring disks. That was shown in a form of the example given later by Finn, and illustrated in Figure 15. Here the outer domain $\Omega_1$ is polygonal, with sides that extend to be tangent to a unit disk $\Omega_0$, as indicated. The angle $\gamma$ is to be chosen so that $0 \le \pi/2 - \gamma \le \alpha_{\min}$, where $\alpha_{\min}$ is the smallest of the interior vertex half-angles of $\Omega_1$. In view of the assumed infinite fluid reservoir, there is no volume constraint, and the governing equation [16] takes the form

$$\operatorname{div} Tu = \kappa u, \qquad \kappa = \rho g/\sigma > 0 \qquad [22]$$

Taking at first the inner domain to be $\Omega_0$, it can be shown that for the corresponding solutions $u^0$ and $u^1$ of [22], there holds $u^0 > u^1$ over $\Omega_0$ for

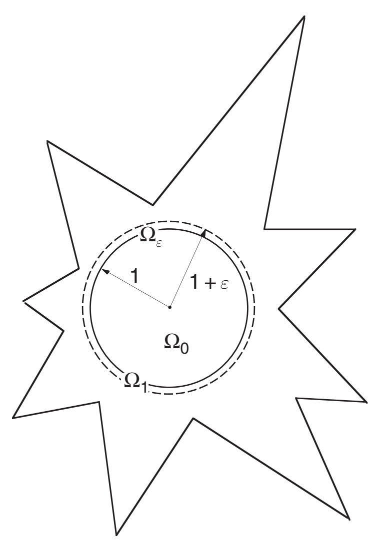


**Figure 15** Discontinuous reversal of limiting height behavior. All sides of the polygonal domain $\Omega_1$ are tangent to the unit disk $\Omega_0$. For the corresponding solution heights $u^0$ in $\Omega_0$, $u^\varepsilon$ in the disk $\Omega_\varepsilon$ of radius $1+\varepsilon$, and $u^1$ in $\Omega_1$, there holds $u^1 - u^0 < 0$, for any downward gravity. But $\lim_{\kappa\to 0}(u^1 - u^\varepsilon) = +\infty$, for any $\varepsilon > 0$.

any $\kappa > 0$, and thus the Miranda question has a positive answer for that configuration. But if we replace $\Omega_0$ by a concentric disk $\Omega_\varepsilon \subset \Omega_1$ of radius $1+\varepsilon$, we find

$$\left| \left\{ \inf_{\Omega_\varepsilon} u^1(x;\kappa) - \sup_{\Omega_\varepsilon} u^\varepsilon(x;\kappa) \right\} - \frac{2\varepsilon}{1+\varepsilon} \frac{\cos\gamma}{\kappa} \right| < \frac{1-\sin\omega}{\cos\gamma} + (1+\varepsilon)\frac{1-\sin\gamma}{\cos\gamma} \qquad [23]$$

where $\omega = \arccos(\cos\gamma/\sin\alpha)$, and $u^\varepsilon$ is the solution of [22], [17] in $\Omega_\varepsilon$. Since $\kappa$ does not appear on the right side of [23], there follows in particular that for any $\varepsilon > 0$, there holds

$$\lim_{\kappa\to 0} \left\{ \inf_{\Omega_\varepsilon} u^1(x;\kappa) - \sup_{\Omega_\varepsilon} u^\varepsilon(x;\kappa) \right\} = \infty \qquad [24]$$

In particular, a negative answer to Miranda's question appears for all gravity sufficiently small. But as observed above, a positive answer occurs in $\Omega_0$, for any positive gravity. Thus, the limiting behavior as $\kappa \to 0$ changes discontinuously, as $\varepsilon \to 0$. We find that the two limiting procedures cannot be interchanged: for any $x \in \Omega_0$, we obtain

$$\begin{aligned} &\lim_{\varepsilon\to 0}\lim_{\kappa\to 0}\left\{u^1(x;\kappa) - u^\varepsilon(x;\kappa)\right\} = +\infty. \\ &\lim_{\kappa\to 0}\lim_{\varepsilon\to 0}\left\{u^1(x;\kappa) - u^\varepsilon(x;\kappa)\right\} \equiv \text{const.} < 0 \end{aligned} \qquad [25]$$

## Existence Questions I

For the general equation [20] there is an established literature on existence of surfaces containing a prescribed space curve. There is very little literature relating to the capillarity boundary condition that the solution surface $S$ meet a prescribed "support" surface $W$ in a prescribed angle $\gamma$. The existence of at least one such surface interior to a prescribed sufficiently smooth closed space domain was proved by Almgren, and then Taylor proved smoothness at the contact curve. These are abstract theorems that are basic for the theory but in general do not provide specific information in particular cases of interest.

Special interest attaches to the nonparametric cases [16] or [18] with boundary condition [17], especially in view of the discontinuous behavior properties described above. These cases were studied in depth by a number of authors, with results that put the above examples into some perspective.

M Emmer proved the existence of a unique solution of [16]–[17] for any compact $\Omega$ having Lipschitz boundary with Lipschitz constant $L$ such that $\sqrt{1+L^2}\cos\gamma < 1-\varepsilon$ for some $\varepsilon > 0$. Finn and Gerhardt (F and G) extended this condition, and showed in particular that solutions exist in general in piecewise smooth $\Omega$. This result contrasts with the zero-gravity case [18] discussed in the section "Existence questions II," for which solutions fail to exist when $\sqrt{1+L^2}\cos\gamma > 1$ at a protruding corner (see the section "Discontinuous dependence I"). However, in the cases $\sqrt{1+L^2}\cos\gamma > 1$ studied by F and G the solution $u(x)$ is necessarily unbounded in the corner. This condition is equivalent to $\alpha < |\gamma - \pi/2|$ at the corner. Concus and Finn showed that if $\alpha \geq |\gamma - \pi/2|$ in a neighborhood $\Omega_\delta$ of a corner with rectilinear sides, as indicated in Figure 11, then the solution $u(x)$ satisfies

$$|u(x;\kappa)| < \frac{2}{\kappa\delta} + \delta \qquad [26]$$

independent of $\alpha, \gamma$ in the range considered. Here it is assumed that [16] is normalized so that $\lambda = 0$; when $\kappa \neq 0$ this can always be achieved by adding a constant to $u$. On the other hand, if $\alpha < |\gamma - \pi/2|$, then

$$u(x;\kappa) \approx \frac{\cos\vartheta - \sqrt{k^2 - \sin^2\vartheta}}{k\kappa r} \qquad [27]$$

where $k = \sin\alpha/\cos\gamma$ and $\vartheta$ is polar angle relative to a bisector at the vertex; hence $u$ becomes unbounded as $O(1/r)$. Thus, the behavior changes discontinuously as the configuration for which $\alpha = |\gamma - \pi/2|$ is crossed.

This prediction was corroborated by T Coburn in a "kitchen sink" experiment in the Medical School at Stanford University. Coburn formed a wedge using two sheets of acrylic plastic, resting on a glass plate, and inserted a drop of distilled water at the base of the wedge. Initially, the wedge was opened sufficiently that $\alpha + \gamma \geq \pi/2$, and he obtained the configuration of **Figure 16a**, with the maximum height slightly lower than that indicated by [26]. By closing down the angle slightly, the liquid rose to over ten times that height, as shown in **Figure 16b**. This experiment was later repeated by Weislogel under laboratory conditions; it incidentally establishes the contact angle of water and acrylic plastic in the Earth's atmosphere as $80° \pm 2°$.

The indicated procedure provides in general a very accurate way to measure contact angles, when the angle is not far from $\pi/2$. For $\gamma$ near zero or $\pi$ in the Earth's gravity field, the discontinuity is confined to a microscopic neighborhood of the vertex, and can be difficult to observe. This technical difficulty was addressed by Fischer and Finn, who introduced "canonical proboscis" domains, the theory of which was further developed by Finn and

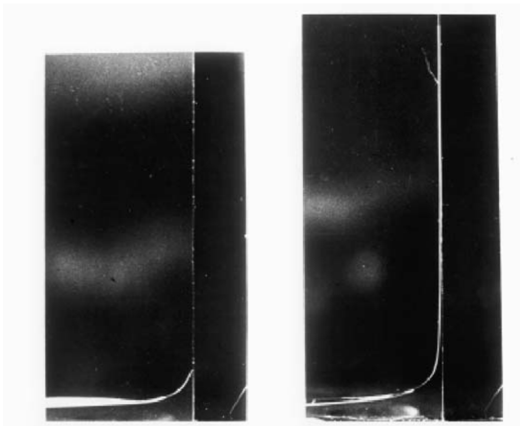

**Figure 16** Distilled water in wedges formed by acrylic plastic plates; $g > 0$. (a) $\alpha + \gamma > \pi/2$; (b) $\alpha + \gamma < \pi/2$. Reproduced from P Concus and R Finn, "On Capillary Free Surfaces in a Gravitational Field" in *Acta Math* 132 (1974) 207–223 with permission of Institut Mittag-Loeffler.

Leise and by Finn and Marek. For such domains the change in behavior is not strictly discontinuous, but it is nearly so, and it extends over large portions of the cylinder section, so that it is easily observable. Concus, Finn, and Weislogel conducted space experiments, demonstrating the feasibility of the method as a means for measuring contact angles in general ranges.

In [26]–[27] no growth conditions at the corner are imposed; the estimates hold for every solution defined in $\Omega_\delta$ and assuming the prescribed data on the side walls, with no data prescribed at the vertex. The formula [27] is the initial term of a formal asymptotic expansion of the solution, in powers of $r$. Miersemann obtained the complete expansion, asymptotic to every order, when $\alpha < |\gamma - \pi/2|$. He obtained somewhat less complete information in the bounded case [26].

Chen, Finn, and Miersemann provided a form of [27] that is applicable for any data $(\gamma_1, \gamma_2)$ on the respective sides of the wedge, that arise from the $D_1^{\pm}$ regions of **Figure 12**. Lancaster and Siegel and independently Chen, Finn, and Miersemann showed that if $-2\alpha \leq \gamma_1 + \gamma_2 - \pi \leq 2\alpha$, then every solution is bounded at the vertex. This result holds also for the zero gravity eqn [18].

In the case of [18], Concus and Finn showed that in the $D_1^{\pm}$ regions no solution exists, regardless of $H$. Again, this result holds without growth conditions.

From these considerations and from remarks in the section "Discontinuous dependence I" follows that for data in $D_2^{\pm}$, all solutions either of [18] or of [16] are bounded but have discontinuous derivatives at the vertex $P$. Extrapolating from the behavior of particular computed solutions, Concus and Finn conjectured that all solutions of [18] or of [16] that arise from data in $D_2^{\pm}$ are discontinuous at $P$. A number of attempts to prove or to disprove this conjecture have till now been unsuccessful.

An existence theorem for [16]–[17] alternative to that of Emmer was obtained independently by Ural'tseva, using a very different approach. This procedure yielded smoothness estimates up to the boundary, but required a hypothesis of boundary smoothness, so that the result does not mesh with the discontinuous dependence behavior as does that of Emmer. Later versions of the existence result, again under boundary smoothness requirements, were given by Gerhardt, Spruck, and Simon and Spruck. In the procedure introduced by Emmer, the boundary trace is shown to exist only in a very weak sense (which, however, suffices for a uniqueness proof). The later work can be adapted to show that the Emmer solutions are smooth on the smooth parts of $\partial\Omega$.

None of the above procedures provides existence for the zero gravity case [18]. As we shall see in the following section, that is not an accident of the methods, but reflects subtle properties of the equations.

## Existence Questions II

We consider here the zero-gravity case [18], over a domain $\Omega$ bounded by a piecewise smooth curve $\Sigma$, under the boundary condition [17]. Integrating [18] over $\Omega$ and using [17], we find $2H|\Omega| = |\Sigma| \cos\gamma$. Let $\Omega^* \subset \Omega, \Sigma^* = \Sigma \cap \partial\Omega^*, \Gamma = \Omega \cap \partial\Omega^*$. The same procedure over $\Omega^*$, using that $|Tu| < 1$ for any $u(x, y)$, leads to the bound

$$\Phi[\Gamma; \gamma] > 0 \qquad [28]$$

where $\Phi$ is defined by

$$\Phi[\Gamma; \gamma] \equiv |\Gamma| - |\Sigma^*| \cos\gamma + 2H|\Omega^*| \qquad [29]$$

The inequality [28] must hold for any choice of $\Omega^* \subset \Omega$. This provides a necessary condition for existence of a solution to [18]–[17] in $\Omega$. E Giusti showed that when $\Omega^*$ is interpreted in a generalized sense as a Caccioppoli set, the condition [28] becomes also sufficient for existence.

It is easy to give specific examples of convex analytic domains $\Omega$, in which subdomains $\Omega^*$ can be found such that [28] fails. Thus, the general existence results for [16] do not carry over to [18], regardless of local domain smoothness. Nevertheless, in many cases of interest (e.g., a circular disk or an ellipse that is not too eccentric), solutions of [18]–[17] do exist for any $\gamma$ and are well behaved. Finn investigated the condition [28] in general by showing the existence of a system of arcs $\{\Gamma\} \subset \Omega$

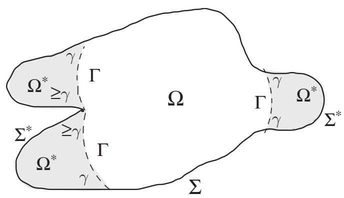

**Figure 17** Extremal configuration for the functional $\Phi$.

that minimize $\Phi$. All such arcs are circular of radius $1/2H$, and meet $\Sigma$ either at smooth points in an angle $\gamma$, or else at a reentrant corner point in an angle $\gamma^* \geq \gamma$, measured on the side of $\Gamma$ opposite to that into which the curvature vector points (Figure 17). All minimizing configurations are bounded by arcs of that form, although not all such configurations minimize. In a typical situation one will encounter only a finite number of such arcs, in which case only a finite number of cases need be examined. If $\Phi > 0$ in each such case, then a solution of [18]–[17] exists for the given $\Omega$ and $\gamma$. It may occur that no such arcs exist; we then observe that since $\Phi[\emptyset;\gamma] = \Phi[\Sigma;\gamma] = 0$, $\Phi$ cannot become nonpositive for any $\Omega^* \subset \Omega$ unless a minimizing $\Gamma$ can be found in $\Omega$, contradicting the assumed nonexistence of minimizers. Thus, the criterion is then vacuously satisfied, and we conclude that a solution of [18]–[17] exists.

One has, of course, to ask what happens physically in cases for which $\Phi[\Gamma;\gamma] \leq 0$ for some $\Gamma$ as above. The possible modes of behavior were studied in particular cases by Tam and later by deLazzer, Langbein, Dreyer, and Rath; Finn and Neel characterized the general case. Formally, the fluid rises to infinity throughout domains $\Omega^*$ of the form indicated, but with $H$ replaced by a value $H^- < H$; on the opposite side of the circular arcs $\Gamma$, the fluid is asymptotic to the vertical cylinders over $\Gamma$. In a physical situation, the fluid will rise to the top of the container in a nearly cylindrical region adjacent to a portion of the container walls, approximating the indicated behavior and partially wetting the top of the container. One sees that behavior in Figure 14b, in which the fluid fills out regions adjacent to the corners. An analogous configuration would still be observed if the corners were smoothed locally. If insufficient fluid is available, a portion of the base $\Omega$ could become unwetted.

### Behavior at a Corner Point

Lancaster and Siegel (L and S) studied the behavior of the limits (which they designate by $Ru$) of bounded solutions of [16] or of [18] along radial segments tending to a corner point $P$ of a domain $\Omega$. These limits can exhibit remarkable idiosyncratic behavior. For simplicity of exposition, we restrict ourselves here to rectilinear boundary segments at $P$, and assume constant boundary angles $\gamma_1, \gamma_2 \neq 0, \pi$ on the two sides. L and S prove first that the limits $Ru$ exist and vary continuously with direction of approach; then they show the existence of "fan" regions of directions adjacent to those of the sides, in which the limits are constant independent of direction, see Figure 18. They obtain that if the opening angle $2\alpha$ at $P$ satisfies $2\alpha < \pi$, then for data in the rectangle $R$ of Figure 12 the fans overlap (see Figure 18a), so that the solution is necessarily continuous at $P$. For data in $D_2^+$, the solution decreases from the $\gamma_1$ side $\Sigma_1$ to the $\gamma_2$ side $\Sigma_2$ ("D" behavior), subject to the Concus–Finn conjecture (see the section "Existence questions I"), with the reverse behavior ("I") in $D_2^-$. Concus and Finn showed that if $2\alpha < \pi$ then in $D_1^\pm$ there is no bounded solution of [16]–[17] or [18]–[17] as a graph. For [16]–[17], unbounded solutions do however exist for such data (see the section "Existence questions I").

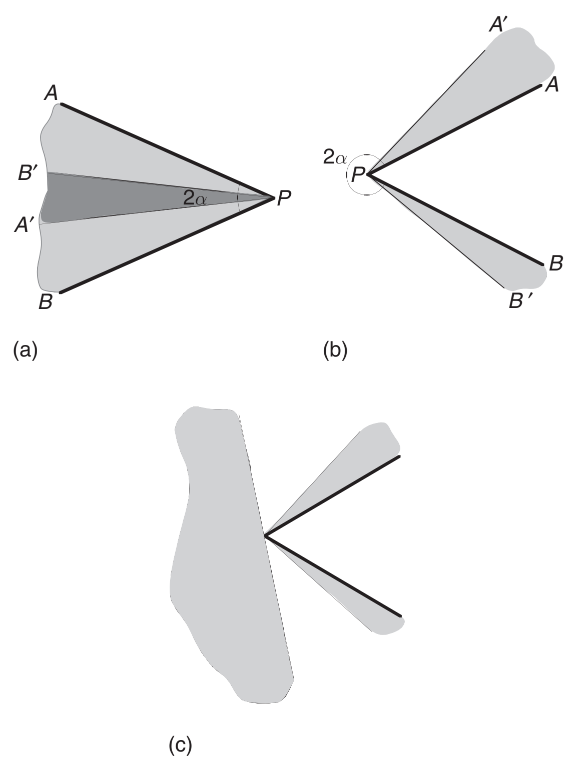

**Figure 18** (a) Fan domains $APA'$ and $BPB'$ of constant limiting values; $2\alpha < \pi$ so that the fans overlap when data are in $R$. (b) $2\alpha > \pi$; case 1. Fans $APA'$ and $BPB'$ of constant radial limits appear. Limiting value changes strictly monotonically as approach direction changes from $A'P$ to $B'P$. (c) $2\alpha > \pi$; case 2. In addition to the two fans adjacent to the sides of the wedge, a half plane of constant radial limits appears.

If $2\alpha > \pi$, then the fans do not overlap, and in fact continuity at $P$ cannot in general be expected. Outside the indicated fan regions adjacent to the wedge sides, the limit values either change strictly monotonically with angle of approach, as in Figure 18b, or else they do so except for approaches within a third, central fan, which covers a full half-space, and interior to which the limiting values again remain constant, see Figure 18c. L and S give an example under which that behavior actually occurs. Remarkably, in the example the prescribed data are the same on both boundary segments. The solution is nevertheless discontinuous at $P$, with an interval in which the radial limit increases, another interval in which it decreases, two fans of constant limit adjacent to the sides, and a fan of breadth $\pi$ in-between.

General conditions for continuity at a reentrant corner ($2\alpha > \pi$) have not yet been established. L and S give a sufficient condition, depending on a hypothesis of symmetry. Since no such hypothesis is needed when $2\alpha < \pi$, one might at first expect it to be superfluous. However, Shi and Finn showed that by introducing an asymmetric domain perturbation that in an asymptotic sense can be arbitrarily small, the solution can be made discontinuous at $P$. That can be done without affecting any other hypotheses of the L and S theorem.

In as yet unpublished work, D Shi characterized all possible behaviors at a reentrant corner, subject to the validity of the Concus–Finn conjecture at a protruding corner. If $\kappa \geq 0$ then all solutions of [16] or of [18] in a neighborhood of $P$ in $\Omega$ are bounded at $P$. The further behavior depends on the particular data, and is indicated in Figure 19. Note the analogy with Figure 12, although the interpretations in the figures differ in detail. Here the symbol I denotes strictly increasing from the side $\Sigma_1$ to $\Sigma_2$, except on the fan regions of constant limits; ID denotes constancy on a fan adjacent to $\Sigma_1$, then strictly increasing, then constancy on a fan of opening $\pi$, then strictly decreasing, then constancy on a fan adjacent to $\Sigma_2$. D and DI are defined analogously. All cases can be realized in particular configurations.

#### Drops in Wedges

Closely related to the material just discussed is the question of the possible configurations of a connected drop of liquid placed into a wedge formed by intersecting plates of possibly differing materials, in the absence of gravity. Thus, one has distinct contact angles $\gamma_1, \gamma_2$ on the two plates. Finn and McCuan showed that if $(\gamma_1, \gamma_2) \in R$ then the only possibility is that the drop surface $S$ is part of a sphere. For data in $D_1^{\pm}$, no such drop can exist, barring exotically singular behavior at the vertex points where the edge of the wedge meets $S$.

For data in $D_2^{\pm}$ the situation is less clear. Concus, Finn, and McCuan (CFM) showed that local behavior exhibiting such data is indeed possible; however, they conjectured that such behavior cannot occur for simple drops. In conjunction with the above results, they were led to the conjecture that the free surface $S$ of any liquid drop in a planar wedge, that meets the wedge in exactly two vertices and the wedge faces in constant contact angles $\gamma_1, \gamma_2$, is necessarily spherical. Here it is supposed only that $0 \leq \gamma_1, \gamma_2 \leq \pi$.

The behavior of a drop of prescribed volume, as the data move from the midpoint of $R$ to the $D$ regions along parallels to the sides of $R$, is displayed in Figure 20. As one moves into the $D_2^{\pm}$ regions, the drop detaches from one side of the wedge and becomes a spherical cap resting on a single planar surface, in accord with the above conjecture. As $D_1^-$ is approached, the liquid becomes a drop of very large radius that fills out a long thin region in the wedge, and disappears to infinity as the boundary of $R$ is crossed. However, as $D_1^+$ is entered, the configuration transforms smoothly into a spherical liquid bridge, connecting the two faces of the wedge without contacting the wedge line.

#### Stability Questions

A number of authors, for example, Langbein, Vogel, Finn and Vogel, Steen, and Zhou, have studied the

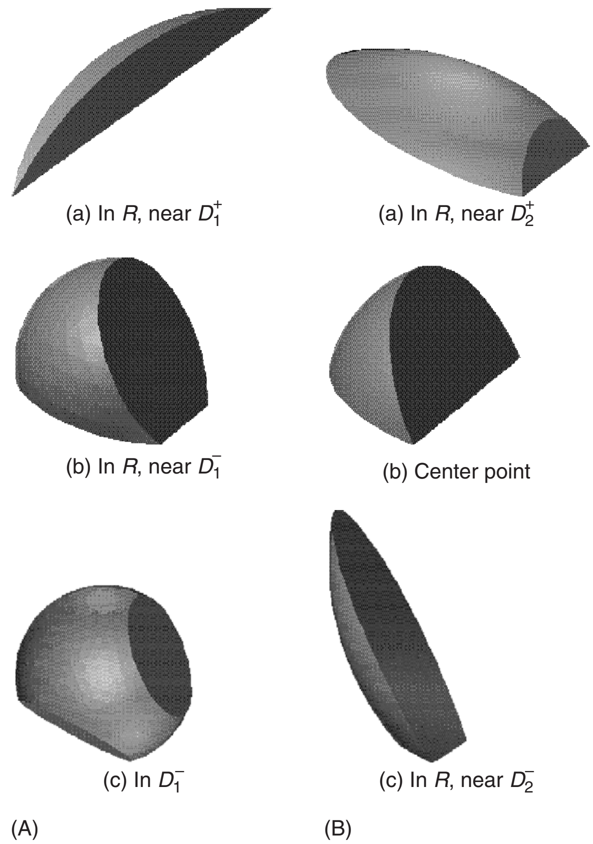

**Figure 20** (A) Drop configurations in wedge with opening angle $2\alpha = 50°$, for three data positions on the line $\gamma_1 = \gamma_2 = \gamma$ (a) $\gamma = 70°$ (in $R$, near $D_1^+$); (b) $\gamma = 90°$ (in $R$, near $D_1^-$); (c) $\gamma = 110°$ (in $D_1^-$). The first two cases yield edge blobs, the third a spherical tube that does not contact the edge line. (B) Drop configurations in a wedge of opening angle $2\alpha = 50°$, for three data choices in $R$, on the line $\gamma_1 = \pi - \gamma_2 = \gamma$; (a) $\gamma = 70°$ (near $D_2^+$); (b) $\gamma = 90°$ (center of $R$); (c) $\gamma = 35°$ (near $D_2^-$). As $D_2^{\pm}$ is entered, original boundary conditions can no longer be satisfied by spherical drop, but configuration changes smoothly into drop on single plane, with prescribed data for that plane. Reproduced with permission from Concus P, Finn R and McCuan J (2001) Liquid bridges, edge blobs, and Scherk-type capillary surfaces. *Indiana University Mathematics Journal* 50: 411–441.

stability of liquid drops trapped between parallel plates, forming an annular liquid bridge joining the plates under the capillarity boundary condition of prescribed contact angles $\gamma_1, \gamma_2$ on the respective plates. These studies consider the effects of disturbances within the fluid, assuming the plates are rigid and perfectly parallel. CFM show that from the point of view of physical prediction, the results of these studies may be open to some question. Specifically, they show that unless the drop is initially of spherical form, then infinitesimal tilting of one of the plates always results in a discontinuous transition of the drop form. Depending on the particular data, the transition can be to a spherical drop; however, it can also occur that the tilting causes the entire fluid to disappear to infinity in the wedge.

CFM proved that if a connected liquid mass with spherical outer surface $S$ cuts off areas $|W_1|, |W_2|$ from plates $\Pi_1, \Pi_2$ which it meets in angles $\gamma_1, \gamma_2$, as in Figure 20, then

$$-\sum_1^2 |W_j| \cos \gamma_j + |S| = \frac{3|V|}{R} \qquad [30]$$

where $|S|$ denotes area of the spherical free surface interface, $|V|$ the enclosed volume, and $R$ the radius. An immediate consequence is that the mechanical energy $E$ of the configuration is

$$E = \frac{3\sigma|V|}{R} \qquad [31]$$

where $\sigma$ is surface tension. Using this result, they show that if a spherical liquid mass meets two wedge faces in angles $\gamma_1, \gamma_2$ in the absence of gravity, then the configuration has smaller mechanical energy than does any connected liquid mass of the same volume that meets only one of the faces in the contact angle for that face. In turn, the drop on a single face has smaller energy than does a spherical ball of the same volume that meets no face. Note that in all zero-gravity cases for which stability relative to plate tilting can be expected, the liquid mass must be spherical.

## Compressibility

Until very recently, all literature on capillarity was based on a hypothesis that the body of the fluid is incompressible. Indeed, from the point of view of macroscopic mechanical measurements, most liquids are nearly incompressible. But all liquids are also to some extent compressible, and this property was even conceptually essential in our characterization in the section "Gauss' contribution: the energy method" of the surface energy, even for the nominally incompressible case. It is as yet unclear to what extent the compressibility properties of the bulk liquid will influence the physical predictions of the theory. In this connection, see the remarks at the end of the section "Uniqueness and nonuniqueness."

### The Equations I

Finn derived two possible equations extending [16] and [17], arising from different modelings. Both characterize equilibrium points as stationary points for the mechanical energy, and both are based on a hypothesized pressure–density relation $\rho = \rho_0 + \chi(p - p_0)$. The first equation takes account of the change in density with height, arising from

the gravity field. For a container consisting of a semi-infinite vertical cylinder, closed at the bottom, one obtains

$$\operatorname{div} Tu = \frac{\rho_0 g}{\sigma} u + \chi g(1 - \cos\omega) + \lambda \qquad [32]$$

where $\omega$ is the angle between the upward directed surface normal and the vertical axis, and $\lambda$ is to be determined by a volume constraint. Athanassenas and Finn proved that for a general smooth domain $\Omega$, prescribed $\gamma$, and prescribed fluid mass $M$ subject to the restriction

$$M < \rho_0 |\Omega| / \chi g \qquad [33]$$

there exists exactly one solution of [32] achieving the boundary data $\gamma$.

The condition [33] is necessary for existence with the prescribed mass.

The methods used for this theorem do not permit regularity conditions to be relaxed to allow domains with corner points. An approximation procedure yields an existence theorem for such cases, however the uniqueness proof then fails; it can be replaced by a weaker result, estimating the difference between two eventual solutions: Let $u$, $v$, be solutions of [32] in a piecewise smooth domain $\Omega$, and suppose $\nu \cdot Tu \le \nu \cdot Tv$ on $\Sigma = \partial\Omega$ except at the corner points, where no data are prescribed. Then

$$u \le v + \chi\sigma/\rho_0 \qquad [34]$$

throughout $\Omega$.

Note that in this result, no growth condition is imposed at the corner points. It can happen that both $u$ and $v$ are unbounded at a corner point; nevertheless, [34] holds uniformly over $\Omega$.

The solutions of [32] emulate many of the characteristics of solutions of [16]. Notably, there is again a dichotomy of behavior, depending on opening angle $2\alpha$ at a corner point, with all solutions either bounded, or unbounded with growth like $1/r$.

### The Equations II

If in addition to taking account of the change of density with height, one accounts for the energy change due to expansion or contraction of volume elements with changing density, one is led to the equation

$$\operatorname{div} Tu = \frac{\rho_0 - \chi p_0}{\sigma\chi}(e^{\chi g u} - 1) + \chi g(1 - \cos\omega) + \Lambda \qquad [35]$$

Here the changes from the incompressible case are much more significant than for [32]. In order to ensure stable behavior of solutions, it seems appropriate to impose the condition $\rho_0 > \chi p_0$. The general existence theorem above can no longer be expected; it is possible to give explicit examples of analytic domains, and constant data $\gamma$, for which no solution of the problem exists. Thus, even in a large downward gravity field, the solutions can emulate the behavior of solutions of [18]. That can happen, however, only for data $\gamma$ exceeding $\pi/2$. The condition [33] is again necessary for existence.

For eqn [34], $\Lambda$ cannot be eliminated by addition of a constant to the solution, and its determination creates a new level of difficulty toward solution of the physical existence question. Athanassenas and Finn proved unique existence of solutions of [35], [17] for a capillary tube of general smooth section $\Omega$ dipped into an infinite liquid bath (which corresponds to $\Lambda = 0$), when $0 \le \gamma \le \pi/2$. If $\gamma > \pi/2$ then solutions do not always exist; it can happen that the surface moves down to the bottom of the tube, regardless of the depth of immersion. Under a hypothesis of radial symmetry, Finn and Luli were able to prove the existence of solutions with prescribed mass in a semi-infinite cylinder closed at the bottom, in the range $0 \le \gamma < \pi$, and uniqueness if $0 \le \gamma \le \pi/2$. Note that in this case, values $\gamma > \pi/2$ are not excluded. For large enough mass, the surface will always cover the base of the tube.

## Closing Remarks

This brief survey is intended only as a general indication of the current state of the theory; much material of interest could not be included. Nor have we addressed hysteresis effects on contact angle. Detailed references to the material discussed and also to further information can be found in the articles listed below. More recent publications can be located by following links in MathSciNet or Zentralblatt.

## Acknowledgmnt

I owe a special debt of thanks to my colleague Paul Concus, who read the material in detail and provided many effectual suggestions, leading to a much-improved exposition.

# Cauchy Problem for Burgers-Type Equations

**G M Henkin**, Université P.-M. Curie, Paris VI, Paris, France

## Burgers Type Equations

We consider here two types of equations: the scalar partial differential equations (PDEs) of the form

$$\frac{\partial f}{\partial t} + \varphi(f)\frac{\partial f}{\partial x} = \varepsilon\frac{\partial^2 f}{\partial x^2}, \quad \varepsilon > 0 \qquad [1]$$

$f = f(x, t)$, $x \in \mathbb{R}$, $t \in \mathbb{R}_+$, and the scalar difference–differential equations of the form

$$\frac{\partial F}{\partial t} + \varphi(F)\frac{F(x,t) - F(x-\varepsilon,t)}{\varepsilon} = 0, \quad \varepsilon > 0 \qquad [2]$$

$F = F(x, t)$, $x \in \mathbb{R}$, $t \in \mathbb{R}_+$.

Equation [1] for the case of linear $f \mapsto \varphi(f)$ was called as Burgers equation by Hopf (1950), who justified this by the remark: "equation was first

$$\frac{\partial f}{\partial t} + f\frac{\partial f}{\partial x} = \varepsilon\frac{\partial^2 f}{\partial x^2}$$

introduced by J. M. Burgers (1940) as a simplest model to the differential equations of fluid flow". In fact, eqn [1] for linear $\varphi(f)$ was introduced earlier in 1915 by Bateman. Equation [1] for general $\varphi(f)$ appeared later in very different models, for example, in the model for displacement of oil by water, in a model of road traffic, etc.

For $\varphi(f) = a + b \cdot f$, Hopf and Cole have studied [1] basing on the substitution

$$f = -\frac{1}{b}\left(a + \varepsilon\frac{\partial g}{\partial x}\Big/ g\right)$$

reducing [1] to the heat equation

$$\frac{\partial y}{\partial t} = \varepsilon\frac{\partial^2 g}{\partial x^2}$$

This transformation (often called as the Hopf–Cole transform) appeared for the first time in 1906 in the book of Forsyth "Theory of differential equations."

Equation [2] first appeared for $\varphi(F) = a + b \cdot F$, $\varepsilon = 1$, $x = n \in \mathbb{Z}$, in Levi, Ragnisco, Bruchi (1983) as a semidiscrete equation reducible to the linear equation

$$\frac{\mathrm{d}G_n(t)}{\mathrm{d}t} = a(G_{n-1}(t) - G_n(t))$$

by the substitution

$$F(n,t) = -\frac{a}{b}\left(\frac{G_n(t) - G_{n-1}(t)}{G_n(t)}\right)$$

Equation [2] for general $\varphi(F)$ was introduced by Henkin, Polterovich (1991) for the description of a Schumpeterian evolution of industry. For any $\varepsilon > 0$, one can consider [2] as the family of difference–differential equations, depending on the parameter $\theta = \{x/\varepsilon\} \in [0, 1)$, where $\{x/\varepsilon\}$ denotes the fractional part of $x/\varepsilon$. For physical applications of [1] (see Gelfand (1959), Landan and Lifschitz (1968), Lax (1973)), the inviscid case ($\varepsilon = +0$) is the most interesting. But, for some special physical models and for some social and biological applications (see Henkin, Polterovich (1991), Serre (1999)), the interesting case concerns eqn [2] with $\varepsilon = 1$ and $x \in \mathbb{Z}$.

The results considered in this article concern mainly the Cauchy problem for eqns [1] and [2] with initial data $f(x,0)$, $F(x,0)$ satisfying the conditions

$$\begin{gathered} f(x,0) \to \alpha^{\pm}, \quad x \to \pm\infty \\ \int_{-\infty}^{0} |f(x,0) - \alpha^-|\mathrm{d}x \\ + \int_0^{\infty} |\alpha^+ - f(x,0)|\mathrm{d}x < \infty \end{gathered} \qquad [3]$$

and correspondingly

$$\begin{gathered} F(k\varepsilon + \theta\varepsilon) \to \alpha^{\pm}, \quad k \to \pm\infty \\ \sum_{k=-\infty}^{0} |F(k\varepsilon + \theta\varepsilon, 0) - \alpha^-| \\ + \sum_{k=0}^{\infty} |\alpha^+ - F(k\varepsilon + \theta\varepsilon, 0)| < \infty \end{gathered} \qquad [4]$$

where $\alpha^- \le \alpha^+$, $\theta \in [0, 1)$ and the mapping $\theta \mapsto \{F(k\varepsilon + \theta\varepsilon, 0) - \alpha^{\operatorname{sgn} k}, k \in \mathbb{Z}\} \in l^1$ is smooth.

The standard classical questions concerning Cauchy problems [1], [3] and [2], [4], namely those relating to existence, unicity, regularity, and conservation laws are well established (see Oleinik (1959), and Serre (1999)). This section formulates only those which are essential for the study of asymptotic behavior of solutions $f(x,t)$ and $F(x,t)$, when $t \to \infty$ or $\varepsilon \to 0$, and of the relation between vanishing viscosity and difference scheme approximations for inviscid Burgers type equations.

One can see that asymptotic behavior of solutions of [2], [4] when $\varepsilon \to +0$ is not the same as the asymptotic behavior of [1], [3] when $\varepsilon \to +0$, in spite of fact that in the limiting case $\varepsilon = +0$ both [1] and [2] look identical. It can be explained by the fact that eqn [2] can be interpreted as a semidiscrete approximation of the nonconservative (nonphysical) equation

$$\frac{\partial F}{\partial t} + \varphi(F)\frac{\partial F}{\partial x} = \frac{\varepsilon}{2}\varphi(F)\frac{\partial^2 F}{\partial x^2}$$

However, the problem [2], [4] can be naturally transformed into conservative (physical) initial problem. Indeed, the substitution

$$f = \int_0^F \frac{\mathrm{d}y}{\varphi(y)}$$

(under condition of integrability of $1/\varphi(y)$) transforms [2] into the equation

$$\frac{\partial f(x,t)}{\partial t} + \frac{\psi(f(x,t)) - \psi(f(x-\varepsilon,t))}{\varepsilon} = 0 \qquad [5]$$

where $\psi'(f) = \varphi(F)$. Equation [5] is the so-called monotone one-sided semidiscrete approximation of conservative viscous equation,

$$\frac{\partial f}{\partial t} + \varphi(F)\frac{\partial f}{\partial x} = \frac{\varepsilon}{2}\frac{\partial}{\partial x}\left(\varphi(F)\frac{\partial f}{\partial x}\right) \qquad [6]$$

where

$$f(x,0) \to \int_0^{\alpha^{\pm}} \frac{\mathrm{d}y}{\varphi(y)}, \quad x \to \pm\infty$$

The results of finite-difference approximations for nonlinear conservation laws (see A. Harten, J. Hyman, P. Lax (1976)) explain both the similarity of behavior of [6] and [5] as well as some difference in the behavior of [1] and [2].

For further exposition the following assumption is useful:

**Assumption 1** Let $\varphi$ in [1], [2] be a positive and continuously differentiable function on the interval $[\alpha^-, \alpha^+]$. Let $\varphi'$ have only isolated zeros.

From references one can deduce the following general properties of Cauchy problems [1], [3] and [2], [4].

**Theorem 0** *Under Assumption 1, we have:*

(i) *There exists a unique (weak) solution $f(x,t)$, $x \in \mathbb{R}$, $t \in \mathbb{R}_+$ of the problem [1], [3]; this solution is necessarily smooth for $t > 0$; besides, it satisfies the following conservation laws for $t > 0$:*

$$f(x,t) \to \alpha^-, \quad x \to -\infty$$
$$f(x,t) \to \alpha^+, \quad x \to +\infty$$
$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_0^{\infty}(\alpha^+ - f(x,t))\right]\mathrm{d}x - \int_{-\infty}^0 (f(x,t) - \alpha^-)\mathrm{d}x = \int_{\alpha^-}^{\alpha^+} \varphi(y)\mathrm{d}y$$

*Moreover, if the initial value $f(x,0)$ is nondecreasing as a function of $x$, then solution $f(x,t)$ is nondecreasing as a function of $x$ for all $t \geq 0$.*

(ii) *There exists a unique solution $F(x,t)$ $x \in \mathbb{R}$, $t \in \mathbb{R}_+$ of the problem [2], [4]; this solution is smooth for $t > 0$; besides, it satisfies the following conservation laws for $t > 0$ and $\theta \in [0, 1)$:*

$$F(k\varepsilon + \theta\varepsilon, t) \to \alpha^-, \quad k \to -\infty$$
$$F(k\varepsilon + \theta\varepsilon, t) \to \alpha^+, \quad k \to +\infty$$
$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\sum_{k=1}^{\infty}\int_{F(k\varepsilon+\theta\varepsilon,t)}^{\alpha^+}\frac{\mathrm{d}y}{\varphi(y)} - \sum_{k=-\infty}^{0}\int_{\alpha^-}^{F(k\varepsilon+\theta\varepsilon,t)}\frac{\mathrm{d}y}{\varphi(y)}\right] = \alpha^+ - \alpha^-$$

*Moreover, if for some $\theta \in [0, 1)$ the $F(k\varepsilon + \theta\varepsilon, 0)$ is nondecreasing as a function of $k \in \mathbb{Z}$ then solution $F(k\varepsilon + \theta\varepsilon, t)$ is also nondecreasing as a function of $k \in \mathbb{Z}$ for all $t \geq 0$ and the same $\theta$.*

## Gelfand's Problem and Iljin–Oleinik Theorem

The main results considered in this article are related to the following problem, formulated explicitly by Gelfand (1959): to find the asymptotic ($t \to \infty$) of the solution $f(x, t)$ of the eqn [1] with the initial condition

$$f(x,0) = \begin{cases} \alpha^{\pm}, & \text{if } \pm x > \pm x^{\pm} \\ f^0(x), & \text{if } x \in [x^-, x^+] \end{cases} \qquad [7]$$

where $\alpha^- \leq \alpha^+$.

Gelfand found a solution to this problem for the inviscid case $\varepsilon = +0$ with initial conditions $f(x, 0) = \alpha^-$ if $x < 0$, and $f(x, 0) = \alpha^+$ if $x \geq 0$ (see below), and remarked that it would be interesting to prove that the main term of the asymptotic ($t \to \infty$) of $f(x, t)$ satisfying [1], [7] coincides with the solution of [1], [7] for $\varepsilon = +0$.

Gelfand's problem admits natural extension for eqn [2] with the initial conditions

$$F(x,0)=\alpha^{\pm}, \qquad \text{if } \pm x > \pm x^{\pm}$$
$$F(x,0)=F^{0}(x), \quad \text{if } x\in[x^{-},x^{+}] \qquad [8]$$

Let us introduce, for $u \in [\alpha^-, \alpha^+]$, the function $\psi(u) = -\int_{\alpha^-}^{u} \varphi(y)\mathrm{d}y$. Let the function $\hat{\psi}(u)$, $u \in [\alpha^-, \alpha^+]$, be upper bound of the convex set

$$\{(u,v)\colon v\le \psi(u),\ u\in[\alpha^{-},\alpha^{+}]\}$$

By Assumption 1, the set $s=\{u\in[\alpha^-, \alpha^+]\colon \psi(u) < \hat{\psi}(u)\}$ is the finite union of intervals, $s=(\alpha^-,\beta_0)\cup(\alpha_1,\beta_1)\cup\cdots(\alpha_L,\alpha^+)$, where $\alpha^-=\alpha_0\le\beta_0\le\alpha_1<\beta_1\cdots\le\alpha_L\le\beta_L=\alpha^+$.

Let us define the function $\hat{f}(x, t)$ by

$$\hat{f}(x,t)=\begin{cases}\alpha^{-}, & \text{if } x<\varphi(\alpha^{-})\cdot t\\ (\hat{\psi}')^{(-1)}(x/t), & \text{if } \varphi(\alpha^{-})\cdot t\le x\le\varphi(\alpha^{+})\cdot t\\ \alpha^{+}, & \text{if } x>\varphi(\alpha^{+})\cdot t\end{cases}$$

where in the case $\hat{\psi}'(u)\equiv\xi_l$, $u\in(\alpha_l,\beta_l)$, $l=0, 1,\ldots,L$; also, by definition, $(\hat{\psi}')^{(-1)}(\xi_l)=[\alpha_l,\beta_l]$.

**Theorem 1** (Gelfand) *The solution* $f(x, t)$ *of the problem* [1], [7] *for the case* $\varepsilon=+0$ *and initial conditions* $f(x,0)=\alpha^{\pm}$, *if* $\pm x>0$, *has the explicit form*: $f(x, t)=\hat{f}(x, t)$.

The analogous statement is valid also for the problem [2], [8] if, in the construction above, one takes

$$\Psi(u)=\int_{0}^{u}\frac{\mathrm{d}y}{\varphi(y)}$$

instead of $\psi(u)$, $u\in[\alpha^-, \alpha^+]$.

The Gelfand problem for [1], [3] and [1], [7] with monotonic $\varphi(f)$ was solved by Iljin and Oleinik (1960). In the case $\alpha^-=\alpha^+$, the solution of this problem follows from an earlier work of Lax (1957). For the case of linear $\varphi(f)$, the solution of this problem follows from an earlier work of Hopf (1950).

For semidiscrete initial problems [2], [4] and [2], [8], the analog of the asymptotic results of Hopf and Iljin–Oleinik have been obtained and applied by Henkin and Polterovich (1991).

The case of increasing $\varphi(f)$ has been studied in detail. In this case, for both initial problems [1], [3] and [2], [4], there is uniform convergence of solutions $f(x, t)$ and $F(x, t)$ to the so-called rarefaction profile

$$g(x/t)=\begin{cases}\alpha^{\pm}, & \pm x>\varphi(\alpha^{\pm})t\\ \varphi^{(-1)}(x/t), & x\in[\varphi(\alpha^{-})\cdot t,\varphi(\alpha^{+})\cdot t]\end{cases}$$

$t\to\infty$ (see Iljin and Oleinik (1960) and Henkin and Polterovich (1991)). More precise result in this case about convergence to the so-called N-wave has been obtained by Dafermos (1977) and Liu (1978).

For the case of a general $\varphi(f)$, in particular, for the case of nonincreasing $\varphi(f)$, we need the notion of shock profile. Following Serre (1999), three definitions can be introduced.

**Definition** The initial problem [1], [3] (correspondingly, [2], [4]) admits $(\alpha^-, \alpha^+)$-shock profile $(\alpha^-<\alpha^+)$ if there exists a traveling-wave solution of this equation, that is, of the form $f=\tilde{f}(x-ct)$ (correspondingly, $F=\tilde{F}(x-Ct)$), such that $\tilde{f}(x)\to\alpha^{\pm}$ when $x\to\pm\infty$ (correspondingly, $\tilde{F}(x)\to\alpha^{\pm}$ when $x\to\pm\infty$).

From the results of Gelfand (1959) and Oleinik (1959), it follows that initial problem [1], [3] admits $(\alpha^-, \alpha^+)$-shock profile iff

$$c=\frac{1}{\alpha^{+}-\alpha^{-}}\int_{\alpha^{-}}^{\alpha^{+}}\varphi(y)\mathrm{d}y < \frac{1}{u-\alpha^{-}}\int_{\alpha^{-}}^{u}\varphi(y)\mathrm{d}y, \quad \forall u\in(\alpha^{-},\alpha^{+}) \qquad [9]$$

From the results of Henkin and Polterovich (1991) and Belenky (1990), it follows that initial problem [2], [4] admits $(\alpha^-, \alpha^+)$-shock profile iff

$$\frac{1}{C}=\frac{1}{\alpha^{+}-\alpha^{-}}\int_{\alpha^{-}}^{\alpha^{+}}\frac{\mathrm{d}y}{\varphi(y)} > \frac{1}{u-u^{-}}\int_{\alpha^{-}}^{u}\frac{\mathrm{d}y}{\varphi(y)}, \quad \forall u\in(\alpha^{-},\alpha^{+}) \qquad [10]$$

In the case $\varepsilon=+0$, the equality in [9] and [10] is called the Rankine–Hugoniot condition, the inequality in [9] and [10] is called the entropy condition (or the Gelfand–Oleinik condition).

**Definition** For initial problem [1], [3] (correspondingly, [2], [4]) admitting $(\alpha^-, \alpha^+)$-shock profile and for $\varepsilon=+0$, we will call by shock waves the weak solutions of [1], [3] (correspondingly, [2], [5], [4]) of the form

$$\tilde{f}^{\alpha^{\pm}}(x-ct)=\alpha^{\pm}, \quad \text{if } \pm x\ge\pm ct$$
$$\tilde{F}^{\alpha^{\pm}}(x-Ct)=\alpha^{\pm}, \quad \text{if } \pm x\ge\pm Ct$$

where $c$, $C$ satisfy Rankine–Hugoniot and entropy conditions [9], [10].

**Definition** The $(\alpha^-, \alpha^+)$-shock profile for [1] (correspondingly, for [2]) is called strict if in addition to [9], [10] we have the Lax (1954) condition:

$$\varphi(\alpha^{+})<c<\varphi(\alpha^{-}) \qquad [11]$$

and correspondingly

$$\varphi(\alpha^{+})<C<\varphi(\alpha^{-}) \qquad [12]$$

The $(\alpha^-, \alpha^+)$-shock profile for [1] or [2] is called semicharacteristic if one of the inequalities in [11] or [12] is strict and the other is an equality. This profile is called characteristic if both inequalities in [11] or [12] are equalities.

One can check (Iljin and Oleinik 1960, Henkin and Polterovich 1991) that if in addition to Assumption 1 the function $\varphi$ on $[\alpha^-, \alpha^+]$ is nonconstant and nonincreasing then eqn [1] (correspondingly, [2]) admits a strict $(\alpha^-, \alpha^+)$-shock profile.

The main result of Iljin–Oleinik (1960) for eqn [1] and analogous statement of Henkin and Polterovich (1991) for eqn [2] can be presented as follows.

**Theorem 2**

(i) *Let the initial problem* [1], [3] *admit a strict* $(\alpha^-, \alpha^+)$*-shock profile* $\tilde{f}$. *Let* $f(x,t)$, $x \in \mathbb{R}$, $t \in \mathbb{R}_+$, *be a solution of* [1], [3]. *Then there exists* $d_0 \in \mathbb{R}$

$$\sup_{x\in\mathbb{R}} |f(x,t) - \tilde{f}(x - ct - d_0)| \to 0, \quad t \to \infty \quad [13]$$

*The value of* $d_0$ *is determined uniquely by relation*

$$\int_{-\infty}^{\infty} \{f(x,0) - \tilde{f}(x - d_0)\}\, dx = 0$$

(ii) *Let the initial problem* [2], [4] *admit a strict* $(\alpha^-, \alpha^+)$*-shock profile* $\tilde{F}$. *Let* $F(x, t)$, $x \in \mathbb{R}$, $t \in \mathbb{R}_+$ *be a solution of* [2], [4]. *Then there exists continuous function* $D_0(\theta)$, $\theta \in [0, 1)$, *such that*

$$\sup_{x\in\mathbb{R}} |F(x,t) - \tilde{F}(x - Ct - D_0(\{x/\varepsilon\})| \to 0, \quad t \to \infty \quad [14]$$

*The function* $D_0(\theta)$, $\theta \in [0, 1]$, *is determined uniquely from relation*

$$\sum_{k=-\infty}^{\infty} \{\Phi(F(n,0)) - \Phi(\tilde{F}(n - D_0))\} = 0$$

*where*

$$\Phi(F) = \int_F^A \frac{dy}{\varphi(y)}, \quad F < A, \ \tilde{F} < A$$

(iii) *If in conditions* (i) *and* (ii), *we take* $\varepsilon = +0$ *then there exist* $d_0$, $D_0$ *such that* $\forall \delta > 0$, *we have*

$$\begin{aligned} &\sup_{x \ge ct+d_0+\delta} |\alpha^+ - f(x,t)| + \sup_{x \le ct+d_0-\delta} |\alpha^- - f(x,t)| \to 0, \quad t \to \infty \\ &\sup_{x \ge Ct+D_0+\delta} |\alpha^+ - F(x,t)| + \sup_{x \le Ct+D_0-\delta} |\alpha^- - F(x,t)| \to 0, \quad t \to \infty \end{aligned} \quad [15]$$

*The values of* $d_0$ *and* $D_0$ *are determined by*

$$\int_{-\infty}^{d_0} (f(x,0) - \alpha^-)\, dx + \int_{d_0}^{\infty} (f(x,0) - \alpha^+)\, dx = 0$$

$$\int_{-\infty}^{D_0} (F(x,0) - \alpha^-)\, dx + \int_{D_0}^{\infty} (F(x,0) - \alpha^+)\, dx = 0$$

**Remarks**

(i) The statements of Theorem 2 give a positive answer to Gelfand's question for the case of initial problem [1], [3] and [2], [4], admitting strict shock profiles.

(ii) For linear $\varphi(f) = a + bf$, $a > 0$, $a + b\alpha^+ > 0$, $b < 0$, the traveling waves $\tilde{f}$, $\tilde{F}$ for [1], [3] and [2], [4] can be found explicitly:

$$\tilde{f} = \alpha^- + \frac{\alpha^+ - \alpha^-}{1 + \exp\{-p(x - ct)\}}$$

$$c = a + \frac{b}{2}(\alpha^+ + \alpha^-), \quad p = \frac{(\alpha^- - \alpha^+)b}{2\varepsilon}$$

$$\tilde{F} = \alpha^- + \frac{\alpha^+ - \alpha^-}{1 + \exp\{-P(x - Ct)\}}$$

$$C = b \Big/ \ln\frac{a + b\alpha^+}{a + b\alpha^-}, \quad P = \frac{\gamma}{\varepsilon}\ln\frac{a + b\alpha^-}{a + b\alpha^+}$$

where

$$b\gamma = (\alpha + b\alpha^-)\left(1 - \left(\frac{a + b\alpha^+}{a + b\alpha^-}\right)^{\gamma}\right)$$

(iii) For initial problems [1], [7] and [2], [8], $\alpha^+ > \alpha^-$, the asymptotic convergence statements [13]–[15] admit the precise asymptotic estimates (see Iljin and Oleinik (1960) for [1], [7]:

$$\sup_{x\in\mathbb{R}} |f(x,t) - \tilde{f}(x - ct - d_0)| = O(e^{-\gamma t}) \quad \gamma > 0, \varepsilon > 0 \quad [16]$$

$$\sup_{x\in\mathbb{R}} |F(x,t) - \tilde{F}(x - Ct - D_0(\{x/\varepsilon\}))| = O(e^{-\gamma t}) \quad \gamma > 0, \varepsilon > 0 \quad [17]$$

$$\begin{aligned} &f(x,t) = \alpha^\pm \quad \text{for} \quad \pm x > \pm(ct + d_0) \\ &t \ge t_0, \ \varepsilon = +0 \\ &F(x,t) = \alpha^\pm \quad \text{for} \quad \pm x > \pm(Ct + D_0) \\ &t \ge t_0, \ \varepsilon = +0 \end{aligned} \quad [18]$$

Theorem 2(i) is proved basing on the following idea. Let $f$ satisfy the initial problem [1], [3] and let

$\tilde{f}(x - ct + d_0)$ be $(\alpha^-, \alpha^+)$-shock profile for [1], satisfying condition [13]. Put

$$\delta(x,t) = \int_{-\infty}^{x} \{f(y,t) - \tilde{f}(y - ct - d_0)\}\mathrm{d}y$$

The function $\delta(x, t)$ satisfies the nonlinear parabolic equation

$$\frac{\partial \delta}{\partial t} + \varphi(\kappa\tilde{f} + (1-\kappa)f)\frac{\partial \delta}{\partial x} = \varepsilon\frac{\partial^2 \delta}{\partial x^2}$$

where $\kappa(x, t)$ is some smooth function of $(x, t)$ with values in $[0, 1]$.

Besides, by conservation law of Theorem 0(i), we have $\delta(x, t) \to 0$, $x \to \pm\infty$, $\forall t \geq 0$.

Estimates basing on maximum principle and appropriate comparison statements give that $\delta(x, t) \rightrightarrows 0$, $x \in \mathbb{R}$, $t \to \infty$. It implies that

$$f(x,t) - \tilde{f}(x - ct - d_0) \rightrightarrows 0, \quad x \in \mathbb{R},\ t \to \infty$$

Theorem 2(ii) is proved in a similar way. Let $F(n, t)$ satisfy the initial problem [2], [4] with $x = n \in \mathbb{Z}$, $\varepsilon = 1$, $\theta = \{x\} = 0$, and let $\tilde{F}(n - Ct - D_0)$ be $(\alpha^-, \alpha^+)$-shock profile for [2], satisfying condition [14]. Put

$$\Delta(n,t) = \sum_{-\infty}^{n}\{\Phi(F(n,t)) - \Phi(\tilde{F}(n - Ct - D_0))\}$$

Then function $\Delta(n, t)$ satisfies the semidiscrete parabolic equation

$$\frac{\mathrm{d}\Delta(n,t)}{\mathrm{d}t} = \varphi(\Phi^{(-1)}(\kappa\Phi(F) + (1-\kappa)\Phi(\tilde{F})))(\Delta(n-1,t) - \Delta(n,t))$$

where $\kappa(n, t)$ is some function with values in $[0, 1]$.

Besides, by conservation law of Theorem 0(ii), we have

$$\Delta(n,t) \to 0, \quad n \to \pm\infty,\ \forall\, t \geq 0$$

Estimates, basing on generalized maximum principle and comparison statements, give that $\Delta(n, t) \rightrightarrows 0$, $n \in \mathbb{Z}$, $t \to \infty$. It implies that

$$F(n,t) - \tilde{F}(n - Ct + D_0) \rightrightarrows 0, \quad n \in \mathbb{Z},\ t \to \infty$$

**Remark** For the cases of nonstrict shock profiles (characteristic or semicharacteristic) the statements of Theorem 2 are not valid. The reason is that, under initial conditions [3], [4] for any $d_0$ and $D_0$, we have

$$\int_{-\infty}^{\infty}\{f(x,o) - \tilde{f}(x - d_0)\}\mathrm{d}x = \infty$$

and, correspondingly,

$$\sum_{-\infty}^{\infty}\{\Phi(\tilde{F}(k\varepsilon + \theta\varepsilon - D_0) - \Phi(F(k\varepsilon + \theta\varepsilon, 0))\} = \infty$$

So, the crucial argument, related to conservation law, does not hold.

One can extend the important Theorems 2(i), 2(ii) for the case of nonstrict shock profiles in two different ways: by changing conditions of these theorems or by changing conclusions of these theorems.

The first method (started by Mei, Matsumura, and Nishihara in 1994) was completed by the following $L^1$-asymptotic stability result (Serre 2004).

**Theorem 3** (Freistühler–Serre). *Let eqns [1], [2] admit $(\alpha^-, \alpha^+)$-shock profiles and $\tilde{f}$, $\tilde{F}$ – the corresponding train-wave solutions of [1], [2]. Let $f(x, t)$, $F(n, t)$, $x \in \mathbb{R}$, $n \in \mathbb{Z}$, $t \in \mathbb{R}_+$ be solutions of eqns [1], [2] with such initial conditions that*

$$\int_{-\infty}^{\infty}|f(x,0) - \tilde{f}(x)|\mathrm{d}x < \infty$$

$$\sum_{-\infty}^{\infty}|F(n,0) - \tilde{F}(n)| < \infty$$

*Then*

$$\int_{-\infty}^{\infty}|f(x,t) - \tilde{f}(x - ct - d_0)|\mathrm{d}x \to 0$$

*and, correspondingly,*

$$\sum_{-\infty}^{\infty}|F(n,t) - \tilde{F}(n - Ct - D_0)| \to 0, \quad t \to \infty$$

*where constants $d_0$ and $D_0$ are calculated from the same relations as in Theorem 2.*

**Remark** For the inviscid case $\varepsilon = +0$, the statement of Theorem 3 is still valid for equations admitting strict shock profiles, but generally is not valid for equations admitting only nonstrict shock profiles (see Serre (2004)).

The second method permits, keeping initial conditions [3], [4], to localize the positions of viscous shock waves for generalized Burgers equations (see the next section).

## Asymptotic Behavior of Solutions of Generalized Burgers Equations

The main current interest and the main difficulty in the study of Gelfand's problem for generalized Burgers equations consist in the following question formulated explicitly for initial problem [1], [3] by Liu *et al.* (1998): “In the Cauchy problem there is

the question of determining the location of viscous shock waves". A similar question and related conjecture were formulated by Henkin and Potterovich (1999) for the initial problem [2], [4].

For solving this problem, it is important to solve it first for the Burgers type equations admitting nonstrict shock profiles.

**Theorem 4** (Henkin–Shananin–Tumanov).

(i) *Let the initial problem* [1], [3] *admit the nonstrict* $(\alpha^-, \alpha^+)$*-shock profile* [9] *and* $\tilde{f}(x - ct)$ *be a corresponding traveling-wave solution. Let*

$$\varphi'(\alpha^-) \neq 0, \quad \text{if} \quad \varphi(\alpha^-) = c$$
$$\varphi'(\alpha^+) \neq 0, \quad \text{if} \quad \varphi(\alpha^+) = c$$

*Let* $f(x, t)$ *be a solution of* [1], [3]. *Then there exist constants* $\gamma_0$ *and* $d_0$ *such that*

$$\sup_{x\in\mathbb{R}} |f(x,t) - \tilde{f}(x - ct - \epsilon\gamma_0 \ln t - d_0)| \to 0, \quad t \to \infty$$

*where*

$$(\alpha^+ - \alpha^-)\cdot\gamma_0 = \begin{cases} -1/\varphi'(\alpha^+), & \text{if } \varphi(\alpha^-) > c = \varphi(\alpha^+) \\ 1/\varphi'(\alpha^-), & \text{if } \varphi(\alpha^-) = c > \varphi(\alpha^+) \\ 1/\varphi'(\alpha^-) - 1/\varphi'(\alpha^+), & \text{if } \varphi(\alpha^-) = c = \varphi(\alpha^+) \end{cases}$$

(ii) *Let the initial problem* [2], [4] *with* $\epsilon = 1$ *admit the nonstrict* $(\alpha^-, \alpha^+)$*-shock profile* [10] *and* $\tilde{F}(n - Ct)$ *be a corresponding traveling-wave solution. Let*

$$\varphi'(\alpha^-) \neq 0, \quad \text{if } \varphi(\alpha^-) = C$$
$$\varphi'(\alpha^+) \neq 0, \quad \text{if } \varphi(\alpha^+) = C$$

*Let* $F(n, t)$ *be a solution of* [2], [4]. *Let*

$$\Delta F(n,0) \overset{\text{def}}{=} F(n,0) - F(n-1,0) \geq 0$$

*Then there exist constants* $\Gamma_0$ *and* $D_0$ *such that*

$$\sup_{n\in\mathbb{Z}} |F(n,t) - \tilde{F}(n - Ct - \Gamma_0 \ln t - D_0)| \to 0, \quad t \to \infty$$

*where*

$$(\alpha^+ - \alpha^-)\cdot\Gamma_0 = \begin{cases} -C/(2\varphi'(\alpha^+)), & \text{if } \varphi(\alpha^-) > C = \varphi(\alpha^+) \\ C/(2\varphi'(\alpha^-)), & \text{if } \varphi(\alpha^-) = C > \varphi(\alpha^+) \\ (C/2)[-1/\varphi'(\alpha^+) + 1/\varphi'(\alpha^-)], & \text{if } \varphi(\alpha^-) = C = \varphi(\alpha^+) \end{cases}$$

**Remarks**

(i) One could think that nonstrict shock profiles as in Theorem 4 can appear only in exceptional cases. But Proposition 2 and Theorem 5 below show, on the contrary, that characteristic shock profiles and, as a consequence, the behavior of initial problems [1], [3] and [2], [4] as in Theorem 4 are rather a rule than an exception.

(ii) The statement of Theorem 4(i) (and also of Theorem 5(i)) below) disprove the Gelfand hope that the main term of asymptotic ($t \to \infty$) of $f(x, t)$, satisfying [1], [7], coincides with the solution of [1], [7] for $\epsilon = +0$ with the same initial condition. Indeed, in conditions of Theorem 4, we have $\varphi(\alpha^-) = c$ or $\varphi(\alpha^+) = c$, but $\varphi'(\alpha^-) \neq \varphi'(\alpha^+)$; then for any $\epsilon > 0$ the traveling wave $\tilde{f}(x - ct - \epsilon\gamma_0 \ln t - d_0)$ for [1], [3], concentrated near the point $x_\epsilon(t) = ct + \epsilon\gamma_0 \ln t + d_0$, moves away ($t \to \infty$) from the shockwave for [1], [7] for $\epsilon = +0$, concentrated near the point $x_0(t) = ct + o(\ln t)$, where $o(\ln t)/\ln t \to 0, \ t \to \infty$.

(iii) Theorem 4 (and also Theorem 5 below) also illustrate another interesting phenomenon: for the case $\varphi'(\alpha^-) \neq \varphi'(\alpha^+)$, one has asymptotic convergence of the solution of [1], [3] (correspondingly of [2], [4]) to the traveling wave $\tilde{f}(x - ct - \epsilon\gamma_0 \ln t - d_0)$ (correspondingly $\tilde{F}(x - Ct - \epsilon\Gamma_0 \ \ln t - D_0)$), which does not satisfy eqn [1] or correspondingly eqn [2]. Such a phenomenon was first discovered by Liu and Yu (1997) in the special boundary-value problem for the classical Burgers equations, if $u(x, t)$ satisfies the following conditions:

$$\text{if } u_t + u\cdot u_x = u_{xx},\ u(0,t) = 1,\ u(\infty,t) = -1,$$
$$u(x,0) = -th\frac{x}{2}, \text{ then}$$
$$|u(x,t) + th\frac{1}{2}(x - \ln(1+t))| \to 0,\ t \to \infty,\ x \geq 0$$

Theorem 4 is proved in basing on the following idea. Let $f(x, t)$ satisfy [1], [3] and $F(n, t)$ satisfy [2], [4]. Let $\tilde{f}(x - ct)$ be the traveling wave for [1], [3] and $\tilde{F}(n - Ct)$ be the traveling wave for [2], [4]. Suppose that $\varphi(\alpha^-) > c = C = \varphi(\alpha^+)$. Let $d_A(t)$ and $D_A(t)$, $A > 0$ be functions such that

$$\int_{ct-A\sqrt{t}}^{ct+A\sqrt{t}} \{f(x,t) - \tilde{f}(x - ct - d_A(t))\}\mathrm{d}x = 0 \qquad [19]$$

and, correspondingly,

$$\sum_{k=[Ct-A\sqrt{t}]}^{[Ct+A\sqrt{t}]} \{\Phi(F(k,t)) - \Phi(\tilde{F}(k - Ct - D_A(t)))\} + (Ct + A\sqrt{t} - [Ct + A\sqrt{t}])(\Phi(F(Ct + A\sqrt{t}] + 1, t)) - \Phi(\tilde{F}([Ct + A\sqrt{t}] + 1 - Ct + D_A(t)) = 0 \qquad [20]$$

The relations [9], [20] can be called "localized conservation law." The proof contains two difficult parts.

The first part consists in proving that for $A > 2\sqrt{c}$ (correspondingly, $A > 2\sqrt{C}$) the following asymptotics are valid:

$$d_A(t) = \frac{\epsilon \cdot \ln t}{(\alpha^- - \alpha^+)\varphi'(\alpha^+)} + d^0 + o(1), \quad t \to \infty$$
$$D_A(t) = \frac{C \ln t}{2(\alpha^- - \alpha^+)\varphi'(\alpha^+)} + D^0 + o(1), \quad t \to \infty \qquad [21]$$

where $d^0$, $D^0$ are independent of $A$.

The second part gives the following convergence statements:

$$\sup_{x \in [ct - A\sqrt{t}, ct + A\sqrt{t}]} \Big| \int_{ct - A\sqrt{t}}^{x} \{f(y,t) - \tilde{f}(y - ct - d_A(t))\} \mathrm{d}y \Big| \to 0, \quad t \to \infty$$
$$\sup_{x \in [Ct - A\sqrt{t}, Ct + A\sqrt{t}]} \Big| \sum_{k=[Ct - A\sqrt{t}]}^{n} \{\Phi(F(k,t)) - \Phi(\tilde{F}(k - Ct - D_A(t)))\} \Big| \to 0, \quad t \to \infty$$

The precise *a priori* estimates of local solutions of [1], [2] play an important role in the proof. An example of such an estimate, also useful for further results, is given below.

**Proposition 1** *Let, in eqn [2],* $C = \varphi(0) > 0$, $\epsilon = 1$, $0 \le \varphi'(0) < \gamma_0$, $\bar{x} \stackrel{\text{def}}{=} (x - Ct)/\sqrt{Ct}$. *Let the function* $F(x, t)$, *defined in the domain* $\Omega_0 = \{(x, t)\colon a_1 < \bar{x} < a_2\}$, $a_2 > 0$, *satisfy eqn [2],*

$$\Delta F(x,t) \stackrel{\text{def}}{=} F(x,t) - F(x-1,t) \ge 0$$
$$|F(x,t)| \le \frac{\Gamma}{\sqrt{Ct}}, \quad (x,t) \in \Omega_0, \; t \ge t_0$$

*Then*

$$\Delta F(x,t) \le \frac{B \cdot \Gamma}{Ct}, \qquad (x,t) \in \Omega_0, \; t \ge t_0$$

*where*

$$B = B_0\left[a_2 + \left(\frac{1}{d} + \frac{\gamma_0 \Gamma}{C}\right)(1 + \ln(1 + a_2))\right]$$
$$d = \min(\bar{x} - a_1, a_2 - \bar{x})$$

*and* $B_0$ *is an absolute constant.*

It is interesting to compare *a priori* estimate of Proposition 1 with some similar (but less precise) estimates in the theory of classical quasilinear parabolic equations (Ladyzhenskaya *et al.* 1968).

We will formulate now the general conjecture concerning asymptotic behavior of solutions of initial problems [1], [3] and [2], [4] and some partial results which confirm this conjecture. To simplify formulation we admit the following.

**Assumption 2** Let $\hat{\psi}(u)$ and $\hat{\Psi}(u)$ be upper bounds of the convex hulls for the graphs of

$$\psi(u) = -\int_{\alpha^-}^{u} \varphi(y)\mathrm{d}y$$

and

$$\Psi(u) = \int_{\alpha^-}^{u} \frac{\mathrm{d}y}{\varphi(y)}$$

respectively, with $u \in [\alpha^-, \alpha^+]$. We suppose that

$$s = \{u \in [\alpha^-, \alpha^+] : \psi(u) < \hat{\psi}(u)\}$$
$$= (\alpha^-, \beta_0) \cup (\alpha_1, \beta_1) \cup \cdots (\alpha_L, \alpha^+)$$

where

$$\alpha^- = \alpha_0 < \beta_0 < \alpha_1 < \beta_1 < \cdots < \alpha_L < \beta_L = \alpha^+$$

or, correspondingly,

$$S = \{u \in [\alpha^-, \alpha^+] : \Psi(u) < \hat{\Psi}(u)\}$$
$$= (\alpha^-, b_0) \cup (a_1, b_1) \cup \cdots (a_M, \alpha^+)$$

where

$$\alpha^- = a_0 < b_0 < a_1 < b_1 < \cdots < a_M < b_M = \alpha^+$$

In addition, we suppose that $\varphi'(\alpha_l) \ne 0, \varphi'(\beta_l) \ne 0, l = 0, 1, \ldots, L$ or, correspondingly, $\varphi'(a_m) \ne 0, \varphi'(b_m) \ne 0$, $m = 0, 1, \ldots, M$.

**Proposition 2** (Weinberger 1990, Henkin and Polterovich 1999). *Under Assumptions 1, 2, one has:*

(i) *If* $u \in [\alpha^-, \alpha^+] \setminus s$ *and, correspondingly,* $u \in [\alpha^-, \alpha^+] \setminus S$, *then following functions are well defined:*

$$g_l\left(\frac{x}{t}\right) = \begin{cases} \beta_l, & \text{if } x < \varphi(\beta_l) \cdot t \\ \varphi^{(-1)}(x/t), & \text{if } \varphi(\beta_l) \cdot t \le x \le \varphi(\alpha_{l+1}) \cdot t \\ \alpha_{l+1}, & \text{if } x > \varphi(\alpha_{l+1}) \cdot t, \end{cases} \quad l = 0, 1, \ldots, L$$

*and, correspondingly,*

$$G_l\left(\frac{x}{t}\right) = \begin{cases} b_m, & \text{if } x < \varphi(b_m) \cdot t \\ \varphi^{(-1)}(x/t), & \text{if } \varphi(b_m) \cdot t \le x \le \varphi(a_{m+1}) \cdot t \\ a_m, & \text{if } x > \varphi(a_{m+1}) \cdot t, \end{cases} \quad m = 0, 1, \ldots, M$$

(ii) *For any interval* $(\alpha_l, \beta_l) \subset s$ *and, correspondingly,* $(a_m, b_m) \subset S$ *there exist traveling waves* $\tilde{f}_l(x - c_l t)$ *for [1] with overfall* $(\alpha_l, \beta_l)$ *and,*

*correspondingly*, $\tilde{F}_m(x - C_m t)$ for [2] *with overfall* $(a_m, b_m)$, *where*

$$c_l = \frac{1}{\beta_l - \alpha_l}\int_{\alpha_l}^{\beta_l} \varphi(y)\mathrm{d}y$$
$$c_l = \varphi(\beta_l), \quad l = 0, \ldots, L-1$$
$$c_l = \varphi(\alpha_l), \quad l = 1, \ldots, L$$

*and*, *correspondingly*,

$$C_m^{-1} = \frac{1}{b_m - a_m}\int_{a_m}^{b_m} \frac{\mathrm{d}y}{\varphi(y)}$$
$$C_m = \varphi(b_m), \quad m = 0, \ldots, M-1$$
$$C_m = \varphi(a_m), \quad m = 1, \ldots, M$$

**Conjecture** (Henkin and Polterovich 1994, 1999, Henkin and Shananin 2004). Let

$$\begin{aligned}\tilde{f}&(x, t, \gamma_0, \ldots, \gamma_L)\\ &= \sum_{l=0}^{L} \tilde{f}_l(x - c_l t - \varepsilon\gamma_l(t)) + \sum_{l=0}^{L-1} g_l\left(\frac{x}{t}\right) - \sum_{l=0}^{L-1}\beta_l\\ &\quad - \sum_{l=1}^{L}\alpha_l, \quad L \geq 1\end{aligned}$$

$$\begin{aligned}\tilde{F}&(n\varepsilon, t, \Gamma_0, \ldots, \Gamma_M)\\ &= \sum_{m=0}^{M} \tilde{F}_m(n\varepsilon - C_m t - \varepsilon\Gamma_m(t)) + \sum_{m=0}^{M-1} G_m\left(\frac{n\varepsilon}{t}\right)\\ &\quad - \sum_{m=0}^{M-1} b_m - \sum_{m=1}^{M} a_m, \quad M \geq 1\end{aligned}$$

Then under Assumptions 1, 2, the following statements are valid:

(i) For any solution $f(x, t)$, $x \in \mathbb{R}$, $t \in \mathbb{R}_+$, of initial problem [1], [3], there exist shift-functions $\gamma_l(t)$:

$$\gamma_l^- \ln t + O(1) \leq \gamma_l(t) \leq \gamma_l^+ \ln t + O(1)$$
$$0 \leq \gamma_l^- \leq \gamma_l^+ < \infty, \quad l = 0, 1, \ldots, L$$

such that

$$\sup_{x\in\mathbb{R}} |f(x, t) - \tilde{f}(x, t, \gamma_0, \gamma_1, \ldots, \gamma_L)| \to 0, \quad t \to \infty$$

(ii) Moreover, in (i) one can take

$$\gamma_l^- = \gamma_l^+ = \frac{\varepsilon}{(\beta_l - \alpha_l)} \times \begin{cases} -\dfrac{1}{\varphi'(\beta_l)}, & \text{if } l = 0 < L, \varphi(\alpha_0) \neq \varphi(\beta_0)\\ \dfrac{1}{\varphi'(\alpha_l)} - \dfrac{1}{\varphi'(\beta_l)}, & \text{if } 0 < l < L\\ \dfrac{1}{\varphi'(\alpha_l)}, & \text{if } l = L > 0, \varphi(\alpha_L) \neq \varphi(\beta_L)\end{cases}$$

(iii) For any solution $F(n\varepsilon, t)$, $n \in \mathbb{Z}$, $t \in \mathbb{R}_+$, of initial problem [2], [4], there exist shift-functions $\Gamma_m(t)$:

$$\Gamma_m^- \ln t + O(1) \leq \Gamma_m(t) \leq \Gamma_m^+ \ln t + O(1)$$
$$0 \leq \Gamma_m^- \leq \Gamma_m^+ < \infty, \quad l = 0, 1, \ldots, L$$

such that

$$\sup_{n\in\mathbb{Z}} |F(n\varepsilon, t) - \tilde{F}(n\varepsilon, t, \Gamma_0, \Gamma_1, \ldots, \Gamma_M)| \to 0, \quad t \to \infty$$

(iv) Moreover, in (iii) one can take

$$\Gamma_m^- = \Gamma_m^+ = \frac{C_m}{(b_m - a_m)} \times \begin{cases} -\dfrac{1}{\varphi'(b_m)}, & \text{if } m = 0 < M, \varphi(a_0) \neq \varphi(b_0)\\ \dfrac{1}{\varphi'(a_m)} - \dfrac{1}{\varphi'(b_m)}, & \text{if } 0 < m < M\\ \dfrac{1}{\varphi'(a_m)}, & \text{if } m = M > 0, \varphi(a_M) \neq \varphi(b_M)\end{cases}$$

The main result confirming formulated conjectures is the following.

**Theorem 5** (Henkin and Shananin). *Conjecture* (i) *for* $L = 1$ *and corresponding conjecture* (iii) *for* $M = 1$ *are true, that is,for solution of initial problem* [1], [3] *there exist shift functions* $\gamma_l(t) = O(\ln t)$ *such that for* $t \to \infty$ *we have*

$$f(x, t) \mapsto \begin{cases} \tilde{f}_0(x - c_0 t - \varepsilon\gamma_0(t)), & \text{if } x \leq c_0 t\\ \varphi^{(-1)}(x/t), & \text{if } c_0 t \leq x \leq c_1 t\\ \tilde{f}_1(x - c_1 t - \varepsilon\gamma_1(t)), & \text{if } x \geq c_1 t\end{cases}$$

*and for solution of initial problem* [2], [4] *there exist shift functions* $\Gamma_m(t) = O(\ln t)$ *such that for* $t \to \infty$ *we have*

$$F(n\varepsilon, t) \mapsto \begin{cases} \tilde{F}_0(n\varepsilon - C_0 t - \varepsilon\Gamma_0(t)), & \text{if } n\varepsilon \leq C_0 t\\ \varphi^{(-1)}(n\varepsilon/t), & \text{if } C_0 t \leq n\varepsilon \leq C_1 t\\ \tilde{F}_1(n\varepsilon - C_1 t - \varepsilon\Gamma_1(t)), & \text{if } n\varepsilon \geq C_1 t\end{cases}$$

The proof of Theorem 5 is of the same nature as the proof of Theorem 4.

**Remarks**

(i) The proof of stronger Conjectures (ii) and (iv) for $L = 1$ or $M = 1$ are in preparation.
(ii) The numerical results, Rykova and Spivak (preprint, 2004), confirm conjecture (iii) for $M = 2$.
(iii) The results of Weinberger (1990) and Henkin and Polterovich (1999) confirm convergence statements of Conjectures (i), (iii) for all $L$ and $M$, but only on the intervals of rarefaction

profiles: $x \in [\varphi(\beta_l)t, \varphi(\alpha_{l+1})t]$ or, correspondingly, $x \in [\varphi(b_m)t, \varphi(a_{m+1})t]$, $t > 0$.

The problem of finding asymptotics ($t \to \infty$) of solutions of (viscous) conservation laws has been posed originally not only for generalized Burgers equations but also for systems of conservation laws in one spatial variable (see Gelfand (1959)). In this direction many important results on existence and asymptotic stability of viscous shock profiles (continuous and discrete) have been obtained and applied (see Benzoni-Gavage (2004), Lax (1973), Serre (1999), Zumbrun and Howard (1998) and references therein). The results of type of Theorems 4,5 have not yet been obtained for systems of conservation laws.

It is also very interesting to study asymptotic behavior of scalar (viscous) conservation laws in several spatial variables (continuous or discrete), basing on the asymptotic properties of Burgers type equations. In this direction there have been several important results and problems (see Bauman and Phillips (1986), Henkin and Polterovich (1991), Hoff and Zumbrun (2000), Serre (1999), Weinberger (1990), and references therein).

# Cellular Automata

**M Bruschi**, Università di Roma "La Sapienza", Rome, Italy
**F Musso**, Università "Roma Tre", Rome, Italy

## What is a Cellular Automaton?

Cellular automata (CAs) were first introduced by J von Neumann in his investigation of "complexity," following an inspired suggestion by S Ulam. But in the last 50 years they have been investigated and used in a number of fields; widely different terminologies have been used by researchers that now it is difficult even to give a precise general definition of a CA. Thus, some definitions and approximations are in order.

First a broad definition:

1. have a number of cells (boxes);
2. at any (discrete) time step, any cell can present itself in a certain "state" among a finite number of different states;
3. the state of any cell can change (evolve) from a time step to the subsequent time step; and
4. there is a rule (evolution law, EL) which determines this transition.

Note that the number of cells can be finite or infinite; the cells can be arranged on a line, on a surface, in the ordinary three-dimensional (3D) space, or possibly in a hyperspace (in any case, the cells can be numbered); the different states of a cell can be denoted by integer numbers but, in different contexts of application of CAs, different imaginative pictures have also been used (e.g., different colors, dead and living cells, number of balls in a box, etc.); the evolution of a CA proceeds in finite time steps (time is also discrete); the EL, provided that it is effective on any possible configuration of a given CA (computability), is otherwise completely arbitrary (indeed, there are not only deterministic and probabilistic ELs, but also those that "evolve" in time – following a meta-EL, which in turn can be deterministic or probabilistic).

Consider some examples of CAs.

**Example 1** (CA1) Consider a linear array of seven boxes (cells; one can number them $c(i)$, $i = 1, 2, \ldots, 7$). Each box can be empty or it can contain a ball (so there are just two states for each cell). Given a configuration of this CA at time $t$, what happens at time $t + 1$ (EL)?

(i) the state of the first box c(1) never changes;
(ii) for each other box $c(i)$, $i = 2, 3, \ldots, 7$;
(iia) if the box is empty and the box on its left is empty then put a ball in the box;
(iib) if there is a ball in the box and also there is a ball in the box on its left then empty the box.

An example of the evolution of such a rather trivial CA is given in Figure 1.

A more precise notation can now be established.

First, let us denote the state of a cell at time $t$ by a "state function," say $S$. According to the point (iib) above, the number of possible states is arbitrary but finite: denote this number by the positive integer $M$ ($M > 1$). Then $S$ takes values on a finite field, say $\mathbb{Z}_M = \mathbb{Z}/M\mathbb{Z} = \{0, 1, 2, \ldots, M - 1\}$ (in plain words, we have denoted the $M$ states for the CA by the first $M$ non-negative integers). Different cells can be labeled with a progressive number: $c(n), n = n_1, n_1 + 1, \ldots, n_2 - 1, n_2$; possibly, in case of an infinite number of cells, one has $n_1 \longrightarrow -\infty$ and/or $n_2 \longrightarrow +\infty$. In the case of $n_1 = -\infty, n_2 = \infty$, one speaks of a unidimensional CA. Of course, the field $S$ depends on $n$ as well as on time (remember that, for a CA, "time" is a discrete variable: $t = 0, 1, 2, \ldots$). The field $S(n, t)$ describes completely the CA. If the EL is deterministic, then one can determine (compute) $S(n, t)$ step by step for $t > 0$ from the initial configuration $S(n, 0)$ (initial datum, ID). Consider only static ELs, namely those that do not change in time. A further distinction can be made: there are ELs such that the future state of the generic cell, $S(n, t + 1)$, depends on the whole current configuration of the CA (these are called nonlocal ELs) and there are ELs for which $S(n, t + 1)$ depends only on

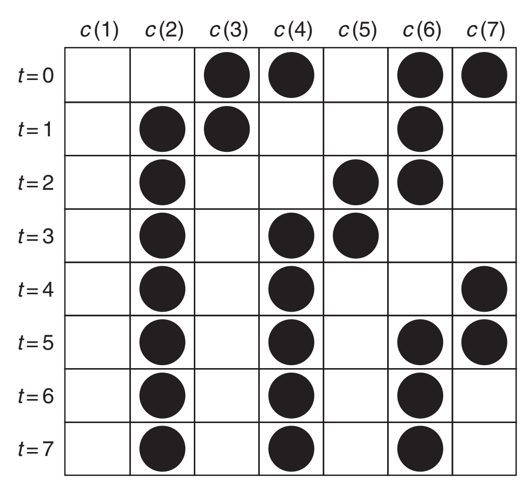

**Figure 1** A seven time-step evolution of CA1 starting from a given ID ($t = 0$). Note that a stable configuration has been reached at $t = 6$.

the current state of a finite number, say $N$, of cells (local ELs):

$$\{S(n+k_i,t)\},\ i=1,2,\ldots,N,k_i\in\mathbb{Z} \Longrightarrow S(n,t+1) \quad [1]$$

Note that, in principle, the set of cells that determine, according to the EL, the future state of the generic cell $n$, could depend on $n$, namely one can have $N=N(n)$, as well $k_i=k_i(n), i=1,2,\ldots,N(n)$ (see CA2 below). In any case, such a set of cells is called the interaction set (IS). Moreover, the distance from the cell $n$ of the farthest cell in the IS is called the range $R$ (of the interaction): $R=\max(|k_i|)$. If $\text{IS}\equiv\{c(n-R),c(n-R+1),\ldots c(n),\ldots c(n+R-1), c(n+R)\}$, then this IS is called a neighborhood of range $R$. It is, moreover, clear that, for unidimensional CA, there exists at least one infinite subset of cells that have the same state. If there is only one such subset, then it is called the vacuum set and the state of its cells is called vacuum state: let $V$ denote the value of this state ($0\leq V<M,\quad S(n,t)\underset{n\to\pm\infty}{\longrightarrow}V$).

**Example 2** (CA2) An example of CA with *n-dependent* IS ($M=2, R=3, V=0$). This is the EL: the cell $c(n)$ changes its state ($0\to1, 1\to0$) iff

(i) $n$ is even and at least one of the two cells on its left is not in the vacuum state;
(ii) $n$ is odd and one or three of the three cells on its right are not in the vacuum state.

An example of the evolution of such a CA is given in Figure 2.

Usually, only a subclass of ELs is considered for which the phenomenon of vacuum excitation cannot occur. Namely, during the evolution of the CA, an infinite subset of the vacuum set cannot change its state in just one time step. In other words: if the set of cells starting from the first cell and ending with the last one for which $S(n,t)\neq V$ be called population set (PS), then PS is a finite set at each time.

Of course, one can easily devise an EL for which this is not true; nevertheless, the EL itself is still valid (computable), for instance,

**Example 3** (CA3) This is an unidimensional CA, namely there are infinite cells on a line ($n\in\mathbb{Z}$). The cells have $M$ states and $V=0$; the EL reads:

the state of each cell cycles in the set of available states ($0\to1, 1\to2,\ldots,M-2\to M-1, M-1\to0$)

Note that the range $R$ is zero, there is a vacuum excitation; nevertheless, the EL is effective.

Deterministic, static, and local ELs that do not give rise to vacuum excitation are called normal ELs (NELs).

Since $M$, $N$ are finite for an NEL, one can give the NEL itself as a table, considering every possible configuration of the IS and specifying the outcome for each configuration (note that there are $M^N$ possible configurations).

**Example 4** (CA4) $n\in\mathbb{Z}, M=2, V=0, \text{IS}\equiv\{c(n), c(n-1), c(n+2)\}, N=3, R=2$. The EL is:

| | | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| $S(n,t)$ | 0 | 0 | 0 | 0 | 1 | 1 | 1 | 1 |
| $S(n-1,t)$ | 0 | 0 | 1 | 1 | 0 | 0 | 1 | 1 |
| $S(n+2,t)$ | 0 | 1 | 0 | 1 | 0 | 1 | 0 | 1 |
| $S(n,t+1)$ | 0 | 1 | 1 | 0 | 1 | 1 | 0 | 1 |

[2]

An example of the evolution of such a CA is given in Figure 3.

However, these NELs can also be given in an alternative representation (more useful in view of the extensions of the concept of CA itself, see below). Namely, an NEL can be given as a discrete-time EL for the state function $S(n,t)$ in the finite field $\mathbb{Z}_M=\{0,1,2,\ldots,M-1\}$.

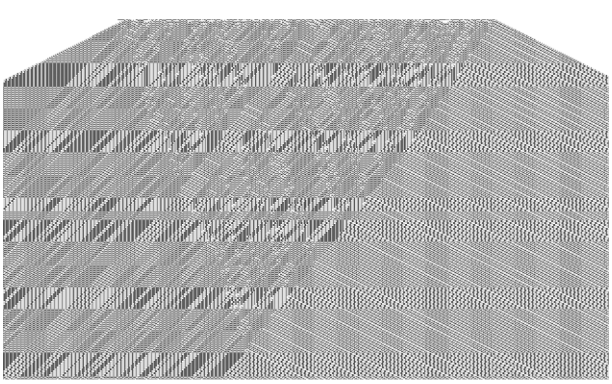

**Figure 2** Three hundred and eighty time steps of CA2, starting from a random chosen initial configuration. Note the left–right asymmetry due to the asymmetry of its IS and EL.

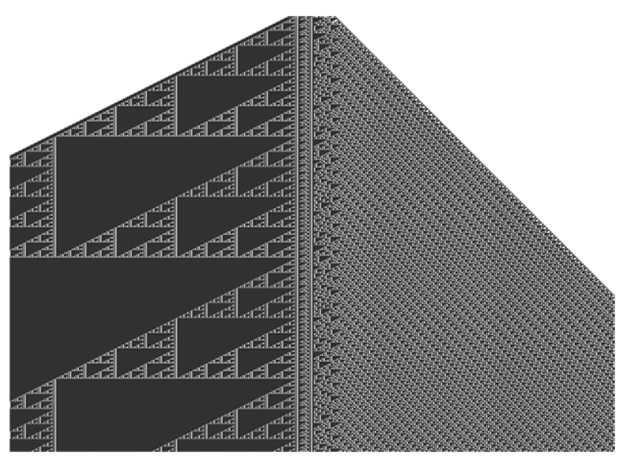

**Figure 3** Four hundred and sixty-one time steps of CA4, starting from a random chosen PS of 50 cells.

For example, the NEL above for CA4 can be expressed as follows:

$$S(n,t+1) \overset{2}{=} S(n-1,t) + S(n,t) + S(n+2,t) + S(n,t)S(n+2,t) + S(n-1,t)S(n,t)S(n+2,t) \quad [3]$$

Here and in the following, the symbol $\overset{M}{=}$ denotes a congruence mod $M$.

Another example is the following.

**Example 5** (CA5) $n \in \mathbb{Z}, M=3, N=3, V=0, R=1$, IS $\equiv \{c(n-1), c(n), c(n+1)\}$. The NEL is:

$$S(n,t+1) \overset{3}{=} S(n-1,t) + S(n,t) + S(n+1,t) + 2S(n-1,t)S(n+1,t) \quad [4]$$

An example of the evolution of such a CA is given in Figure 4.

### Classification of ELs

Considering a CA with given $M > 1, N \geq 1$, the number $L$ of possible deterministic, static ELs is

$$L(M,N) = M^{(M^N)} \quad [5]$$

Of course, this number can be very large for relatively small values of $M$ and $N$ also. Nevertheless, it is a finite positive integer, so that, for given $M$, $N$, one could denote every EL by an integer number and investigate the typical behavior of each EL. A considerable reduction of this number is obtained if one limits attention to totalistic ELs, namely to those whose outcome depends only on the global configuration of the IS, often just on

$$\sigma(n,t) = \sum_{i=1}^{N} S(n+k_i); \quad i=1,2,\ldots,N, \, k_i \in \mathbb{Z} \quad [6]$$

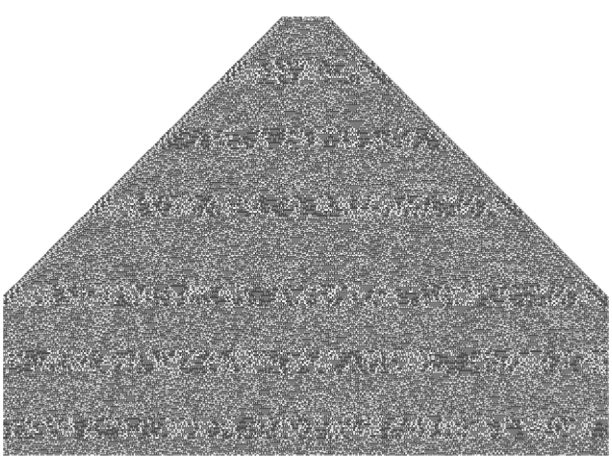

**Figure 4** Four hundred and sixty-one time steps of CA5, starting from a random chosen PS of 50 cells.

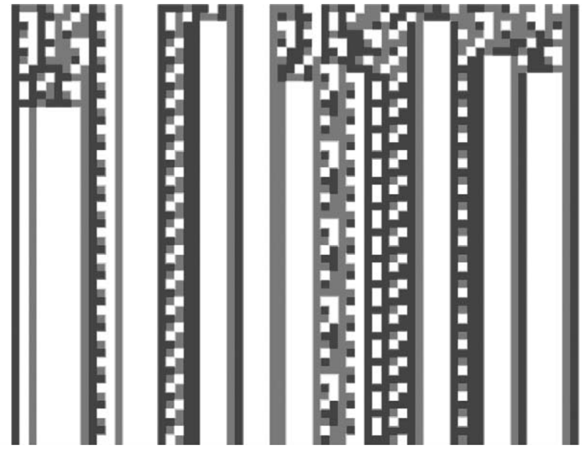

**Figure 5** A class-1 CA: every ID rapidly evolves to periodic structures; $M=3, V=0, R=2$, EL: $S(n,t+1) \overset{3}{=} S(n,t) + S(n-1,t)S(n+2,t)$.

Deep and extensive computer investigations have been exploited for unidimensional CAs with small values of $M$, $N$. Surprisingly enough, it seems that the typical behavior of all these CAs can be (roughly and heuristically) classified in just four classes (Wolfram 2002):

- Class 1 (simple): possibly after a complicated transient, simple patterns emerge.
- Class 2 (fractalic): possibly after a transient, overall regular nested structures are obtained.
- Class 3 (chaotic): complicated but seemingly random behavior.
- Class 4 (complex): possibly after a transient, localized structures emerge that interact in complex ways.

Due to the looseness of the above definitions, perhaps a better way to distinguish between classes is to train one's eye. Consider some examples of CAs for each class: the typical behavior of class-1 CA is shown in Figures 5 and 6, of class-2 CA in Figures 7 and 8, of class-3 CA in Figures 4 and 9, of class-4 CA in Figures 10 and 11. Note, however, that often one has "mixed type" CA: for example, CA4 is of class 1 on the right and of class 2 on the left (see Figure 3); Figure 12 exhibits a CA where the typical behaviors of classes 2 and 3 are superimposed.

## Extensions

The concept of a CA is so simple that many extensions of the above-sketched definition of a CA can be easily devised. A (nonexhaustive) survey of such extensions follows.

**Figure 6** A class-1 CA, a random ID vanishes after 337 time steps, $M=5, V=0, R=2$, EL: $S(n,t+1) \overset{5}{=} S(n-1,t)S(n-2,t)+S(n+1,t)S(n+2,t)+S(n-1,t)S(n+1,t)+S(n-2,t)S(n+2,t)$.

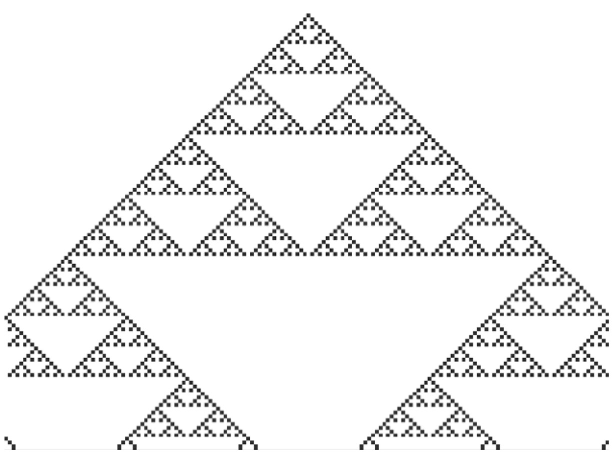

**Figure 7** A class-2 CA: Sierpinsky triangles appear; $M=2$, $V=0, R=1$, EL: $S(n,t+1) \overset{2}{=} S(n-1,t)+S(n+1,t)$.

### Vector CA

In this extension, the state function $S(n,t)$ is considered as a "vector," namely $S(n,t) \equiv (S_1(n,t), S_2(n,t), \dots S_L(n,t)), L$ being a positive integer. Each component $S_l(n,t) (l=1,2,\dots,L)$ takes values in a finite field, say $\mathbb{Z}_{M_l} = \{0, 1, 2, \dots, M_l - 1\}$, and evolves, according to some EL, interacting with the other components. Of course, one can give separately the time evolution for each component; however, it is also possible to give a global representation of a vector CA, introducing a global function $\tilde{S}(n,t)$ that takes values in the finite field $\mathbb{Z}_M, M = M_1 M_2 \dots M_L$; for example,

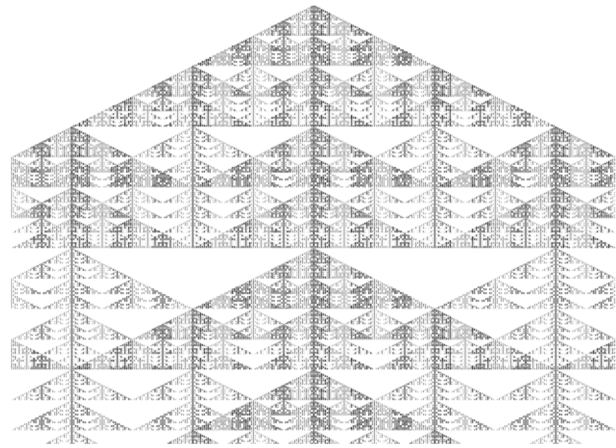

**Figure 8** A class-2 CA: a double fractal structure appears; $M=4$, $V=0, R=2$, EL: $S(n,t+1) \overset{4}{=} S(n-2,t)+S(n,t)+S(n+2,t)$.

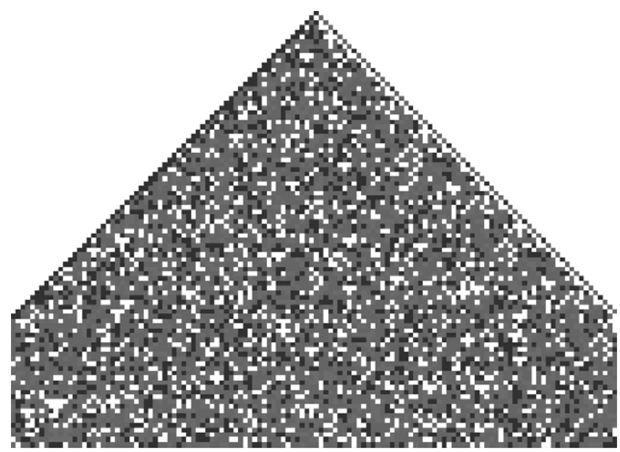

**Figure 9** A class-3 CA: $M=5, V=0, R=2$, EL: $S(n,t+1) \overset{5}{=} 2S(n-1,t)+S(n+1,t)+S(n,t)(S(n+1,t)+S(n+2,t))+S(n-1,t)S(n+1,t)$.

$$\tilde{S}(n,t) = S_L(n,t) + \sum_{l=1}^{L-1} \left( S_l(n,t) \prod_{k>l}^{L} M_k \right) \qquad [7]$$

Thus, in a sense, vector CAs are still usual CAs with a complicated EL.

**Example 6** (CA6) A two-component vector CA:

$$S_1(n,t+1) \overset{M_1}{=} S_1(n,t)S_1(n+1,t) + (M_1-1)S_2(n-1,t)S_2(n,t) + c_1 \qquad [8]$$

$$S_2(n,t+1) \overset{M_2}{=} S_1(n-1,t)S_2(n,t) + S_1(n,t)S_2(n+1,t) + c_2 \qquad [9]$$

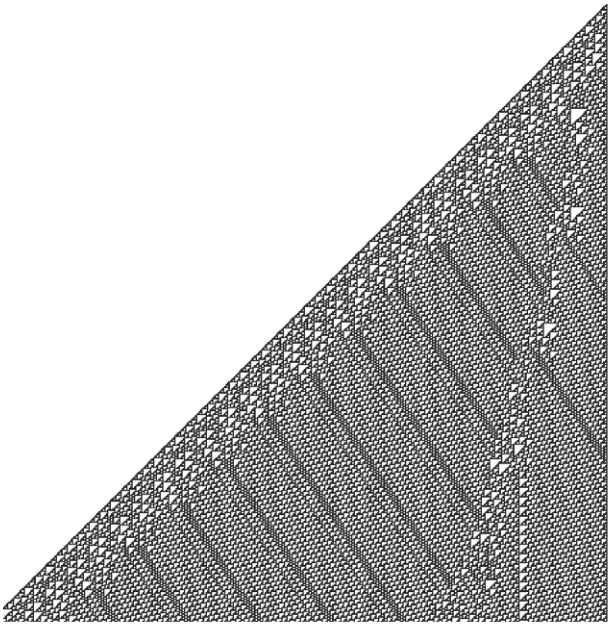

**Figure 10** A class-4 CA (Wolfram CA 110): $M=2$, $V=0$, $R=1$, EL: $S(n,t+1)\overset{2}{=}S(n,t)+S(n+1,t)+S(n,t)S(n+1,t)+S(n-1,t)$ $S(n,t)S(n+1,t)$.

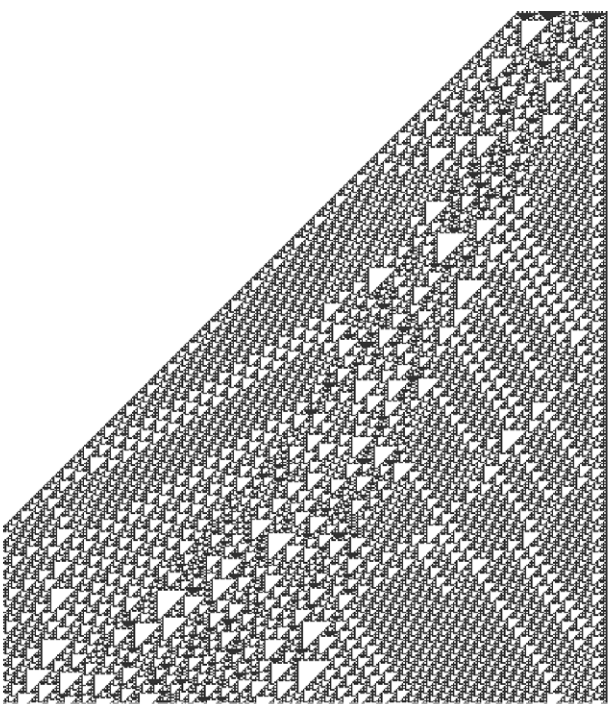

**Figure 11** A class-4 CA. Note the interacting moving structures on the left and on the right; note also the apparently chaotic behavior in the center; $M=2, V=0, R=2$, EL: $S(n,t+1)\overset{2}{=}$ $S(n,t)+S(n+1,t)+S(n-1,t)S(n+2,t)$.

The global behavior of this CA can be expressed, for example, through the global state function

$$\tilde{S}(n,t) = M_2 S_1(n,t) + S_2(n,t) \qquad [10]$$

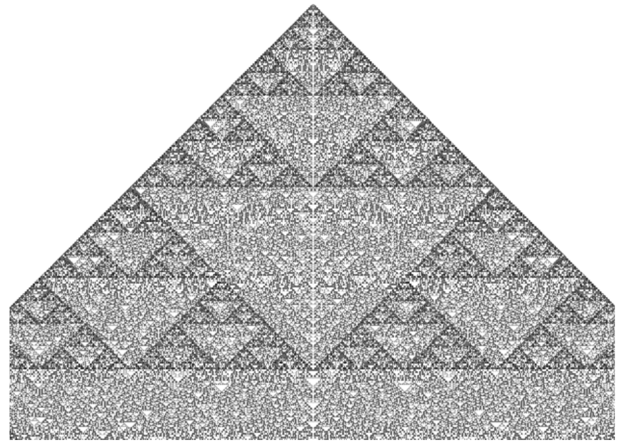

**Figure 12** A mixed-class CA: a fractalic structure is superimposed on a chaotic one; $M=4$, $V=0$, $R=2$, EL: $S(n,t+1)\overset{2}{=}$ $S(n,t)(S(n-2,t)+S(n+2,t))+S(n-1,t)S(n+1,t)$.

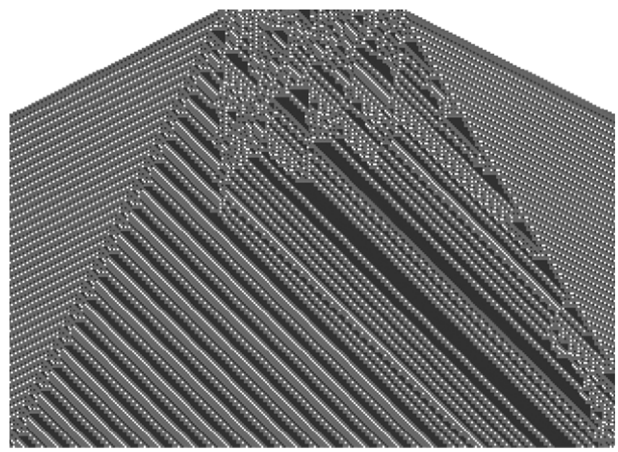

**Figure 13** Global behavior of the vector CA6.

Obviously, $\tilde{S}\in\mathbb{Z}_M$ with $M=M_1M_2$. Figure 13 represents the global behavior of this CA with $M_1=2, M_2=3, c_1=1, c_2=1, V=0$.

Note that this CA can be considered as an extension of the celebrated quadratic map.

### Multidimensional CA

Up to now we have considered CAs with finite number of cells (finite CAs) or with an infinite number of cells arranged on a line (unidimensional CAs). Now we consider CAs with cells arranged on a surface, usually a plane (bidimensional CAs), or on 3-space (tridimensional CAs), or even on a hyperspace (multidimensional CAs). In any case, if the number of cells is finite, the evolution of such CAs, according to an NEL, must end up to a final cycle: this is due to the finiteness of the "phase space" (thus, these CAs should be classified as class 1; however, note that, if the "phase space" is large enough, the dynamics of

such CAs can still be very rich). Usually, one considers an infinite number of cells tessellating the whole $s$-space, $s = 2, 3, \ldots$ (e.g., squares or hexagons on the plane, cubic cells in 3-space). The changes in the previous notation and definitions are plain: for example, for a bidimensional CA, the state function depends now on two discrete "space" variables $(S(n_1, n_2, t), n_1 \in \mathbb{Z}, n_2 \in \mathbb{Z})$; furthermore, there is a greater freedom in choosing a neighborhood of range $R$. Two most-used neighborhoods of range 1 are shown below:

$$
\begin{array}{c}
\text{Neumann neighborhood} \\
\begin{array}{ccccc}
\bigcirc & \bigcirc & \bigcirc & \bigcirc & \bigcirc \\
\bigcirc & \bigcirc & \otimes & \bigcirc & \bigcirc \\
\bigcirc & \otimes & \odot & \otimes & \bigcirc \\
\bigcirc & \bigcirc & \otimes & \bigcirc & \bigcirc \\
\bigcirc & \bigcirc & \bigcirc & \bigcirc & \bigcirc
\end{array} \\
\text{Moore–Conway neighborhood} \\
\begin{array}{ccccc}
\bigcirc & \bigcirc & \bigcirc & \bigcirc & \bigcirc \\
\bigcirc & \otimes & \otimes & \otimes & \bigcirc \\
\bigcirc & \otimes & \odot & \otimes & \bigcirc \\
\bigcirc & \otimes & \otimes & \otimes & \bigcirc \\
\bigcirc & \bigcirc & \bigcirc & \bigcirc & \bigcirc
\end{array}
\end{array}
\qquad [11]
$$

The most famous (and interesting) bidimensional CA is "Life", introduced by J H Conway, which is discussed next.

**Example 7** (CA "Life"; Moore–Conway neighborhood, $V = 0, M = 2$). A cell in the vacuum state 0 is called "dead"; a cell in the state 1 is called "alive." The EL is as follows:

(i) If a cell is dead at time $t$, it comes alive at time $t + 1$ if and only if exactly three of its eight neighbors are alive at time $t$ (reproduction).
(ii) If a cell is alive at time $t$, it dies at time $t + 1$ if and only if fewer than two (loneliness) or more than three (overcrowding) neighbors are alive at time $t$.

Clearly, this is a totalistic NEL. Now considering the explicit form of $\sigma$ (see [6]):

$$
\sigma(n_1, n_2, t) = -S(n_1, n_2, t) + \sum_{k_1=-1}^{1} \sum_{k_2=-1}^{1} S(n_1 + k_1, n_2 + k_2, t) \qquad [12]
$$

the above EL can be simply expressed as:

$$
S(n_1, n_2, t + 1) = \delta_{3,\sigma} + \delta_{2,\sigma} S(n_1, n_2, t) \qquad [13]
$$

where $\delta_{3,\sigma}$ is the Kroenecker symbol.

Life is a class-4 CA; it exhibits a rich variety of interesting structures: stable structures, oscillators (periodic structures), gliders and ships (moving structures), emitters and absorbers (namely, structures that, after a time period, reconstitute themselves, but meanwhile they have emitted or adsorbed moving structures). These structures are essential to prove that Life can be used to construct a universal Turing machine (see below). One can get a rough idea of such "richness" from Figure 14.

As in the previous case of vector CA, one could object that also multidimensional CAs are not true extensions of the unidimensional CAs. Indeed, since the whole set of cells is still a countable set, one could number the cells with just a discrete "space" variable (say $n \in \mathbb{Z}$ ). For example, in the case of a square tessellation of the plane, we could enumerate the cells in the plane starting from the origin as follows:

$$
\begin{array}{ccccccc}
 & & & 22 & \longrightarrow & & \\
 & & & & & & \\
 & & & 21 & 20 & 19 & 18 \\
-13 & -12 & -11 & 4 & 5 & 6 & 17 \\
-14 & -9 & -10 & 3 & 2 & 7 & 16 \\
-15 & -8 & -1 & 0 & 1 & 8 & 15 \\
-16 & -7 & -2 & -3 & 10 & 9 & 14 \\
-17 & -6 & -5 & -4 & 11 & 12 & 13 \\
-18 & -19 & -20 & -21 & & & \\
 & & & & & & \\
 & & \longleftarrow & -22 & & &
\end{array}
\qquad [14]
$$

Thus, any multidimensional CA could in principle be viewed as a unidimensional one. Of course, one has to pay a price for this: ISs and ELs that are simple for a multidimensional CA become cumbersome for its unidimensional version and vice versa.

### Higher Time Derivatives

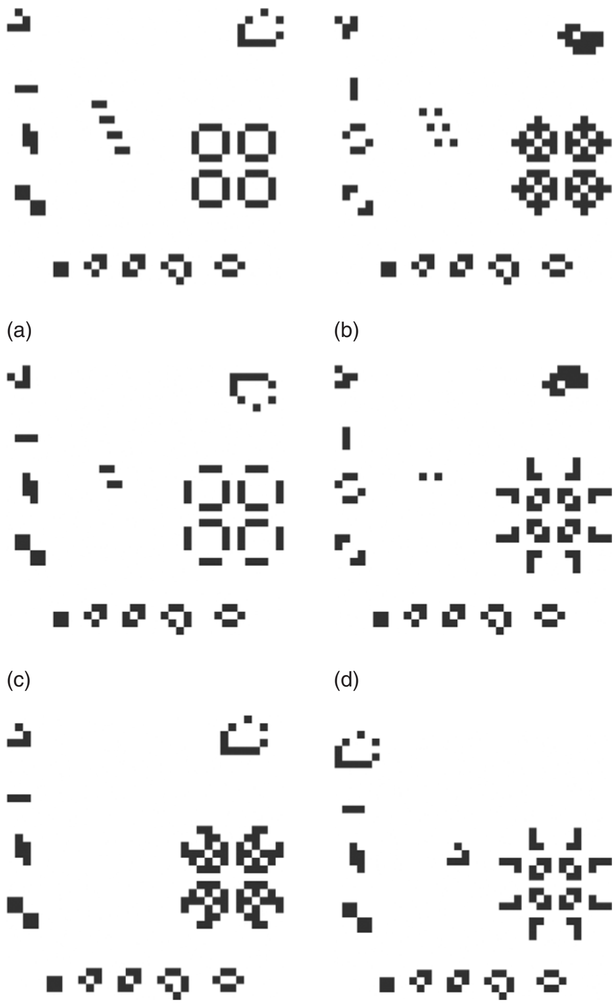
Up to now, we have considered CAs whose evolved state $S(t + 1)$ depends only on the state $S(t)$, namely the state of the CA itself at the previous time step. In other words the EL involves just the first (discrete) time derivative (1_CA). One can easily extend all the previous definitions to consider higher-order discrete time derivatives ($K$_CA). Of course, the ID and the IS for such a CA involve the state of the CA at $K$ subsequent time steps.

An example of a unidimensional 2_CA is given below.

**Example 8** (CA7) $M = 3, V = 0, R = 1$. The EL is:

$$
S(n, t + 1) \overset{3}{=} S(n - 1, t) + S(n, t - 1) + S(n + 1, t) \qquad [15]
$$

An example of the evolution of such a CA is given in Figure 15.



(a) (b) (c) (d) (e) (f)

**Figure 14** CA "Life": (a) Time 0. Near the lower border, five stable structures (from the left to the right: a "block", a "boat", a "ship", a "loaf", a "beehive"); near the left border three "blinkers" (period-2 oscillators); near the right corner, a symmetric structure that, in one time step, evolves into a "pulsar" (a period-3 oscillator), on the left-up corner a "glider" (a moving structure); on the right-up corner a "medium weight spaceship" (another moving structure); in the center, a configuration that vanishes in a few time steps. (b) Time 1. The structures on the lower border are unchanged, the blinkers, the glider, and the space ship are in an intermediate state, on the right border, the pulsar starts to pulse. (c) Time 2. The three blinkers on the left border are again in their original configurations (periodic structure with period 2), the pulsar, the glider and the spaceship are in another intermediate state. (d) Time 3. The pulsar is in its second state, the glider and the spaceship in their third, the structure in the center is going to vanish. (e) Time 4. The pulsar has completed its pulsation (period-3 oscillator, see **Figure 14b**); the structure in the center has vanished, the glider and the spaceship have recovered their original configurations (see **Figure 14a**) but meanwhile they have moved of a cell in four time steps (1\4 of the highest velocity attainable by a moving structure in a CA of range 1). The glider is moving downward and to the right, the space ship in horizontal to the left. (f) Time 60. The space ship has almost completed its crossing, the glider has reached the center and it is in a collision route with the pulsar.

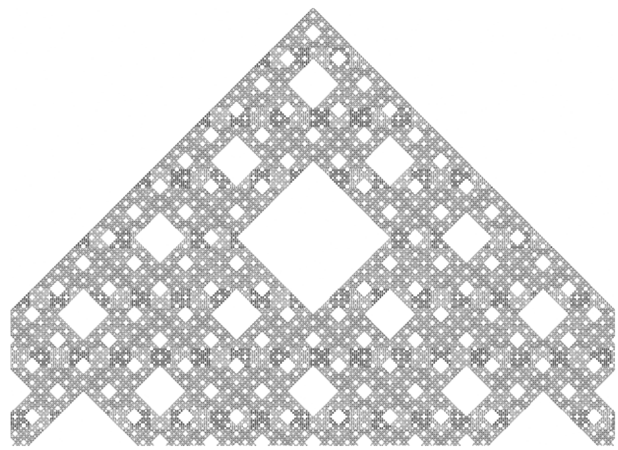


**Figure 15** CA7, clearly a class-2 CA.

It is plain that taking a suitable continuum limit of a $K$_CA one gets a partial differential equation of order $K$ for the evolution. However, there are also special and interesting CAs, called "filter" CAs, that in a suitable continuum limit end up in integral evolution equations. For a filter unidimensional CA, the evolved state at the cell $n$, $S(n,t+1)$, depends also on the (already) evolved states of the cells on its left (or right): for example, an NEL of the type

$$\begin{aligned} &S(n,t+1) \stackrel{M}{=} F(S(n+k_i,t), S(n-\tilde{k}_j,t+1)) \\ &\quad i=1,2,\ldots,N; \quad k_i \in \mathbb{Z} \\ &\quad j=1,2,\ldots,\tilde{N}; \quad \tilde{k}_j \in \mathbb{N} \qquad [16] \end{aligned}$$

is still valid (computable). Extensions to $K$_CAs or vector CAs or multidimensional CA are plain. Very often filter CAs exhibit a class-4 behavior with particle-like structures moving and interacting in a complex way; see the following example and examples in the next section.

**Example 9** (CA8) $M=2, V=0, R=2$. The EL is:

$$\begin{aligned} S(n,t+1) \stackrel{2}{=} &S(n-1,t-1)S(n-2,t) \\ &+ S(n,t) + S(n+1,t)S(n+2,t) \qquad [17] \end{aligned}$$

An example of the evolution of such a CA is given in Figure 16.

### Invertible CA

For most of the ELs there is a loss of information in the course of the evolution (see, e.g., Figures 5 and 6). Indeed, different definitions of "CA entropy" have been introduced to measure the "randomness" in the behavior of a given CA. However, since CAs are important in physical

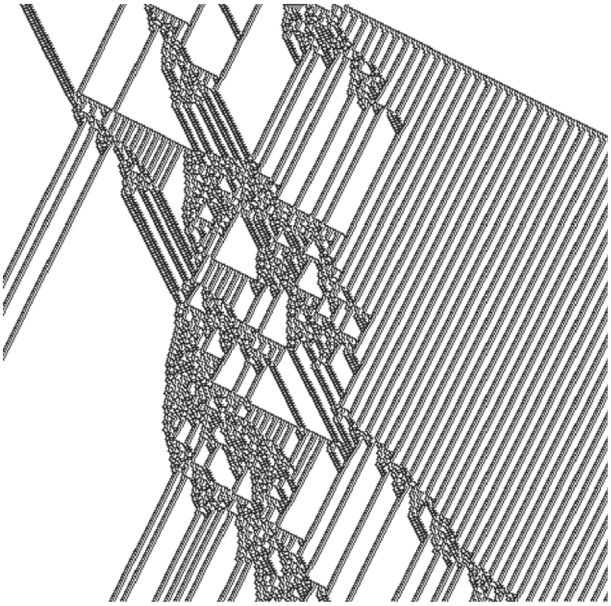

**Figure 16** CA8, a "filter" CA. Note the emerging of particle-like structures moving to the left and to the right and interacting in complex ways.

modeling as well as in cryptography and data compression, there is great interest in a special subclass of CAs which are "invertible" (time reversible). Namely, for an "invertible" CA following a given EL and starting from an arbitrary ID, there exists an "inverse" EL such that one can recover the ID from the evolved states. Invertible CAs can be easily devised in the case of $K_CA\,(K > 1)$. For example, if $K = 2, 3 \ldots$, one can consider ELs of the form

$$S(n,t+1) \stackrel{M}{=} S(n,t-K+1) + F\Big(S(n+k_i^j, t-j)\Big) \quad [18a]$$

where

$$\begin{aligned} &i = 1, 2, \ldots, N^j; \quad k_i^j \in \mathbb{Z} \\ &j = 0, 1, 2, \ldots, K-2 \end{aligned} \quad [18b]$$

and $F$ is an arbitrary polynomial function.

It is then clear that the inverse EL reads

$$\begin{aligned} \tilde{S}(n,\tilde{t}+1) \stackrel{M}{=} &\tilde{S}(n,\tilde{t}-K+1) \\ &+ (M-1)F\Big(\tilde{S}(n+k_i^j, \tilde{t}+j-K+2\Big) \end{aligned} \quad [19]$$

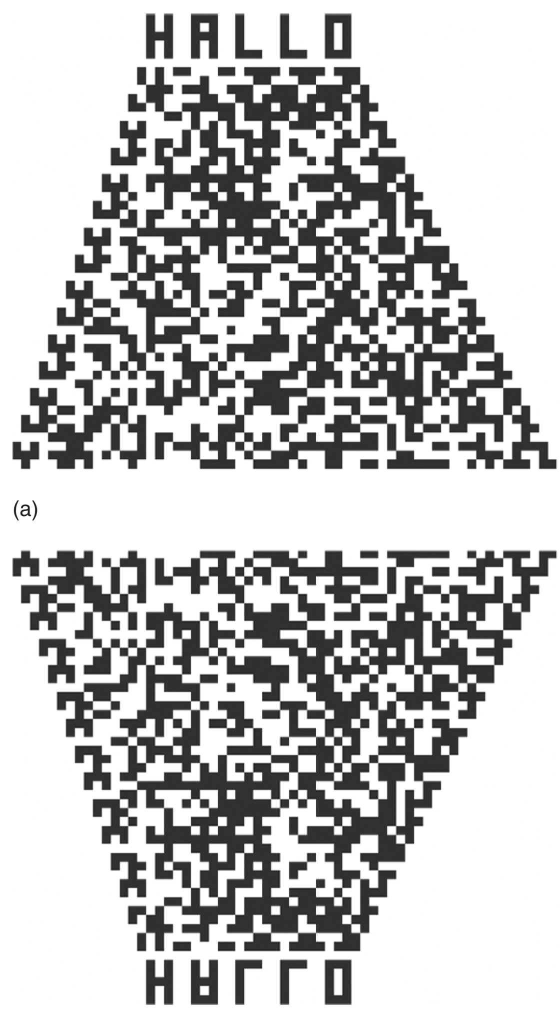
Indeed, if an arbitrary ID evolves according to the EL [18], then applying the inverse EL [19] to $K$ subsequent evolved states (taken in reversed order), eventually the original ID is recovered (in reversed order) (see the following example).

**Example 10** (CA9) A 6_CA: $M = 2, V = 0, R = 1$. The EL is:

$$\begin{aligned} S(n,t+1) \stackrel{2}{=} &S(n,t-5) + S(n,t-3) + S(n+1,t-2) \\ &+ S(n-1,t-1) \\ &+ S(n,t-2)S(n+1,t-2) \\ &+ S(n,t)S(n-1,t) \end{aligned} \quad [20]$$

The inverse EL, according to [19], reads (Figure 17)

$$\begin{aligned} \tilde{S}(n,\tilde{t}+1) \stackrel{2}{=} &\tilde{S}(n,\tilde{t}-5) + \tilde{S}(n,\tilde{t}-1) + \tilde{S}(n+1,\tilde{t}-2) \\ &+ \tilde{S}(n-1,\tilde{t}-3) \\ &+ \tilde{S}(n,\tilde{t}-2)\tilde{S}(n+1,\tilde{t}-2) \\ &+ \tilde{S}(n,\tilde{t}-4)\tilde{S}(n-1,\tilde{t}-4) \end{aligned} \quad [21]$$



(a)

(b)

**Figure 17** CA9, a 6_CA: (a) a 50 time-step evolution from a peculiar ID; (b) a 50 time-step evolution of the inverse EL, starting from the last six configurations of Figure 17a (taken in inverse order); the ID of Figure 17a is recovered (in inverse order).

Of course, more complicated invertible ELs can be devised. Invertible ELs can be also easily devised for "filter" CA, for example, if an NEL for a "filter" CA reads

$$S(n,t+1) \overset{M}{=} S(n,t) + F(S(n+k_i,t), S(n-\tilde{k}_j,t+1)) \quad [22]$$

where $k_i$ and $\tilde{k}_j$ are positive integers $(i=1,2,\ldots,N; j=1,2,\ldots,\tilde{N})$ and $F$ is an arbitrary (polynomial) function, then it is invertible and the inverse NEL reads

$$\tilde{S}(n,\tilde{t}+1) \overset{M}{=} \tilde{S}(n,\tilde{t}) + (M-1) \times F(\tilde{S}(n+k_i,\tilde{t}+1), \tilde{S}(n-\tilde{k}_j,\tilde{t})) \quad [23]$$

Note that [22] is computable starting from $n=-\infty$, whereas [23] is computable starting from $n=+\infty$.

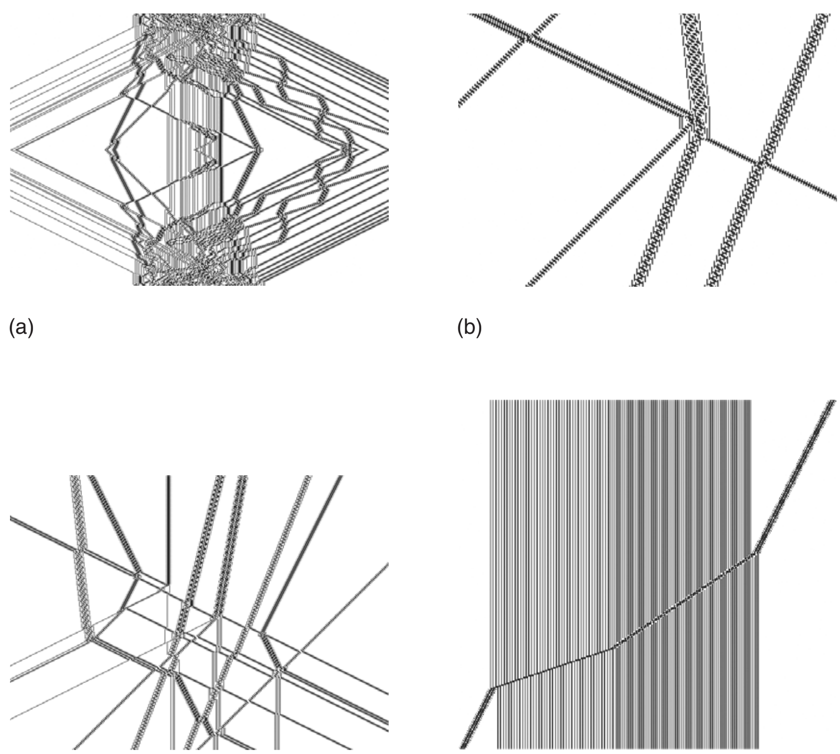
**Example 11** (CA10) A 1.5_CA, $M=2$, $V=0$, $R=3$. The EL is:

$$\begin{aligned} S(n,t+1) \overset{2}{=} & S(n,t) + S(n-3,t+1)S(n-2,t+1) \\ & + S(n+2,t)S(n+3,t) \\ & + S(n-2,t+1)S(n-1,t+1) \\ & + S(n+1,t)S(n+2,t) \end{aligned} \quad [24]$$

Note that this EL is of the form [22]; therefore, it is invertible (see **Figure 18a**). According to [23], the inverse EL reads:

$$\begin{aligned} \tilde{S}(n,\tilde{t}+1) \overset{2}{=} & S(n,\tilde{t}) + \tilde{S}(n+3,\tilde{t}+1)\tilde{S}(n+2,\tilde{t}+1) \\ & + \tilde{S}(n-2,t)\tilde{S}(n-3,t) \\ & + \tilde{S}(n+2,\tilde{t}+1)\tilde{S}(n+1,\tilde{t}+1) \\ & + \tilde{S}(n-1,\tilde{t})\tilde{S}(n-2,\tilde{t}) \end{aligned} \quad [25]$$

This CA exhibits a very rich dynamics: any complex ID rapidly decays in a great variety of coherent particle-like structures, steady or moving to the right or



(a) (b) (c) (d)

**Figure 18** CA10: (a) 230 time-step evolution, then the inverse EL is applied for 230 further time step in order to recover the initial configuration. (b) Collisions between different kinds of particle-like coherent moving structures. The last collision (on the right) is a solitonic one: the interaction produces just a phase shift, preserving number, shape, and velocities of the involved "particles." (c) "Particles" moving with different velocities and interacting in complex ways (solitonic collisions, particle creations and annihilations). (d) A particle goes through a nonhomogeneous medium and undergoes refraction by the medium itself.

to the left with different velocities. The interactions between different particles may be solitonic (the particles emerge unchanged but shifted) or annihilation–creation phenomena can occur (see Figures 18a–d).

## Applications of CAs

### CAs as Universal Constructors and Turing Machines

In the 1950s, von Neumann, who contributed to the development of the first computer (ENIAC), decided to work out a mathematical theory of automata. Such a theory was finalized to give an answer to the following question: is it possible to build an automaton such that it allows universal computation (i.e., it embodies a universal Turing machine) and, moreover, it is able to build (in order of decreasing generality)

1. an arbitrary automata (universal constructor);
2. a copy of itself (self-reproducing); and
3. an automaton that is itself a universal Turing machine (constructor)?

The last question von Neumann had intention to address was if in the process of automata self-reproduction (if possible) a process of evolution could take place, that is, if a simpler automaton could generate a more complex one.

In the beginning, the idea of von Neumann was to describe, using mathematical axioms, an automaton moving inside a warehouse and selecting various elementary spare parts (e.g., “muscles,” switches, rigid girders) and then assembling them into a new automaton. While this original idea was very realistic, it was also very difficult to pursue, so that von Neumann, following a suggestion by Ulam, decided to consider his questions in the more abstract framework of CAs.

The particular CA he considered is an infinite square CA with 29 possible states. The transition rule is dependent upon the cell to update and its north, east, south, and west neighbor cell (the von Neumann neighborhood). Among the 29 possible states there is one state that is “quiescent” (the vacuum state).

von Neumann proved the existence of a configuration of $\sim$50 000 cells immersed in a sea of quiescent states that embodies a universal Turing machine and that is a universal constructor. An infinite one-dimensional “tape” is used to store a description of the automaton to build. The universal constructor reads the description on the tape, develops a “constructing arm” that builds the configuration described on the tape in an unoccupied part of the cellular space, makes a copy of the tape and finally attaches it to the newly built automaton and retracts the constructing arm. When on the tape, it stores a description of the universal constructor itself, then it self-reproduces. The total size of the self-reproducing automaton amounts to $\sim$200 000 cells. (Some computer simulations of von Neumann self-reproducing automaton are available on the web.)

Since von Neumann’s CA is a very complex one, it led researchers to think that a CA able to simulate a universal Turing machine should also be quite complex. The perspective changed completely after the introduction of CA Life. Conway was looking for a simple CA with a possible rich dynamics; however, it was subsequently realized that Life was much more complicated that anyone could have thought. Finally, thanks to the development of faster computers that allowed visualization of the evolution of quite large populations and through the contribution of a large number of researchers, it was proved that a universal Turing machine could be embedded in Life.

The discovery that even a simple CA such as Life could incorporate a universal Turing machine led to the question whether it could be possible to build a universal Turing machine inside a simple one-dimensional CA. This is indeed the case: up to now, the simplest CA capable of universal computation is the W110 CA (see Figure 10), as proved recently by Cook after a conjecture formulated by Wolfram in 1985.

### CAs for Computer Simulations

One of the major applications of CAs is the computer simulation of various dynamical processes. Even if CAs were not invented for this purpose, they possess peculiarities that make them particularly suitable for this task. The main advantage of using a CA for a dynamical simulation is due to their completely discrete nature that allows exact simulations on a computer. Thus, any spurious effect due to rounding errors is ruled out. Another advantage is that the EL of a CA can be seen as a function between finite sets. For this reason, one can specify the EL through a “lookup table” (see [2]): then when running the simulations, the computer has only to access the table instead of computing the function every time, shortening considerably the computation time. Another great advantage of CAs in computer simulations is that, for their very nature (at least for local EL), they can be implemented on parallel machines. These two concepts are at the basis of dedicated computers for CAs simulations developed by Toffoli, Margolus, and co-workers (CAM series). The possibility to use efficiently parallel computers for CA simulation could prove

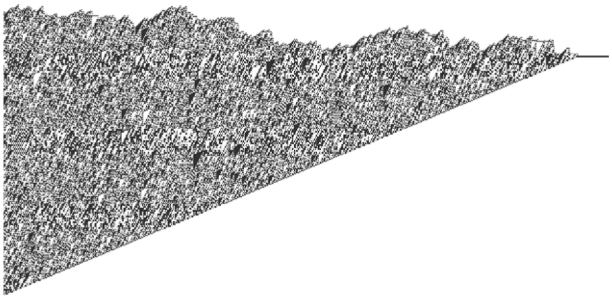


**Figure 19** A CA that "computes" the $3n+1$ Collatz–Ulam map. The ID for the CA is the initial number for the iterated map (binary notation, order $2^{300}$, randomly chosen, displayed on the left vertical axis). The CA, according to the Collatz conjecture, ends up to the final stable configuration (horizontal line on the right for the CA, $1 \rightarrow 4 \rightarrow 2 \rightarrow 1$ for the map).

to be fundamental when computer speeds approach saturation. Moreover, CAs themselves can mimic parallel computations, see, for example, Figure 19, where a nonlocal CA "computes" very efficiently the celebrated Collatz–Ulam $3n+1$ map.

### CAs in Physics

Since Newton, physics has been described through differential equations and continuous functions. However, such a mathematical description is not fit for simulation on a computer, and some discretizations must be considered. First, one has to discretize space and time passing from differential equations to (finite systems of) finite difference equations; second, one has to round off the values of the functions to store them in the memory of the computer. The main drawback of this procedure is that in chaotic systems such approximations can rapidly lead to great differences between the real and the simulated behavior. As already noticed, this problem does not appear in CA. Thus, one would like to use this good characteristic of CAs in physical modeling taking due account of the continuous nature of the physics involved. This requires attention and ingenuity in constructing reliable CA models for physical processes. For example, this goal has been achieved in the so-called lattice gas automata (LGAs).

LGAs are CA models for the microscopic dynamics of fluids and gases. The thermodynamic limit of these CAs yields the correct continuous functions for the macroscopic quantities (density, pressure, viscosity, etc.).

The first step toward LGAs was the discovery that the HPP model developed in the 1970s by Hardy, Pomeau and De Pazzis was in fact a CA. The HPP model describes the behavior of a fluid (or a gas) in a plane. The configuration space is given by a bidimensional square lattice and the particles are described by arrows lying on the edges of the lattices and pointing to some vertex (see Figure 20a).

The particles are assumed to be all identical and with the same velocity, and particles on the same edge with the same direction are not allowed (exclusion principle). The EL prescribes that particles move with unitary velocity along the edges in the direction pointed by the arrow (free flight) unless there are exactly two particles on the edges connected to a given vertex and they point in opposite directions (collision); in this case they are replaced by two arrows pointing outward on the previously empty edges (see Figure 20b). Clearly, the EL conserves the number and the momentum of the particles.

The HPP model can be described algebraically. The admissible particle velocities are just

$$c_1 = +\hat{x}, \quad c_2 = +\hat{y}, \quad c_3 = -\hat{x}, \quad c_4 = -\hat{y} \qquad [26]$$

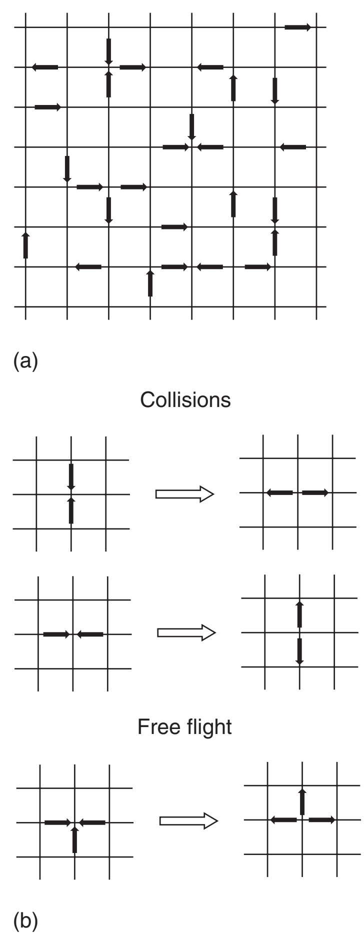

**Figure 20** (a) An example of configuration for the HPP model. (b) Head on collisions and three particle collisions in the HPP model.

Accordingly, only four bits $n_j(\boldsymbol{x},t)$, $j=1,2,3,4$, are required to denote the presence (1) or the absence (0) of a particle with velocity $c_j$ pointing vertex $\boldsymbol{x}$ at time $t$. The dynamical rule for HPP can be written in the form

$$n_j(\boldsymbol{x}+c_j,t+1)=n_j(\boldsymbol{x},t)+\omega_j(\boldsymbol{x},t) \qquad [27]$$

where term $n_j(\boldsymbol{x},t)$ on the right-hand side accounts for the free flight of particles, while $\omega_j(\boldsymbol{x},t)$ modifies the trajectories in the case of collisions. The $\omega_j$ are determined by the state of the system according to the following rules:

$$\omega_1=-n_1(1-n_2)n_3(1-n_4) + (1-n_1)n_2(1-n_3)n_4 \qquad [28a]$$

$$\omega_2=-n_2(1-n_3)n_4(1-n_1) + (1-n_2)n_3(1-n_4)n_1 \qquad [28b]$$

$$\omega_3=-n_3(1-n_4)n_1(1-n_2) + (1-n_3)n_4(1-n_1)n_2 \qquad [28c]$$

$$\omega_4=-n_4(1-n_1)n_2(1-n_3) + (1-n_4)n_1(1-n_2)n_3 \qquad [28d]$$

It is plain that eqns [27] and [28] can be interpreted as the EL for a CA.

In the thermodynamic limit, the equations governing the dynamics of the macroscopic quantities of the fluid are given by the continuity equation and by anisotropic Navier–Stokes equations. The anisotropy in the Navier–Stokes equations is due to the fact that the invariance group of the square lattice is too small. This problem was solved by Frisch, Hasslacher, and Pomeau in 1986, with the introduction of the FPP model. It turns out that a hexagonal lattice has enough symmetries to recover the isotropic Navier–Stokes equations in the thermodynamic limit. So, the FPP model is an example of a model where even if the microscopic dynamics is almost a caricature of the real dynamics, the thermodynamic limit gives rise to the correct physical equations.

CAs have been used to simulate many other physical processes (unfortunately, there is no space here for a sufficiently elaborate description). The principal fields of application are: percolation theory, magnetism, diffusion phenomena, sandpiles, models of earthquakes, crystal growth, etc.

The more intriguing aspect of some even simple CAs (e.g., CA9, CA10: see Figures 16 and 18) is their very rich particle-like dynamics. For instance, the existence of solitonic collisions suggested that the techniques recently developed to find and treat "integrable" nonlinear dynamical systems (nonlinear continuous and discrete evolution equations, many-body problems) could profitably be extended to find "integrable" CAs. Indeed, many such CAs have been found that exhibit "solitons" and are endowed with nontrivial conservation laws (of course, this is very important in physical modeling). Moreover, the above-cited similarity between certain CA behaviors and elementary particle physics phenomena suggests that the fundamental structure of reality (at the Planck level) could indeed be that of a CA (cells of Plank length, discrete time flow): attempts to construct this underlying CA physics have been pursued.

### Other Applications

CAs exhibit a great plasticity, which makes them well suited to model systems in a wide range of fields. This is mainly due to the fact that CAs with very simple rules can also simulate universal Turing machines, so that they can exhibit a very rich and complicated overall dynamics (in principle, one could simulate any dynamical system using a simple CA). There is another reason for the wide applicability of CA modeling even outside of physics: namely, it is well known that algorithms, not differential equations, are better instruments to schematize dynamical processes for complex and organized systems. Since simple algorithms can be naturally implemented on CAs, the latter are very useful for realizing simple models and simulations in many fields: biology, economics, ecology, neural networks, traffic models, etc.

Moreover, applications of CAs in informatics and specifically in cryptography and data compression have been investigated.

**P Bonckaert**, Universiteit Hasselt, Diepenbeek, Belgium

## Introduction

We consider differentiable dynamical systems generated by a diffeomorphism or a vector field on a manifold. We restrict to the finite-dimensional case, although some of the ideas can also be developed in the general case (Vanderbauwhede and Iooss 1992). We also restrict to the behavior near a stationary point or a periodic orbit of a flow.

Let the origin 0 of $\boldsymbol{R}^n$ be a stationary point of a $C^1$ vector field $X$, that is, $X(0)=0$. We consider the linear approximation $A=\mathrm{d}X(0)$ of $X$ at 0 and its spectrum $\sigma(A)$, which we decompose as $\sigma(A)=\sigma_s\cup\sigma_c\cup\sigma_u$, where $\sigma_s$ resp. $\sigma_c$ resp. $\sigma_u$ consists of those eigenvalues with real part $<0$ resp. $=0$ resp. $>0$. If $\sigma_c=\emptyset$ then there is no central manifold, and the stationary point 0 is called hyperbolic. Let $E_s, E_c$, and $E_u$ be the linear $A$-invariant subspaces corresponding to $\sigma_s$ resp. $\sigma_c$ resp. $\sigma_u$. Then $\boldsymbol{R}^n=E_s\oplus E_c\oplus E_u$. We look for corresponding $X$-invariant manifolds in the neighborhood of 0, in the form of graphs of maps. More precisely:

**Theorem 1** *Let the vector field $X$ above be of class $C^r$ $(1\leq r<\infty)$. There exist map germs $\phi_{ss}:(E_s,0)\to E_c\oplus E_u$, $\phi_{sc}:(E_s\oplus E_c,0)\to E_u$, $\phi_{uu}:(E_u,0)\to E_s\oplus E_c$, $\phi_{cu}:(E_c\oplus E_u,0)\to E_s$, and $\phi_c:(E_c,0)\to E_s\oplus E_u$ of class $C^r$ such that the graphs of these maps are invariant for the flow of $X$. Moreover, these maps are of class $C^r$, and their linear approximation at 0 is zero, that is, their graphs are tangent to, respectively, $E_s, E_s\oplus E_c, E_u, E_c\oplus E_u$, and $E_c$. If $X$ is of class $C^\infty$ then $\phi_{ss}$ and $\phi_{uu}$ are also of class $C^\infty$. If $X$ is analytic then $\phi_{ss}$ and $\phi_{uu}$ are also analytic.*

The graph of $\phi_c$ is called the (local) central (or, center) manifold of $X$ at 0 and it is often denoted by $W^c$. Thus, it is an invariant manifold of $X$ tangent at the generalized eigenspace of $\mathrm{d}X(0)$ corresponding to the eigenvalues having zero real part.

## (Non) uniqueness, Smoothness

Most proofs in the literature (Vanderbauwhede 1989) use a cutoff in order to construct globally defined objects, and then obtain the invariant graph as the solution of some fixed-point problem of a contraction in an appropriate function space. Although this solution is unique for the globalized problem, this is not the case at the germ level: another cutoff may produce a different germ of a central manifold. In other words, locally a central manifold might not be unique, as is easily seen on the planar example $x^2\partial/\partial x-y\partial/\partial y$. On the other hand, the $\infty$-jet of the map $\phi_c$, in case of a $C^\infty$ vector field, is unique, so if there would exist an analytic central manifold then this last one is unique; in the foregoing example, it is the $x$-axis. But for the (polynomial) example $(x-y^2)\partial/\partial x+y^2\partial/\partial y$ one can calculate that the $\infty$-jet of $x=\phi_c(y)$ is given by $j_\infty\phi_c(y)=\sum_{n\geq 1} n!y^{n+1}$, which has a vanishing radius of convergence, so there is no analytic central manifold. On the other hand, by the Borel theorem we can choose a $C^\infty$-representative for $\phi_c$. This can be generalized in the planar case:

**Proposition 1** *If $n=2$ and if $X$ is $C^\infty$ and if the $\infty$-jet of $X$ in the direction of the central manifold is nonzero, then this central manifold is $C^\infty$. In particular, if $X$ is analytic then the central manifold is either an analytic curve of stationary points or is a $C^\infty$ curve along which $X$ has a nonzero jet.*

For proofs and additional reading, the reader is referred to Aulbach (1992). In general, a central manifold is not necessarily $C^\infty$ (van Strien 1979, Arrowsmith and Place 1990): for the system in $\boldsymbol{R}^3$ given by

$$(x^2-z^2)\frac{\partial}{\partial x}+(y+x^2-z^2)\frac{\partial}{\partial y}+0\cdot\frac{\partial}{\partial z}$$

one can find a $C^k$ central manifold for every $k$ but there is no $C^\infty$ central manifold. Indeed, in this case the domain of definition of $\phi_c$ shrinks to zero when $k$ tends to infinity.

## Central Manifold Reduction

The importance of a central manifold lies in the principle of central manifold reduction, which roughly says that for local bifurcation phenomena it is enough to study the behavior on the central manifold, that is, if two vector fields, restricted to their central manifolds, have homeomorphic integral curve portraits, and if the dimensions of $E_s$ and $E_u$ are equal, then the two vector fields have homeomorphic integral curve portraits in $\boldsymbol{R}^n$, at least locally near 0. Let us be more precise:

**Theorem 2** *Let $m$ be the dimension of $E_c$. There exists $p$, $0 \leq p \leq n-m$, such that $X$ is locally $C^0$-conjugate to*

$$X' = \sum_{i=1}^{m} \tilde{X}_i(z_1, \ldots, z_m)\frac{\partial}{\partial z_i} + \sum_{i=m+1}^{m+p} z_i \frac{\partial}{\partial z_i} - \sum_{i=m+p+1}^{n} z_i \frac{\partial}{\partial z_i}$$

*where $(z_1, \ldots, z_m)$ is a coordinate system on a central manifold, $(z_1, \ldots, z_n)$ is a coordinate system on $\boldsymbol{R}^n$ extending $(z_1, \ldots, z_m)$ and $\sum_{i=1}^{m} \tilde{X}_i\, \partial/\partial z_i$ is the restriction of $X$ to a central manifold. Moreover, if*

$$Y = \sum_{i=1}^{m} \tilde{Y}_i(z_1, \ldots, z_m)\frac{\partial}{\partial z_i} + \sum_{i=m+1}^{m+p} z_i \frac{\partial}{\partial z_i} - \sum_{i=m+p+1}^{n} z_i \frac{\partial}{\partial z_i}$$

*and if $\sum_{i=1}^{m} \tilde{Y}_i\, \partial/\partial z_i$ is $C^0$-equivalent (resp. $C^0$-conjugate) to $\sum_{i=1}^{m} \tilde{X}_i\, \partial/\partial z_i$ then $X$ is $C^0$-equivalent (resp. -conjugate) to $Y$.*

For a proof and further reading (a generalization) see Palis and Takens (1977).

In case that more smoothness than just $C^0$ is needed, we have the principle of normal linearization along the central manifold. More concretely, let $x$ denote a coordinate in the central manifold and let $y$ be a complementary variable, that is, let $X = X_c \partial/\partial x + X_h \partial/\partial y$. We define the normally linear part along the central manifold by

$$NX := X_c(x, 0)\frac{\partial}{\partial x} + \frac{\partial X_h}{\partial y}(x, 0) \cdot y \frac{\partial}{\partial y}$$

Under certain nonresonance conditions (Takens 1971, Bonckaert 1997) on the real parts of the eigenvalues of $\mathrm{d}X(0)$, there exists a $C^r$ local conjugacy between $X$ and $NX$ for each $r \in \boldsymbol{N}$ (assuming $X$ to be of class $C^\infty$). If there are resonances, then one can conjugate with the so-called seminormal or renormal form containing higher-order terms (see Bonckaert (1997, 2000) and references therein; here one can also find results for cases where extra constraints should be respected, like symmetry, reversibility, or invariance of some given foliation etc.).

### Parameters

Having an eigenvalue with zero real part is ungeneric, so in bifurcation problems we consider $p$-parameter families $X_\lambda$ near, say, $\lambda = 0$. With respect to the results above, we remark that such a family can be considered as a vector field near $(0,0) \in \boldsymbol{R}^n \times \boldsymbol{R}^p$ tangent to the leaves $\boldsymbol{R}^n \times \{\lambda\}$. In fact, the parameter direction $\boldsymbol{R}^p$ is contained in $E_c$. In all the results mentioned, this structure "of being a family" is respected. For example, in Theorem 2 we replace $\tilde{X}_i(z_1, \ldots, z_m)$ by $\tilde{X}_i(z_1, \ldots, z_m, \lambda)$. Hence, if $\tilde{X}_\lambda$ is a versal unfolding of $\tilde{X}_0$ then $X_\lambda$ is a versal unfolding of $X_0$. By this, the search for versal unfoldings is reduced to the unfolding of singularities whose linear approximation at 0 has a purely imaginary spectrum.

### Diffeomorphisms, Periodic Orbits

A completely analogous theory can be developed for fixed points of diffeomorphisms $f : (\boldsymbol{R}^n, 0) \to \boldsymbol{R}^n$. Here we split up the spectrum of the linear part $L = \mathrm{d}f(0)$ at 0 as $\sigma(L) = \sigma_s \cup \sigma_c \cup \sigma_u$, where $\sigma_s$ resp. $\sigma_c$ resp. $\sigma_u$ consists of those eigenvalues with modulus $<1$ resp. $=1$ resp. $>1$. This theory can be applied to the time-$t$ map of a vector field (and will give the same invariant manifolds) and to the Poincaré map of a transversal section of a periodic orbit of a vector field (Chow *et al.* 1994).

## Normal Forms

The general idea of a normal form is to put a (complicated) system into a form "as simple as possible" by means of a change of coordinates. This idea was already developed to a great extent by H Poincaré. Simple examples are: (1) putting a square matrix into Jordan form, (2) the flow box theorem (Arrowsmith and Place 1990) near a nonsingular point. Depending on the context and on the purpose of the simplification, this concept may vary greatly. It depends on the kind of changes of coordinates that are tolerated (linear, polynomial, formal series, smooth, analytic) and on the possible structures that must be preserved (e.g., symplectic, volume-preserving, symmetric, reversible etc.). Let us restrict to local normal forms, that is, in the vicinity of a stationary point of a vector field or a diffeomorphism (the latter can be

applied to the Poincaré map of a periodic orbit). We concentrate on the simplification of the Taylor series. The general idea is to apply consecutive polynomial changes of variables; at each step we simplify terms of a degree higher than in the step before. The ideal simplification would be to put all higher-order terms to zero, which would (at least at the level of formal series) linearize the system. But as soon as there are resonances (see below), this is impossible: the planar system $2x\partial/\partial x + (y + x^2)\partial/\partial y$ cannot be formally linearized.

### Setting

Let $X$ be a $C^{r+1}$ vector field defined on a neighborhood of $0 \in \boldsymbol{R}^n$, and denote $A = \mathrm{d}X(0)$ (its linear approximation at 0). The Taylor expansion of $X$ at 0 takes the form

$$X(x) = A \cdot x + \sum_{k=2}^{r} X_k(x) + O(|x|^{r+1})$$

where $X_k \in H^k$, the space of vector fields whose components are homogeneous polynomials of degree $k$. The classical formal normal-form theorem is as follows. We define the operator $L_A$ on $H^k$ by putting $L_A h(x) = \mathrm{d}h(x) \cdot A \cdot x - A \cdot h(x)$; one calls $L_A$ the homological operator. One checks that $L_A(H^k) \subset H^k$. One also denotes this by ad $A(h)(x)$: see further in the Lie algebra setting. Let $R^k$ be the range of $L_A$, that is, $R^k = L_A(H^k)$. Let $G^k$ denote any complementary subspace to $R^k$ in $H^k$. The formal normal-form theorem states, under the above settings:

**Theorem 3** (Chow *et al.* 1994, Dumortier 1991) *There exists a composition of near identity changes of variables of the form*

$$x = y + \xi^k(y) \qquad [1]$$

*where the components of $\xi^k$ are homogeneous polynomials of degree $k$, such that the vector field $X$ is transformed into*

$$Y(y) = A \cdot y + \sum_{k=2}^{r} g_k(y) + O(|y|^{r+1})$$

*where $g_k \in G^k, k = 2, \ldots, r$.*

Sometimes this theorem is applied to the restriction of a vector field to its central manifold, for reasons explained in the last section. This is the reason why we did not assume $X$ to be $C^\infty$; in the latter case one can let $r \to \infty$ and obtain a normal form on the level of formal Taylor series (also called $\infty$-jets). Using a theorem of Borel, we infer the existence of a $C^\infty$ change of variables $\phi$ such that the Taylor series of $\phi_*(X)$ is $A \cdot y + \sum_{k=2}^{\infty} g_k(y)$. For practical computations, it is often appropriate to first simplify the linear part $A$ and to diagonalize it whenever possible. Hence, it is convenient to use a complexified setting and to use complex polynomials or power series. One can show that all involved changes of variables preserve the property of "being a complex system coming from a real system," that is, at the final stage we can return to a real system (see, e.g., Arrowsmith and Place (1990) for a more precise mathematical description).

Hence, we can assume that $A$ is an upper triangular matrix. Let the eigenvalues be $\lambda_1, \ldots, \lambda_n$. It can be calculated that the eigenvalues of $L_A$, as an operator $H^k \to H^k$, are then the numbers $\langle \lambda, \alpha \rangle - \lambda_j$ where $\alpha \in \boldsymbol{N}^n$, $\sum_{j=1}^{n} \alpha_j = k$ and $1 \le j \le n$. Hence, if these would all be nonzero then $B^k = H^k$, and then we have an ideal simplification, that is, all $g_k$ equal to zero. However, if such a number is zero, that is,

$$\langle \lambda, \alpha \rangle - \lambda_j = 0 \qquad [2]$$

it is called a resonance between the eigenvalues. In such a case, we have to choose a complementary space $G^k$. From linear algebra it follows that one can always choose

$$G^k = \ker(L_{A^*}) \qquad [3]$$

where $A^*$ is the adjoint operator. But this choice [3] is not unique and is, from the computational point of view, not always optimal, especially if there are nilpotent blocks. This fact has been exploited by many authors. A typical example is the case where $A = y\partial/\partial x$. On the other hand, if $A$ is semisimple we can choose the complementary space to be $\ker(L_A)$, so $L_A g_k = 0$; we can assume it to be the (complex) diagonal$[\lambda_1, \ldots, \lambda_n]$. In that case we can be more explicit as follows. Let $e_j = \partial/\partial x_j$ denote the standard basis on $\boldsymbol{C}^n$. For a monomial one can calculate that

$$L_A(x^\alpha e_j) = (\langle \lambda, \alpha \rangle - \lambda_j) x^\alpha e_j \qquad [4]$$

If the latter is zero, then the monomial is called resonant. This implies that the normal form can be chosen so that it only contains resonant monomials.

Putting a system into normal form not only simplifies the original system, it also gives more geometric insight on the Taylor series. To be more precise, suppose (for simplicity, this can be generalized (Dumortier 1997)) that $A$ is semisimple. One can calculate that the condition $L_A g_k = 0$ implies: $\exp(-At) g_k(\exp(At)x) = g_k(x)$ for all $t \in \boldsymbol{R}$. This means that $g_k$ is invariant for the one-parameter group $\exp(At)$. A typical example in the plane is: $A$ has eigenvalues $\mathrm{i}\lambda, -\mathrm{i}\lambda$. Note that the (only) resonances are $\langle(\mathrm{i}\lambda, -\mathrm{i}\lambda), (p+1, p)\rangle - \mathrm{i}\lambda = 0$ and

$\langle(\mathrm{i}\lambda, -\mathrm{i}\lambda),(p,p+1)\rangle + \mathrm{i}\lambda = 0$ for all $p \in \boldsymbol{N}$. We suppose that the original system was real, that is, on $\boldsymbol{R}^2$; we can choose linear coordinates such that for $z = x + \mathrm{i}y$, $\bar{z} = x - \mathrm{i}y$ the linear part is $A = \text{diagonal}[\mathrm{i}\lambda, -\mathrm{i}\lambda]$. Applying the remarks above, we conclude that the normal form only contains the monomials $(z\bar{z})^p z\partial/\partial z$ and $(z\bar{z})^p \bar{z}\partial/\partial\bar{z}$. The geometric interpretation here is that these monomials are invariant for rotations around $(0,0)$. This can also be seen on the real variant of this: the Taylor series of the (real) normalized system has the form $(\lambda + f(x^2+y^2))(x\partial/\partial y - y\partial/\partial x) + g(x^2+y^2)(x\partial/\partial x + y\partial/\partial y)$ and is invariant for rotations. Warning: the dynamic behavior of a formal normal form in the central manifold can be very different from that of the original vector field, since we are only looking at the formal level. A trivial example is (take $f = g = 0$ in the foregoing example) $X(x,y) = \lambda(x\partial y - y\partial x) - \exp(-1/(x^2))\partial/\partial x$, where orbits near $(0,0)$ spiral to $(0,0)$, whereas the normal form is just a linear rotation. This difference is due to the so-called flat terms, that is, the difference between the transformed vector field and a $C^\infty$-realization of its normalized Taylor series (or polynomial). In case of analyticity of $X$, one can ask for analyticity of the normalizing transformation $\phi$. Generically, this is not the case in many situations. The precise meaning of this "genericity condition" is too elaborate to explain in this brief review article. We provide some suggestions for further reading in the next section. One could roughly say that, in the central manifold, the normal form has too much symmetry and is too poor to model more complicated dynamics of the system, which can be "hidden in the flat terms." To quote Il'yashenko (1981): "In the theory of normal forms of analytic differential equations, divergence is the rule and convergence the exception ...."

In many applications, we want to preserve some extra structure, such as a symplectic structure, a volume form, some symmetry, reversibility, some projection etc.; the case of a projection is important since it includes vector fields depending on a parameter. Sometimes a superposition of these structures appears (e.g., a family of volume-preserving systems). We would like that the normal-form procedure respects this structure at each step. One can often formulate this in terms of vector fields belonging to some Lie subalgebra $\mathcal{L}_0$. The idea is then to use changes of variables like [1], where $\xi_k$ is then generated by a vector field in $\mathcal{L}_0$. This will guarantee that all changes of variables are "compatible" with the extra structure. Unlike the general case where we could work with monomials as in [4], we will have to consider vector fields $h_k$ in $\mathcal{L}_0$ whose components are homogeneous polynomials of degree $k$. If this can be done, one says that $\mathcal{L}_0$ respects the grading by the homogeneous polynomials. In order to fix ideas, suppose that $\mathcal{L}_0$ are the divergence-free planar vector fields. Note that a monomial $x^i y^j \partial/\partial x$ is not divergence free. We can instead use time mappings of homogeneous vector fields of the form $a(q+1)x^{p+1}y^q\partial/\partial x - a(p+1)x^p\ y^{q+1}\partial/\partial y$. Up to terms of higher order we can use the time-one map of $h_k$ instead of $x + h_k(x)$. In case that one asks for a $C^\infty$-realization of the normalizing transformation, we need an extra assumption on the extra structure, that is, on $\mathcal{L}_0$, called the Borel property: denote by $J_{\infty,0}$ the set of formal series such that each truncation is the Taylor polynomial of an element of $\mathcal{L}_0$. The extra assumption is: each element of $J_{\infty,0}$ must be the Taylor series of a $C^\infty$ vector field in $\mathcal{L}_0$. It can be proved (Broer 1981) that the following structures respect the grading and satisfy the Borel property: being an $r$-parameter family, respecting a volume form on $\boldsymbol{R}^n$, being a Hamiltonian vector field ($n$ even), and being reversible for a linear involution.

One could consider other types of grading of the Lie-algebras involved.

This method, using the framework of the so-called filtered Lie algebras, is explained and developed systematically in a more general and abstract context in Broer (1981).

In nonlocal bifurcations, such as near a homoclinic loop, for example, it is not enough to perform central manifold reduction near the singularity: a simplified smooth model in a full neighborhood of the singularity is often needed, for example, in order to compute Poincaré maps.

Let us start with the "purely" hyperbolic case (i.e., $\dim E_c = 0$). First we compute the formal normal form such as the above. If there are no resonances [2] then we can formally linearize the vector field $X$. If $X$ is $C^\infty$ then a classical theorem of Sternberg (1958) states that this linearization can be realized by a $C^\infty$ change of variables (i.e., no more flat terms remaining). In case there are resonances, we must allow nonlinear terms: the resonant monomials. In this case we can also reduce $C^\infty$ to this normal form. Using the same methods, it is also possible to reduce to a polynomial normal form, but this time using $C^k (k < \infty)$ changes of variables. More precisely, if $k$ is a given number and if we write the vector field as $X = X_N + R_N$, where $X_N$ is the Taylor polynomial up to order $N$ (which can be assumed to be in normal form) and where $R_N(x) = O(|x|^{N+1})$, then for $N$ sufficiently large there is a $C^k$ change of variables conjugating $X$ to $X_N$ near 0. The number $N$ depends on the spectrum of $A = \mathrm{d}X(0)$. An elegant proof of these facts can be found in Il'yashenko and Yakovenko (1991). For the case when extra structure must be

preserved, see Bonckaert (1997), which also deals with the partially hyperbolic case ($\dim E_c \geq 1$). As already remarked above, the case of a parameter-dependent family can be regarded as a partially hyperbolic stationary point preserving this extra structure.

The question of an analytic normal form, also in the hyperbolic case, leads to convergence questions and calls upon the so-called small-divisor problems. The classical results are due to Poincaré and Siegel. Let us summarize them; they are formulated in the complex analytic setting:

**Theorem 4**

(i) *If the convex hull of the spectrum of A does not contain $0 \in \mathbf{C}$ then X can locally be put into normal form by an analytic change of variables. Moreover, this normal form is polynomial.*

(ii) *If the spectrum $\{\lambda_1, \ldots, \lambda_n\}$ of A satisfies the condition that there exists $C > 0$ and $\mu > 0$ such that for any $m \in \mathbf{N}^n$ with $\sum_j m_j \geq 2$:*

$$|\langle(\lambda_1, \ldots, \lambda_n), m\rangle - \lambda_j| \geq \frac{C}{|m|^\mu} \qquad [5]$$

*for $1 \leq j \leq n$ then X can be locally linearized by an analytic change of variables.*

Note that case (i) contains the case where 0 is a hyperbolic source or sink. This case (i) in Theorem 4 can be extended if there are parameters: if $X$ depends analytically on a parameter $\varepsilon \in \mathbf{C}^p$ near $\varepsilon = 0$ then the change of variables is also analytic in $\varepsilon$; moreover, the normal form is then a polynomial in the space variables whose coefficients are analytically dependent on the parameter $\varepsilon$.

For case (ii) this is surely not the case, since the condition [5] is fragile: a small distortion of the parameter generically causes resonances, be it of a high order. To fix ideas, consider $n = 2$ and suppose $\lambda_1 < 0 < \lambda_2$. By a generic but arbitrary small perturbation, we can have that the ratio of these eigenvalues becomes a negative rational number $-p/q$, which gives a resonance of the form [2] with $j = 1$ and $\alpha = (q + 1, p)$, so [5] is violated.

So analytic linearization, or even a polynomial analytic normal form, is ungeneric for families of such hyperbolic stationary points. The search for analytic normal forms, that is, simplified models, for families is still under investigation. A first simplification is obtained via the stable and unstable manifold from Theorem 1, that is, the graphs of $\phi_{ss}$ and $\phi_{uu}$. When $X$ is analytic near 0 then these manifolds are also analytic. So, up to an analytic change of variables, we can assume that $E_s$ and $E_u$ are invariant, which gives a simplification of the expression of $X$. Moreover, there is analytic dependence on parameters.

For local diffeomorphisms there are completely similar theorems pertaining to all the cases considered above.

## Concluding Remarks

The concept of central manifold can be extended to more general invariant sets (see Chow *et al.* (2000) and references therein). It can also be extended to the infinite-dimensional case and can be applied to partial differential equations (Vanderbauwhede and Iooss 1992).

Concerning the generic divergence of normalizing transformations, the reader is referred to Broer and Takens (1989), Bruno (1989), Il'yashenko (1981), and Il'yashenko and Pyartli (1991). Although the power series giving the normalizing transformation generally diverges, the study of the dynamics is often performed by truncating the normal form at a certain order. Recently, Iooss and Lombardi (2005) considered the question as to what an optimal truncation is. It is shown, in case $dX(0)$ is semisimple, that the order of the normal form can be optimized so that the remainder satisfies some estimate shrinking exponentially fast to zero as a function of the radius of the domain.

Concerning normal forms preserving the Hamiltonian structure, see Birkhoff (1966) and Siegel and Moser (1995) for a starting point; this is an extended subject on its own, sometimes called Birkhoff normal form, and it would require another review article.

Further simplifications of the normal form can sometimes be obtained by taking into account nonlinear terms (instead of just $A$) in order to obtain reductions of higher-order terms (see Gaeta (2002) and especially the references therein).

Applications of normal forms and central manifolds to bifurcation theory have been explained in Dumortier (1991).

# Channels in Quantum Information Theory

**M Keyl**, Università di Pavia, Pavia, Italy

## Introduction

Consider a typical quantum system such as a string of ions in a trap. To "process" the quantum information the ions carry, we have to perform in general many steps of a quite different nature. Typical examples are: free time evolution (including unwanted but unavoidable interactions with the environment), controlled time evolution (e.g., the application of a "quantum gate" in a quantum computer), preparations and measurements. Each processing step can be described by a channel which transforms input systems into output system of a possibly different type (e.g., a measurement transforms quantum systems into classical information).

### Systems, States, and Algebras

To get a unified mathematical description of systems of different physical nature, it is useful to consider $C^*$-algebras (which are, in our case, always finite dimensional): quantum systems can be represented in terms of the algebra $\mathcal{B}(\mathcal{H})$ of (bounded) operators on the Hilbert space $\mathcal{H} = \mathbb{C}^d$; for classical information we have to choose the set $\mathcal{C}(X)$ of (continuous), complex-valued functions on the finite alphabet $X$; and the tensor product of both $\mathcal{B}(\mathcal{H}) \otimes \mathcal{C}(X)$ describes hybrid systems which are half-classical and half-quantum. Assume now that $\mathcal{A}$ is one of these algebras. Effects (i.e., yes/no measurements on the system in question) are then described by $A \in \mathcal{A}$ satisfying $0 \leq A \leq \mathbb{1}$, states are positive, normalized linear functionals $\omega : \mathcal{A} \to \mathbb{C}$, and the probability to get the result "yes" during an $A$ measurement on a system in the state $\omega$ is given by $\omega(A)$. Since $\mathcal{A}$ is assumed to be finite dimensional, each state $\omega$ on $\mathcal{B}(\mathcal{H})$ is represented by a density operator $\rho$, that is, $\omega(A) = \mathrm{tr}(\rho A)$. Likewise, a state $\omega$ on $\mathcal{C}(X)$ has the form $\omega(A) = \sum_x A(x) p_x$, where $(p_x)_{x \in X}$ denotes a probability distribution on $X$, and a state $\omega$ on $\mathcal{B}(\mathcal{H}) \otimes \mathcal{C}(X)$ is described by a sequence $(\rho_x)_{x \in X}$ of positive (trace-class) operators on $\mathcal{B}(\mathcal{H})$ with $\sum_x \mathrm{tr}(\rho_x) = 1$ such that $\omega(A) = \sum_x \mathrm{tr}(\rho_x A_x)$. Here

we have used the fact that an element $A \in \mathcal{B}(\mathcal{H}) \otimes \mathcal{C}(X)$ can be represented in a canonical way by a sequence $(A_x)_{x\in X}$ of operators on $\mathcal{H}$. The set of states will be denoted in the following by $\mathcal{S}(\mathcal{A})$ and the set of effects by $\mathcal{E}(\mathcal{A})$.

### Completely Positive Maps

Our aim is now to get a mathematical object which can be used to describe a channel. To this end, consider two $C^*$-algebras, $\mathcal{A}, \mathcal{B}$, describing the input and output system, respectively, and an effect $A \in \mathcal{B}$ of the output system. If we invoke first a channel which transforms $\mathcal{A}$ systems into $\mathcal{B}$ systems, and measure $A$ afterwards on the output systems, we end up with a measurement of an effect $T(A)$ on the input systems. Hence, we get a map $T : \mathcal{E}(\mathcal{B}) \to \mathcal{E}(\mathcal{A})$ which completely describes the channel (note that the direction of the mapping arrow is reversed compared to the natural ordering of processing). Alternatively, we can look at the states and interpret a channel as a map $T^* : \mathcal{S}(\mathcal{A}) \to \mathcal{S}(\mathcal{B})$ which transforms $\mathcal{A}$ systems in the state $\rho \in \mathcal{S}(\mathcal{A})$ into $\mathcal{B}$ systems in the state $T^*(\rho)$. To distinguish between both maps, we can say that $T$ describes the channel in the Heisenberg picture and $T^*$ in the Schrödinger picture. On the level of the statistical interpretation, both points of view should coincide of course, that is, the probabilities $(T^*\rho)(A)$ and $\rho(TA)$ to get the result "yes" during an $A$ measurement on $\mathcal{B}$ systems in the state $T^*\rho$, respectively a $TA$ measurement on $\mathcal{A}$ systems in the state $\rho$, should be the same. Since $(T^*\rho)(A)$ is linear in $A$, we see immediately that $T$ must be an affine map, that is, $T(\lambda_1 A_1 + \lambda_2 A_2) = \lambda_1 T(A_1) + \lambda_2 T(A_2)$ for each convex linear combination $\lambda_1 A_1 + \lambda_2 A_2$ of effects in $\mathcal{B}$, and this in turn implies that $T$ can be extended naturally to a linear map, which we will identify in the following with the channel itself, that is, we say that $T$ *is* the channel.

Let us now change slightly our point of view and start with a linear operator $T : \mathcal{A} \to \mathcal{B}$. To be a channel, $T$ must map effects to effects, that is, $T$ has to be positive: $T(A) \geq 0 \,\forall A \geq 0$ and bounded from above by $\mathbb{1}$, that is, $T(\mathbb{1}) \leq \mathbb{1}$. In addition, it is natural to require that two channels in parallel are again a channel. More precisely, if two channels $T : \mathcal{A}_1 \to \mathcal{B}_1$ and $S : \mathcal{A}_2 \to \mathcal{B}_2$ are given, we can consider the map $T \otimes S$ which associates to each $A \otimes B \in \mathcal{A}_1 \otimes \mathcal{A}_2$ the tensor product $T(A) \otimes S(B) \in \mathcal{B}_1 \otimes \mathcal{B}_2$. It is natural to assume that $T \otimes S$ is a channel which converts composite systems of type $\mathcal{A}_1 \otimes \mathcal{A}_2$ into $\mathcal{B}_1 \otimes \mathcal{B}_2$ systems. Hence, $S \otimes T$ should be positive as well.

**Definition 1** Consider two observable algebras $\mathcal{A}, \mathcal{B}$ and a linear map $T : \mathcal{A} \to \mathcal{B} \subset \mathcal{B}(\mathcal{H})$.

(i) $T$ is called positive if $T(A) \geq 0$ holds for all positive $A \in \mathcal{A}$.
(ii) $T$ is called completely positive (CP) if $T \otimes \mathrm{Id} : \mathcal{A} \otimes \mathcal{B}(\mathbb{C}^n) \to \mathcal{B}(\mathcal{H}) \otimes \mathcal{B}(\mathbb{C}^n)$ is positive for all $n \in \mathbb{N}$. Here Id denotes the identity map on $\mathcal{B}(\mathbb{C}^n)$.
(iii) $T$ is called unital if $T(\mathbb{1}) = \mathbb{1}$ holds.

Consider now the map $T^* : \mathcal{B}^* \to \mathcal{A}^*$ which is dual to $T$, that is, $T^*\rho(A) = \rho(TA)$ for all $\rho \in \mathcal{B}^*$ and $A \in \mathcal{A}$. It is called the Schrödinger-picture representation of the channel $T$, since it maps states to states provided $T$ is unital. (Complete) positivity can be defined in the Schrödinger picture as in the Heisenberg picture, and we immediately see that $T$ is (completely) positive iff $T^*$ is.

It is natural to ask whether the distinction between positivity and complete positivity is really necessary, that is, whether there are positive maps which are not CP. If at least one of the algebras $\mathcal{A}$ or $\mathcal{B}$ is classical, the answer is no: each positive map is CP in this case. If both algebras are quantum however, complete positivity is not implied by positivity alone. The most prominent example for this fact is the transposition map.

If item (ii) holds only for a fixed $n \in \mathbb{N}$, the map $T$ is called $n$-positive. This is obviously a weaker condition than complete positivity. However, $n$-positivity implies $m$-positivity for all $m \leq n$, and for $\mathcal{A} = \mathcal{B}(\mathbb{C}^d)$ complete positivity is implied by $n$-positivity, provided $n \geq d$ holds.

Let us consider now the question whether a channel should be unital or not. We have already mentioned that $T(\mathbb{1}) \leq \mathbb{1}$ must hold since effects should be mapped to effects. If $T(\mathbb{1})$ is not equal to $\mathbb{1}$, we get $\rho(T\mathbb{1}) = T^*\rho(\mathbb{1}) < \mathbb{1}$ for the probability to measure the effect $\mathbb{1}$ on systems in the state $T^*\rho$, but this is impossible for channels which produce an output with certainty, because $\mathbb{1}$ is the effect which is always true. In other words, if a CP map is not unital, it describes a channel which sometimes produces no output at all and $T(\mathbb{1})$ is the effect which measures whether we have got an output. We will assume henceforth that channels are unital if nothing else is explicitly stated.

## Quantum Channels

In this section we will discuss some basic properties of CP maps which transform quantum systems into quantum systems, in particular the Stinespring theorem, which constitutes the most important structural result. For a more detailed presentation, including generalizations to more general input/

output algebras the reader should consult the textbook by Paulsen (2002).

### The Stinespring Theorem

Hence consider channels between quantum systems, i.e., $\mathcal{A}=\mathcal{B}(\mathcal{H}_1)$ and $\mathcal{B}=\mathcal{B}(\mathcal{H}_2)$. A fairly simple example (not necessarily unital) is given in terms of an operator $V:\mathcal{H}_1 \to \mathcal{H}_2$ by $\mathcal{B}(\mathcal{H}_1) \ni A \mapsto VAV^* \in \mathcal{B}(\mathcal{H}_2)$. A second example is the restriction to a subsystem, which is given in the Heisenberg picture by $\mathcal{B}(\mathcal{H}) \ni A \mapsto A \otimes \mathbb{1}_{\mathcal{K}} \in \mathcal{B}(\mathcal{H} \otimes \mathcal{K})$. Finally the composition $S \circ T = ST$ of two channels is again a channel. The following theorem says that each channel can be represented as a composition of these two examples [7].

**Theorem 2** (Stinespring dilation theorem). *Every completely positive map $T:\mathcal{B}(\mathcal{H}_1) \to \mathcal{B}(\mathcal{H}_2)$ has the form*

$$T(A) = V^*(A \otimes \mathbb{1}_{\mathcal{K}})V \qquad [1]$$

*with an additional Hilbert space $\mathcal{K}$ and an operator $V:\mathcal{H}_2 \to \mathcal{H}_1 \otimes \mathcal{K}$. Both (i.e., $\mathcal{K}$ and $V$) can be chosen such that the span of all $(A \otimes \mathbb{1})V\phi$ with $A \in \mathcal{B}(\mathcal{H}_1)$ and $\phi \in \mathcal{H}_2$ is dense in $\mathcal{H}_1 \otimes \mathcal{K}$. This particular decomposition is unique (up to unitary equivalence) and is called the* minimal *decomposition.*

By introducing a family $|\chi_j\rangle\langle\chi_j|$ of one-dimensional projectors with $\sum_j |\chi_j\rangle\langle\chi_j| = \mathbb{1}$, we can define the "Kraus operators" $\langle\psi, V_j\phi\rangle = \langle\psi \otimes \chi_j, V\phi\rangle$. In terms of these, we can rewrite eqn [1] in the following form (Kraus 1983):

**Corollary 3** (Kraus form). *Every CP map $T:\mathcal{B}(\mathcal{H}_1) \to \mathcal{B}(\mathcal{H}_2)$ can be written in the form*

$$T(A) = \sum_{j=1}^{N} V_j^* A V_j \qquad [2]$$

*with operators $V_j:\mathcal{H}_2 \to \mathcal{H}_1$.*

To get a third representation of channels, consider the Stinespring form [1] of $T$ and a vector $\psi \in \mathcal{K}$ such that $U(\phi \otimes \psi) = V(\phi)$ can be extended to a unitary map $U:\mathcal{H} \otimes \mathcal{K} \to \mathcal{H} \otimes \mathcal{K}$. It is then easy to see that the dual $T^*$ of $T$ can be written as:

**Corollary 4** (Ancilla form). *Assume that $T:\mathcal{B}(\mathcal{H}) \to \mathcal{B}(\mathcal{H})$ is a channel. Then there is a Hilbert space $\mathcal{K}$, a pure state $\rho_0$, and a unitary map $U:\mathcal{H} \otimes \mathcal{K} \to \mathcal{H} \otimes \mathcal{K}$ such that*

$$T^*(\rho) = \mathrm{tr}_{\mathcal{K}}(U(\rho \otimes \rho_0)U^*) \qquad [3]$$

*holds.*

This representation of a channel has a (seemingly) very nice physical interpretation, because we can look at eqn [3] as the unitary interaction of the system with an unobservable environment, which is initially in the state $\rho_0$. The problem, however, is that there is a great arbitrariness in the choice of $U$ and $\rho_0$. This is the weakness of the ancilla form compared to the Stinespring representation.

Finally, let us state a related result. It characterizes all decompositions of a given completely positive map into completely positive summands. By analogy with results for states on abelian algebras (i.e., probability measures), we will call it a Radon–Nikodym theorem (see Arveson (1969) for a proof).

**Theorem 5** (Radon–Nikodym theorem). *Let $T_x:\mathcal{B}(\mathcal{H}_1) \to \mathcal{B}(\mathcal{H}_2), x \in X$ be a family of CP maps and let $V:\mathcal{H}_2 \to \mathcal{H}_1 \otimes \mathcal{K}$ be the Stinespring operator of $\bar{T} = \sum_x T_x$; then there are uniquely determined positive operators $F_x$ in $\mathcal{B}(\mathcal{K})$ with $\sum_x F_x = \mathbb{1}$ and*

$$T_x(A) = V^*(A \otimes F_x)V \qquad [4]$$

### The Jamiołkowski Isomorphism

The subject of this section is a relation between CP maps and states of bipartite systems, first discovered by Jamiołkowski (1972), and which is very useful in translating properties of bipartite systems into properties of positive maps and vice versa.

The idea is based on the following setup. Alice and Bob share a bipartite system in a maximally entangled state

$$\chi = \frac{1}{\sqrt{d}} \sum_{\alpha=1}^{d} e_\alpha \otimes e_\alpha \in \mathcal{H} \otimes \mathcal{H} \qquad [5]$$

(where $e_1, \ldots, e_d$ denote an orthonormal basis of $\mathcal{H}$). Alice applies to her subsystem a channel $T:\mathcal{B}(\mathcal{H}) \to \mathcal{B}(\mathcal{H}')$ while Bob does nothing. At the end of the processing, the overall system ends up in a state

$$R_T = (T \otimes \mathrm{Id})|\chi\rangle\langle\chi| \qquad [6]$$

Mathematically, eqn [6] makes sense if $T$ is only linear but not necessarily positive or CP (but then $R_T$ is not positive either). If we denote the space of all linear maps from $\mathcal{B}(\mathcal{H})$ into $\mathcal{B}(\mathcal{H}')$ by $\mathcal{L}$, we get a map

$$\mathcal{L} \ni T \mapsto R_T \in \mathcal{B}(\mathcal{K} \otimes \mathcal{H}) \qquad [7]$$

which is easily shown to be linear (i.e., $R_{\mu T + \lambda S} = \mu R_T + \lambda R_S$ for all $\lambda, \mu \in \mathbb{C}$ and all $T, S \in \mathcal{L}$). Furthermore, this map is bijective, hence a linear isomorphism.

**Theorem 6** *The map defined in eqns [7] and [6] is a linear isomorphism. The inverse map is given by*

$$\mathcal{B}(\mathcal{H}\otimes\mathcal{H}') \ni \rho \mapsto T_\rho \in \mathcal{L} \qquad [8]$$

*with*

$$\langle e'_\mu, T_\rho(\sigma)e'_\nu\rangle = d\,\mathrm{tr}\Big(\rho(|e'_\nu\rangle\langle e'_\mu| \otimes \sigma^{\mathrm{T}})\Big) \qquad [9]$$

*where $e'_1,\ldots,e'_{d'} \in \mathcal{H}'$ denote an (arbitrary) orthonormal basis of $\mathcal{H}'$ and the transposition of $\sigma$ is defined with respect to the basis $e_\alpha, \alpha = 1,\ldots,d$ used to define $\chi$ in [5].*

From the definition of $R_T$ in eqn [6], it is obvious that $R_T$ is positive, if $T$ is CP. To see that the converse is also true is not as trivial (because a transposition is involved), but it requires only a short calculation, which is omitted here. Hence, we get:

**Corollary 7** *The operator $R_T$ is positive, iff the map $T$ is CP.*

## Examples

Let us return now to the general case (i.e., arbitrary input and output algebras) and discuss several examples.

### Channels Under Symmetry

It is often useful to consider channels with special symmetry properties. To be more precise, consider a group $G$ and two unitary representations $\pi_1, \pi_2$ on the Hilbert spaces $\mathcal{H}_1$ and $\mathcal{H}_2$, respectively. A channel $T:\mathcal{B}(\mathcal{H}_1) \to \mathcal{B}(\mathcal{H}_2)$ is called covariant (with respect to $\pi_1$ and $\pi_2$) if

$$T[\pi_1(U)A\pi_1(U)^*] = \pi_2(U)T[A]\pi_2(U)^* \quad \forall A \in \mathcal{B}(\mathcal{H}_1)\,\forall U \in G \qquad [10]$$

holds. The general structure of covariant channels is governed by a fairly powerful variant of Stinesprings theorem (Keyl and Werner 1999).

**Theorem 8** *Let $G$ be a group with finite-dimensional unitary representations $\pi_j : G \to \mathrm{U}(\mathcal{H}_j)$ and $T:\mathcal{B}(\mathcal{H}_1) \to \mathcal{B}(\mathcal{H}_2)$ a $\pi_1, \pi_2$-covariant channel.*

(i) *Then there is a finite-dimensional unitary representation $\tilde{\pi} : G \to \mathrm{U}(\mathcal{K})$ and an operator $V:\mathcal{H}_2 \to \mathcal{H}_1 \otimes \mathcal{K}$ with $V\pi_2(U) = \pi_1(U) \otimes \tilde{\pi}(U)V$ and $T(A) = V^*A \otimes \mathbb{1}V$.*
(ii) *If $T = \sum_\alpha T^\alpha$ is a decomposition of $T$ in CP and covariant summands, there is a decomposition $\mathbb{1} = \sum_\alpha F^\alpha$ of the identity operator on $\mathcal{K}$ into positive operators $F^\alpha \in \mathcal{B}(\mathcal{K})$ with $[F^\alpha, \tilde{\pi}(g)] = 0$ such that $T^\alpha(X) = V^*(X \otimes F^\alpha)V$.*

The most prominent examples of covariant channels arise with $\mathcal{H}_1 = \mathcal{H}_2 = \mathbb{C}^d, G = \mathrm{U}(d)$ and $\pi_1(U) = \pi_2(U) = U$. All channels of this type are of the form

$$T(A) = (1-\vartheta)A + \vartheta d^{-1}\mathrm{tr}(A)\mathbb{1} \quad \text{with } \vartheta \in [0, d^2/(d^2-1)] \qquad [11]$$

and are known as "depolarizing channels." They often serve as a standard model for noise. Two particular cases are the ideal channel arising with $\vartheta = 0$, and the completely depolarizing channel ($\vartheta = 1$) which erases all information. If we choose $\pi_2(U) = \bar{U}$ (where the bar denotes complex conjugate) instead of $\pi_2(U) = U$, we get

$$T(A) = \frac{\vartheta}{d+1}\left[\mathrm{tr}(A)\mathbb{1} + A^{\mathrm{T}}\right] + \frac{1-\vartheta}{d-1}\left[\mathrm{tr}(A)\mathbb{1} - A^{\mathrm{T}}\right], \quad \vartheta \in [0,1] \qquad [12]$$

If we map these channels to states of bipartite systems (using the Jamiołkowski isomorphism from the last section), we get "Isotropic states" from eqn [11] and "Werner states" from [12].

### Classical Channels

The classical analog to a quantum operation is a channel $T:\mathcal{C}(X) \to \mathcal{C}(Y)$ which describes the transmission or manipulation of classical information. As already mentioned in the subsection "Completely positive maps," positivity and complete positivity are equivalent in this case. Hence, we have to assume only that $T$ is positive and unital. Obviously, $T$ is characterized by its matrix elements $T_{xy} = \delta_y(Te_x)$, where $\delta_y \in \mathcal{C}^*(X)$ denotes the Dirac measure at $y \in Y$ and $e_x \in \mathcal{C}(X)$ is the canonical basis in $\mathcal{C}(X)$. More precisely, $\delta_y$ and $e_x$ denote, respectively, the probability distribution and the function on $X$, given by

$$\delta_y = (\delta_{xy})_{x\in X} \quad \text{and} \quad e_x(y) = \delta_{xy} \qquad [13]$$

We will keep this notation up to the end of this article. Positivity and normalization of $T$ imply that $0 \le T_{xy} \le 1$ and

$$1 = \delta_y(\mathbb{1}) = \delta_y(T(\mathbb{1})) = \delta_y\left[T\left(\sum_x e_x\right)\right] = \sum_x T_{xy} \qquad [14]$$

holds. Hence the family $(T_{xy})_{x\in X}$ is a probability distribution on $X$ and $T_{xy}$ is, therefore, the transition probability to get the information $x \in X$ at the output side of the channel if $y \in Y$ was sent.

### Observables

Let us consider now a channel which transforms quantum information $\mathcal{B}(\mathcal{H})$ into classical information $\mathcal{C}(X)$. Since positivity and complete positivity are again equivalent, we just have to look at a positive and unital map $E:\mathcal{C}(X) \to \mathcal{B}(\mathcal{H})$. With the canonical basis $e_x, x \in X$, of $\mathcal{C}(X)$, we get a family $E_x = E(e_x)$, $x \in X$, of positive operators $E_x \in \mathcal{B}(\mathcal{H})$ with $\sum_{x\in X} E_x = \mathbb{1}$. Hence, the $E_x$ form a positive operator valued (POV) measure, i.e., an observable. If, on the other hand, a POV measure $E_x \in \mathcal{B}(\mathcal{H})$, $x \in X$, is given, we can define a quantum-to-classical channel $E:\mathcal{C}(X) \to \mathcal{B}(\mathcal{H})$ by

$$E(f) = \sum_{x\in X} f(x)E_x \qquad [15]$$

This shows that the observable $E_x, x \in X$, and the channel $E$ can be identified.

### Preparations

Let us now exchange the role of $\mathcal{C}(X)$ and $\mathcal{B}(\mathcal{H})$; in other words, let us consider a channel $R:\mathcal{B}(\mathcal{H}) \to \mathcal{C}(X)$ with a classical input and a quantum output algebra. In the Schrödinger picture, we get a family of density matrices $\rho_x := R^*(\delta_x) \in \mathcal{B}^*(\mathcal{H}), x \in X$, where $\delta_x \in \mathcal{C}^*(X)$ denotes again the Dirac measure on $X$. Hence, we get a parameter-dependent preparation that can be used to encode the classical information $x \in X$ into the quantum information $\rho_x \in \mathcal{B}^*(\mathcal{H})$.

### Instruments

An observable describes only the statistics of measuring results, but does not contain information about the state of the system after the measurement. To get a description which fills this gap, we have to consider channels which operate on quantum systems and produce hybrid systems as output, that is, $T:\mathcal{B}(\mathcal{H}) \otimes \mathcal{C}(X) \to \mathcal{B}(\mathcal{K})$. Following Davies (1976), we will call such an object an instrument. From $T$ we can derive the subchannel

$$\mathcal{C}(X) \ni f \mapsto T(\mathbb{1} \otimes f) \in \mathcal{B}(\mathcal{K}) \qquad [16]$$

which is the observable measured by $T$, that is, $\mathrm{tr}(T(\mathbb{1} \otimes e_x)\rho)$ is the probability to measure $x \in X$ on systems in the state $\rho$. On the other hand, we get for each $x \in X$ a quantum channel (which is not unital)

$$\mathcal{B}(\mathcal{H}) \ni A \mapsto T_x(A) = T(A \otimes e_x) \in \mathcal{B}(\mathcal{K}) \qquad [17]$$

It describes the operation performed by the instrument $T$ if $x \in X$ was measured. More precisely, if a measurement on systems in the state $\rho$ gives the result $x \in X$, we get (up to normalization) the state $T_x^*(\rho)$ after the measurement, while

$$\mathrm{tr}\big(T_x^*(\rho)\big) = \mathrm{tr}\big(T_x^*(\rho)\mathbb{1}\big) = \mathrm{tr}(\rho T(\mathbb{1} \otimes e_x)) \qquad [18]$$

is (again) the probability to measure $x \in X$ on $\rho$. The instrument $T$ can be expressed in terms of the operations $T_x$ by

$$T(A \otimes f) = \sum_x f(x)T_x(A) \qquad [19]$$

Hence, we can identify $T$ with the family $T_x, x \in X$. Finally, we can consider the second marginal of $T$

$$\mathcal{B}(\mathcal{H}) \ni A \mapsto T(A \otimes \mathbb{1}) = \sum_{x\in X} T_x(A) \in \mathcal{B}(\mathcal{K}) \qquad [20]$$

It describes the operation we get if the outcome of the measurement is ignored.

The best-known example of an instrument is a von Neumann–Lüders measurement associated with a PV measure given by family of projections $E_x, x = 1, \ldots, d$; for example, the eigenprojections of a self-adjoint operator $A \in \mathcal{B}(\mathcal{H})$. It is defined as the channel

$$T : \mathcal{B}(\mathcal{H}) \otimes \mathcal{C}(X) \to \mathcal{B}(\mathcal{H}) \quad \text{with } X = \{1, \ldots, d\} \text{ and } T_x(A) = E_x A E_x \qquad [21]$$

Hence, we get the final state $\mathrm{tr}(E_x\rho)^{-1}E_x\rho E_x$ if we measure the value $x \in X$ on systems initially in the state $\rho$ – this is well known from quantum mechanics.

### Parameter-Dependent Operations

Let us change now the role of $\mathcal{B}(\mathcal{H}) \otimes \mathcal{C}(X)$ and $\mathcal{B}(\mathcal{K})$; in other words, consider a channel $T:\mathcal{B}(\mathcal{K}) \to \mathcal{B}(\mathcal{H}) \otimes \mathcal{C}(X)$ with hybrid input and quantum output. It describes a device which changes the state of a system depending on the additional classical information. As for an instrument, $T$ decomposes into a family of (unital!) channels $T_x:\mathcal{B}(\mathcal{K}) \to \mathcal{B}(\mathcal{H})$ such that we get $T^*(\rho \otimes p) = \sum_x p_x T_x^*(\rho)$ in the Schrödinger picture. Physically, $T$ describes a parameter-dependent operation: depending on the classical information $x \in X$, the quantum information $\rho \in \mathcal{B}(\mathcal{K})$ is transformed by the operation $T_x$.

Finally, we can consider a channel $T:\mathcal{B}(\mathcal{H}) \otimes \mathcal{C}(X) \to \mathcal{B}(\mathcal{K}) \otimes \mathcal{C}(Y)$ with hybrid input and output to get a parameter-dependent instrument: similarly to the above discussion, we can define a family of instruments $T_y:\mathcal{B}(\mathcal{H}) \otimes \mathcal{C}(X) \to \mathcal{B}(\mathcal{K}), y \in Y$, by the equation $T^*(\rho \otimes p) = \sum_y p_y T_y^*(\rho)$. Physically, $T$ describes the following device: it receives the classical information $y \in Y$ and a quantum system in the state $\rho \in \mathcal{B}^*(\mathcal{K})$ as input. Depending on $y$, a measurement with the instrument $T_y$ is performed, which in turn produces the measuring value $x \in X$ and leaves the quantum system in the state (up to normalization) $T_{y,x}^*(\rho)$; with $T_{y,x}$ given as in eqn [17] by $T_{y,x}(A) = T_y(A \otimes e_x)$.

# Chaos and Attractors

**R Gilmore**, Drexel University, Philadelphia, PA, USA

## Introduction

Chaos is a type of behavior that can be exhibited by a large class of physical systems and their mathematical models. These systems are deterministic. They are modeled by sets of coupled nonlinear ordinary differential equations (ODEs):

$$\dot{x}_i = \frac{\mathrm{d}x_i}{\mathrm{d}t} = f_i(x; c) \qquad [1]$$

called dynamical systems. The coordinates $x$ designate points in a state space or phase space. Typically, $x \in R^n$ or some $n$-dimensional manifold for some $n \geq 3$, and $c \in R^k$ are called control parameters. They describe parameters that can be controlled in physical systems, such as pumping rates in lasers or flow rates in chemical mixing reactions. The most important mathematical property of dynamical systems is the uniqueness theorem, which states that there is a unique trajectory through every point at which $f(x; c)$ is continuous and Lipschitz and $f(x; c) \neq 0$. In particular, two distinct periodic orbits cannot have any points in common.

The properties of dynamical systems are governed, in lowest order, by the number, stability, and distribution of their fixed points, defined by $\dot{x}_i = f_i(x; c) = 0$. It can happen that a dynamical system has no stable fixed points and no stable limit cycles ($x(t) = x(t+T)$, some $T > 0$, all $t$). In such cases, if the solution is bounded and recurrent but not periodic, it represents an unfamiliar type of attractor. If the system exhibits "sensitivity to initial conditions" ($|x(t) - y(t)| \sim e^{\lambda t}|x(0) - y(0)|$ for $|x(0) - y(0)| = \epsilon$ and $\lambda > 0$ for most $x(0)$), the solution set is called a "chaotic attractor." If the attractor has fractal structure, it is called a "strange attractor."

Tools to study strange attractors have been developed that depend on three types of mathematics: geometry, dynamics, and topology.

Geometric tools attempt to study the metric relations among points in a strange attractor. These include a spectrum of fractal dimensions. These real numbers are difficult to compute, require very long, very clean data sets, provide a number without error estimates for which there is no underlying statistical theory, and provide very little information about the attractor.

Dynamical tools include estimation of Lyapunov exponents and a Lyapunov dimension. They include globally averaged exponents and local Lyapunov exponents. These are eigenvalues related to the different stretching ($\lambda > 0$) and squeezing ($\lambda < 0$) eigendirections in the phase space. To each globally averaged Lyapunov exponent $\lambda_i$, $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_n$, there corresponds a "partial dimension" $\epsilon_i$, $0 \leq \epsilon_i \leq 1$, with $\epsilon_i = 1$ if $\lambda_i \geq 0$. The Lyapunov dimension is the sum of the partial dimensions $d_{\mathrm{L}} = \sum_{i=1}^{n} \epsilon_i$. That the partial dimension $\epsilon_i = 1$ for $\lambda_i \geq 0$ indicates that the flow is smooth in the stretching ($\lambda_i > 0$) and flow directions and fractal in the squeezing ($\lambda_i < 0$) directions with $\epsilon_i < 1$. Dynamical indices provide some useful information about a strange attractor. In particular, they can be used to estimate some fractal properties of a strange attractor, but not vice versa.

Topological tools are very powerful for a restricted class of dynamical systems. These are dynamical systems in three dimensions ($n = 3$). For such systems there are three Lyapunov exponents $\lambda_1 > \lambda_2 > \lambda_3$, with $\lambda_1 > 0$ describing the stretching direction and responsible for "sensitivity to initial conditions," $\lambda_2 = 0$ describing the direction of the flow, and $\lambda_3 < 0$ describing the squeezing direction

and responsible for "recurrence." Strange attractors are generated by dissipative dynamical systems, which satisfy the additional condition $\lambda_1 + \lambda_2 + \lambda_3 < 0$. For such attractors, $\epsilon_1 = \epsilon_2 = 1$ and $\epsilon_3 = \lambda_1/|\lambda_3|$ by the Kaplan–Yorke conjecture, so that $d_L = 2 + \epsilon_3 = 2 + \lambda_1/|\lambda_3|$.

A number of tools from classical topology have been exploited to probe the structure of strange attractors in three dimensions. These include the Gauss linking number, the Euler characteristic, the Poincaré–Hopf index theorem, and braid theory. More recent topological contributions include several definitions for entropy, the development of a theory for knot holders or braid holders (also called branched manifolds), the Birman–Williams theorem for these objects, and relative rotation rates, a topological index for individual periodic orbits and orbit pairs.

Three-dimensional strange attractors are remarkably well understood; those in higher dimensions are not. As a result, the description that follows is largely restricted to strange attractors with $d_L < 3$ that exist in $R^3$ or other three-dimensional manifolds (e.g., $R^2 \times S^1$). The obstacle to progress in higher dimensions is the lack of a higher-dimensional analog of the Gauss linking number for orbit pairs in $R^3$.

## Overview

The program described below has two objectives:

1. classify the global topological structure of strange attractors in $R^3$; and
2. determine the "perestroikas" (changes) that such attractors can undergo as experimental conditions or control parameters change.

Four levels of structure are required to complete this program. Each is topological and discretely quantifiable. This provides a beautiful interaction between a rigidity of structure, demanded by topological constraints, and freedom within this rigidity. These four levels of structure are:

1. basis sets of orbits,
2. branched manifolds or knot holders,
3. bounding tori, and
4. embeddings of bounding tori.

## Branched Manifolds: Stretching and Squeezing

A strange attractor is generated by the repetition of two mechanisms: stretching and squeezing. Stretching occurs in the directions identified by the positive Lyapunov exponents and squeezing occurs in the directions identified by the negative Lyapunov exponents. In $R^3$ there is one stretching direction and one squeezing direction.

A simple stretch-and-squeeze mechanism that nature appears to be very fond of is illustrated in Figure 1. In this illustration, a cube of initial conditions at (a) is advected by the flow in a short time to (b). During this process, the cube is deformed by being stretched ($\lambda_1 > 0$). It also shrinks in a transverse direction ($\lambda_3 < 0$). During the initial phase of this deformation, two nearby points typically separate exponentially in time. If they were to continue to separate exponentially for all times, the invariant set would not be bounded. Therefore, this separation cannot continue indefinitely, and in fact it must somehow reverse itself after some time because the motion is recurrent. The mechanism shown in Figure 1 involves folding, which begins between (b) and (c) and continues through to (d). Squeezing occurs where points from distant parts of the attractor approach each other exponentially, as at (d). Finally, the cube, shown deformed at (d), returns to the neighborhood of initial conditions (a). This process repeats itself and builds up the strange attractor. As can be inferred from this figure, the strange attractor constructed by the repetitive process is smooth in the expanding ($\lambda_1$) and flow ($\lambda_2 = 0$) directions but fractal in the squeezing ($\lambda_3$) direction. The attractor's fractal dimension is $\epsilon_1 + \epsilon_2 + \epsilon_3 = 2 + \epsilon_3 = 2 + \lambda_1/|\lambda_3|$.

Figure 1 summarizes the boundedness and recurrence conditions that were introduced to define strange attractors, and illustrates one stretching and squeezing mechanism that occurs repetitively to build up the fractal structure of the strange attractor

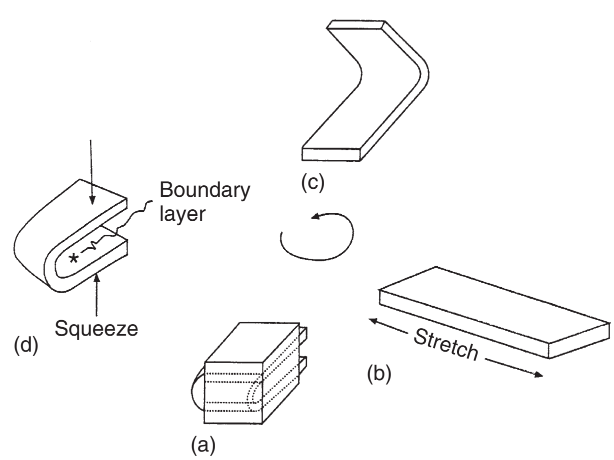

**Figure 1** A common stretch-and-fold mechanism generates many experimentally observed strange attractors. *The Topology of Chaos*; R Gilmore and M Lefranc; Copyright © 2002, Wiley. This material is used by permission of John Wiley & Sons, Inc.

and to organize all the (unstable) periodic orbits in it in a unique way. The particular mechanism shown in Figure 1 is called a stretch-and-fold mechanism. Other mechanisms involve stretch and roll, and tear and squeeze.

The stretch-and-squeeze mechanisms are well summarized by the cartoons shown in Figure 2. On the left, a cube of initial conditions (top) is deformed under the flow. The flow is downward. Stretching occurs in one direction (horizontal) and shrinking occurs in a transverse direction (perpendicular to the page). In the limit of extreme shrinking ($\lambda_3 \rightarrow -$"$\infty$"), the dynamics of the stretching part of the flow is represented by the two-dimensional surface shown on the bottom left. This surface fails to be a manifold because of the singularity, called a splitting point. This singularity represents an initial condition that flows to an unstable fixed point with at least one stable direction. On the right (squeezing), two distant cubes of initial conditions (top) in the flow are deformed and brought to each other's proximity under the flow (middle). In the limit of extreme dissipation, two two-dimensional surfaces representing inflows are joined at a branch line to a single surface representing an outflow. This surface fails to be a manifold because of the branch line, which is a singularity of a different kind. Points below the branch line in this representation of the flow (on the

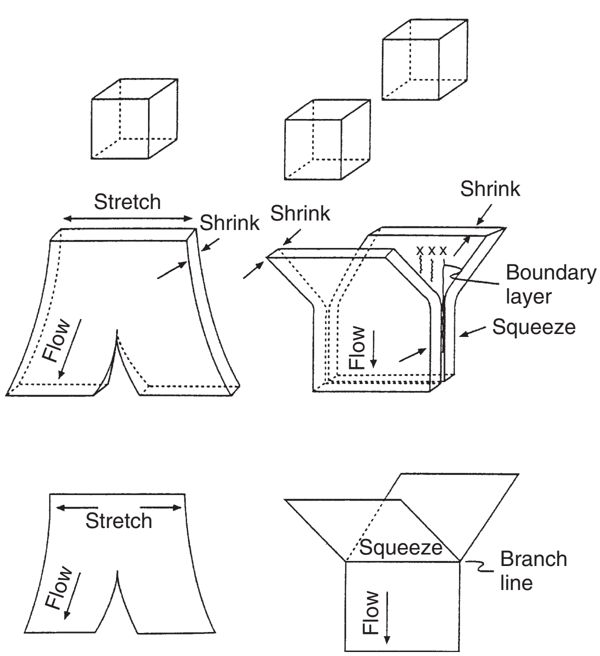

**Figure 2** Left: The stretch mechanism is modeled by a two-dimensional surface with a splitting point singularity. This material is used by permission of John Wiley & Sons, Inc.

outflow side of the branch line) have two preimages above the branch line, one in each inflow sheet. This structure generates positive entropy.

A beautiful theorem of Birman and Williams justifies the use of the two cartoons shown at the bottom of Figure 2 to characterize strange attractors in $R^3$. As preparation for the theorem, Birman and Williams introduced an important identification for the nongeneric or atypical points that "are not sensitive to initial conditions"

$$x \sim y \quad \text{if} \quad |x(t) - y(t)| \stackrel{t\rightarrow\infty}{\longrightarrow} 0 \qquad [2]$$

That is, two points in a strange attractor are identified if they have asymptotically the same future. In practice, this amounts to projecting the flow down along the stable ($\lambda_3 < 0$) direction onto a two-dimensional surface described by the stretching ($\lambda_1 > 0$) and the flow ($\lambda_2 = 0$) directions. This surface is not a manifold because of lower-dimensional singularities: splitting points and branch lines. The two-dimensional surface has many names, for example, knot holder (because it holds the periodic orbits that exist in abundance in strange attractors), braid holders, templates, branched manifolds. The flow, restricted to this surface, is called a semiflow. Under the semiflow, points in the branched manifold have a unique future but do not have a unique past. The degree of nonuniqueness is measured by the topological entropy of the dynamical system. The Birman–Williams theorem is:

**Theorem** *Assume that a flow* $\Phi_t$

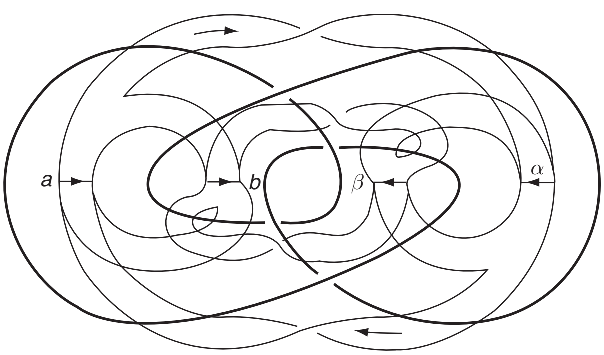
(i) *on* $R^3$ *is dissipative* ($\lambda_1 > 0$, $\lambda_2 = 0$, $\lambda_3 < 0$ *and* $\lambda_1 + \lambda_2 + \lambda_3 < 0$);
(ii) *generates a hyperbolic strange attractor* (*the eigenvectors of the local Lyapunov exponents* $\lambda_1$, $\lambda_2$, $\lambda_3$ *span everywhere on the attractor*).

*Then the projection* [2] *maps the strange attractor* $\mathcal{SA}$ *to a branched manifold* $\mathcal{BM}$ *and the flow* $\Phi_t$ *on* $\mathcal{SA}$ *to a semiflow* $\hat{\Phi}_t$ *on* $\mathcal{BM}$ *in* $R^3$. *The periodic orbits in* $\mathcal{SA}$ *under* $\Phi_t$ *correspond* 1:1 *with the periodic orbits in* $\mathcal{BM}$ *under* $\hat{\Phi}_t$ *with perhaps one or two specified exceptions. On any finite subset of orbits the correspondence can be taken via isotopy.*

The beauty of this theorem is that it guarantees that a flow $\Phi_t$ that generates a (fractal) strange attractor $\mathcal{SA}$ can be continuously deformed to a new flow $\hat{\Phi}_t$ on a simple two-dimensional structure $\mathcal{BM}$. During this deformation, periodic orbits are neither created nor destroyed. The uniqueness theorem for ODEs is satisfied during the deformation, so orbit segments do not pass through each other. As a result, the topological organization of all the

unstable periodic orbits in the strange attractor is the same as the topological organization of all the unstable periodic orbits in the branched manifold. In fact, the branched manifold (knot holder) defines the topological organization of all the unstable periodic orbits that it supports. Topological organization is defined by the Gauss linking number and the relative rotation rates, another braid index.

The significance of this theorem is that strange attractors can be characterized – in fact classified – by their branched manifolds. Figure 3 shows a branched manifold "for a figure-8 knot" as well as the figure-8 knot itself (dark curve). If a constant current is sent through a conducting wire tied into the shape of a figure-8 knot, a discrete countable set of magnetic field lines will be closed. These closed field lines can be deformed onto the two-dimensional surface shown in Figure 3. Each of the eight branches of this branched manifold can be named. One way to do this specifies the two branch lines that are joined by the branch in the sense of the flow (e.g., $(a\alpha)$ and $(\beta\alpha)$ (but not $(a\beta)$). Every closed field line can be labeled by a symbol sequence that is unique up to cyclic permutation. This symbol sequence provides a symbolic name for the orbit. For example, $(a\alpha)(\alpha\beta)(\beta b)(ba)$ is a period-4 orbit. The structure of a branched manifold is determined in part by a transition matrix $T$. The matrix element $T_{ij}$ is 1 if the transition from branch $i$ to branch $j$ is allowed, 0 otherwise. The transition matrix for the figure-8 branched manifold is shown in Figure 3.



| | ab | aα | αβ | αa | ba | bβ | βα | βb |
|---|---|---|---|---|---|---|---|---|
| ab | 0 | 0 | 0 | 0 | 1 | 1 | 0 | 0 |
| aα | 0 | 0 | 1 | 1 | 0 | 0 | 0 | 0 |
| αβ | 0 | 0 | 0 | 0 | 0 | 0 | 1 | 1 |
| αa | 1 | 1 | 0 | 0 | 0 | 0 | 0 | 0 |
| ba | 1 | 1 | 0 | 0 | 0 | 0 | 0 | 0 |
| bβ | 0 | 0 | 0 | 0 | 0 | 0 | 1 | 1 |
| βα | 0 | 0 | 1 | 1 | 0 | 0 | 0 | 0 |
| βb | 0 | 0 | 0 | 0 | 1 | 1 | 0 | 0 |

**Figure 3** Figure-8 knot (dark curve) and the figure-8 branched manifold. Transition matrix for the eight branches of the figure-8 branched manifold is also shown. The Birman–Williams theorem is stronger than its statement suggests. More systems satisfy the statement of the theorem than do the assumptions of the theorem. The figure-8 knot, and its attendant magnetic field, is not dissipative – in fact, it is not even a dynamical system, yet the closed loops can be isotoped to the figure-8 knot holder. There are other ways in which the Birman–Williams theorem is stronger than its statement suggests.

It is apparent from Figure 3 that the figure-8 branched manifold can be built up Lego© fashion from the two basic building blocks shown in Figure 2. This is more generally true. Every branched manifold can be built up, Lego© fashion, from the stretch (with a splitting point singularity) and the squeeze (with a branch line singularity) building blocks, subject to the following two conditions:

1. outputs flow to inputs and
2. there are no free ends.

The figure-8 branched manifold is built up from four stretch and four squeeze building blocks. As a result, there are eight branches and four branch lines.

Two often-studied strange attractors are shown in Figures 4 and 5. Figure 4 shows the details of the Rössler dynamical system. A similar spectrum of features is shown in Figure 5 for the Lorenz equations. The knot holder in Figure 5e is obtained from the caricature in Figure 5d by twisting the right-hand lobe by $\pi$ radians.

Branched manifolds can be used to characterize all three-dimensional strange attractors. Branched manifolds that classify the strange attractors generated by four familiar sets of equations (for some control parameter values) are shown in Figure 6. The sets of equations, and one set of parameter values that generate strange attractors, are presented in Table 1.

The beauty of this topological classification of strange attractors is that it is apparent, just by inspection, that there is no smooth change of variables that will map any of these systems to any of the others for the parameter values shown.

Branched manifolds can be described algebraically. In Figure 7 we provide the algebraic

description of two branched manifolds. Figure 7a shows the branched manifold that describes experimental data generated by many physical systems. The mechanism is a simple stretch-and-fold deformation with zero global torsion that generates a typical Smale horseshoe. There are two branches. The diagonal elements of the matrix identify the local torsion of the flow through the corresponding branch, measured in units of $\pi$. Branch 0 has no local torsion, and branch 1 shows a half-twist and has local torsion +1. The off-diagonal matrix elements are twice the linking number of the period-1 orbits in the corresponding pair of branches. Since the period-1 orbits in these two branches do not link, the off-diagonal matrix elements are 0. The period-1 orbits in the branches labeled 1 and 2 in Figure 7b have linking number +1, so the off-diagonal matrix elements are $T(1, 2) = T(2, 1) = 2 \times +1$. The array identifies the order (above, below) that the two branches are joined at the branch line, the smaller the value, the closer to the viewer. These two pieces of information, four integers in Figure 7a and eight in

Figure 7b, serve to determine the topological organization of all the unstable periodic orbits in any strange attractor with either branched manifold.

The periodic orbits are identified by a repeating symbol sequence of least period $p$, which is unique up to cyclic permutation. The symbol sequence consists of a string of integers, sequentially identifying the branches through which the orbit passes. For a branched manifold with two branches, there are two symbols. The number of orbits of period $p, N(p)$, obeys the recursion relation

$$pN(p) = 2^p - \sum_{1=k|p}^{k \leq p/2} kN(k) \qquad [3]$$

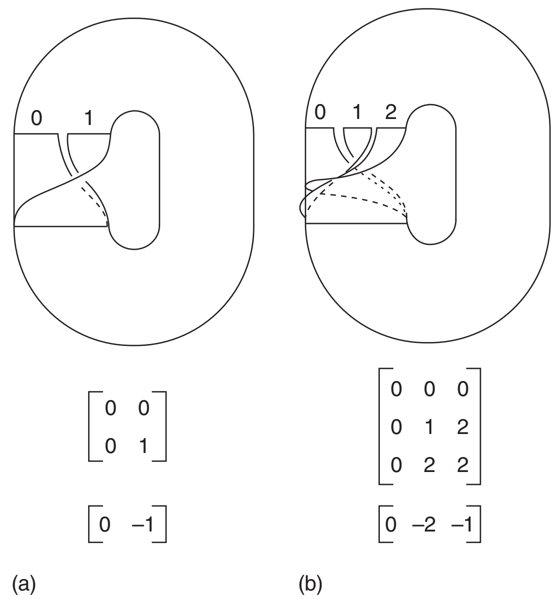

**Figure 7** Branched manifolds are described algebraically. The diagonal matrix elements describe the twist of each branch. The off-diagonal matrix elements are twice the linking number of the period-1 orbits in each of the two branches. The array describes the order in which the branches are connected at the branch line. (a) Smale horseshoe branched manifold. (b) Beginning of a "gateau roulé" (jelly roll) branched manifold.

Table 2 shows the number of orbits of period $p \leq 20$ for the branched manifolds with two and three branches shown in Figure 7. The number of orbits of period $p$ grows exponentially with $p$, and the limit $h_T = \lim_{p \to \infty} \log(N(p))/p$ defines the topological entropy $h_T$ for the branched manifold. The limits are $\ln 2$ and $\ln 3$ for the branched manifolds with two and three branches, respectively. The linking numbers of orbits up to period 5 in the Smale horseshoe branched manifold are shown in Table 3, which identifies each of the orbits by its symbol sequence (e.g., 00111).

**Table 2** Number of orbits of period $p$ on the branched manifolds with two and three branches, shown in **Figure 7**. The integers $N_3(p)$ are constructed by replacing $2^p$ by $3^p$ in eqn [3]

| *Period* $p$ | *Two branches* $N_2(p)$ | *Three branches* $N_3(p)$ | *Period* $p$ | *Two branches* $N_2(p)$ | *Three branches* $N_3(p)$ |

Tables of linking numbers have been used successfully to identify mechanisms that nature uses to generate chaotic data. This analysis procedure is called topological analysis. Segments of data are identified that closely approximate unstable periodic orbits existing in the strange attractor. These data segments are then embedded in $R^3$. Each orbit is given a trial identification (symbol sequence). Their pairwise linking numbers are computed either by counting signed crossings or using the time-parametrized data segments and estimating the integers numerically using the Gauss linking integral

$$\mathrm{Link}(A, B) = \frac{1}{4\pi} \oint \oint \frac{\boldsymbol{r}_A(t_1) - \boldsymbol{r}_B(t_2)}{|\boldsymbol{r}_A(t_1) - \boldsymbol{r}_B(t_2)|^3}\, \mathrm{d}\boldsymbol{r}_A(t_1) \times \mathrm{d}\boldsymbol{r}_B(t_2)$$

This table of experimental integers is compared with the table of linking numbers for orbits with the same symbolic name on a trial branched manifold. This procedure serves to identify the branched manifold and refine the symbolic identifications of the experimental orbits, if necessary. The procedure is vastly overdetermined. For example, the linking numbers of only three low-period orbits serve to identify the four pieces of information required to specify a branched manifold with two branches. Since six or more surrogate periodic orbits can typically be extracted from experimental data, providing $\binom{6}{2} = 15$ or more linking numbers, this topological analysis procedure has built-in self-consistency checks, unlike analysis procedures based on geometric and dynamical tools.

## Basis Sets of Orbits

A branched manifold determines the topological organization of all the periodic orbits that it supports. Whenever a low-dimensional strange attractor is subjected to topological analysis, it is always the case that fewer periodic orbits are present and identified than are allowed by the branched manifold that classifies it. This is the case for strange attractors generated by experimental data as well as strange attractors generated by ODEs. The full spectrum occurs only in the hyperbolic limit, which has never been seen.

The orbits that are present are organized exactly as in the hyperbolic limit – that is, as determined by the underlying branched manifold. As control parameters change, the strange attractor undergoes perestroikas. New orbits are created and/or old orbits are annihilated in direct or inverse period-doubling and saddle–node bifurcations. The orbits that are present are always organized as determined by the branched manifold. Orbits are not created or annihilated independently of each other. Rather, there is a partial order ("forcing order") involved in orbit creation and annihilation. This partial order is poorly understood for general branched manifolds. It is much better understood for the two-branch Smale horseshoe branched manifold.

The forcing diagram for this branched manifold is shown in Figure 8 for orbits up to period 8. It is typically the case that the existence of one orbit in a strange attractor forces the presence of a spectrum of additional orbits. Forcing is transitive, so if orbit $A$ forces orbit $B (A \Rightarrow B)$ and $B$ forces $C$, then $A$ forces $C$: if $A \Rightarrow B$ and $B \Rightarrow C$ then $A \Rightarrow C$. For this reason, it is sufficient to show only the first-order forcing in this figure. The orbits shown are labeled by their period and the order in which they are created in a particular highly dissipative limit of the dynamics: the logistic map (U-sequence order in Figure 8). For example, $5_2$ describes the second (pair) of period-5 orbits created in the

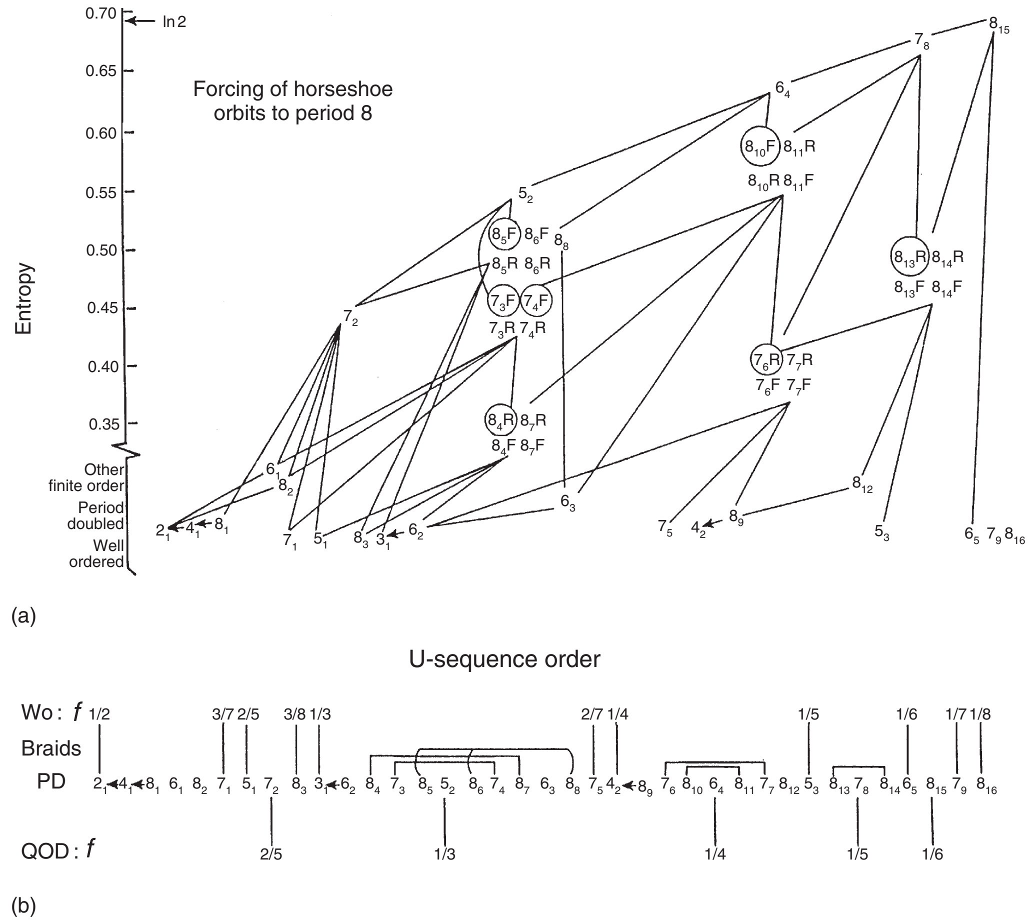

**Figure 8** (a) Forcing diagram for orbits up to period 8 in the Smale horseshoe branched manifold. (b) The sequence ("universal order") in which orbits are created in the highly dissipative limit, which is the logistic map. *The Topology of Chaos*; R Gilmore and M Lefranc; Copyright © 2002, Wiley. This material is used by permission of John Wiley & Sons, Inc.

logistic map in the transition from simple, nonchaotic behavior to fully chaotic (hyperbolic) behavior.

The orbits in the forcing diagram are organized according to their one-dimensional entropy (horizontal axis, U-sequence order) and their two-dimensional entropy (vertical axis). Nonchaotic ("laminar") behavior occurs at the lower left of this figure, where both entropies are zero. Fully chaotic behavior occurs at the upper right, where both entropies are ln 2. As control parameters change, a dynamical system that can exhibit chaos generated by a stretch-and-fold mechanism follows a path in the forcing diagram from the lower left to the upper right. Each such path is a "route to chaos." The Smale horseshoe mechanism exhibits many different routes to chaos: each follows a different path in the forcing diagram.

The state of a strange attractor at any stage in its route to chaos can be specified by a "basis set of orbits." This is a set of orbits whose presence forces the existence of all other orbits that can concurrently be found in the attractor, up to any finite period. The basis set of orbits can be constructed algorithmically. The algorithm is as follows:

1. Write down all the orbits that are present in order of increasing two-dimensional entropy from left to right.
2. For orbits with the same two-dimensional entropy, order by increasing one-dimensional entropy.
3. Remove the "highest" (rightmost) orbit from this list, together with all the orbits that it forces. This is the first basis orbit.
4. Of the orbits remaining, again remove the rightmost and all the orbits that it forces. This is the second basis orbit.
5. Continue until all orbits have been removed.

For any finite period, the above algorithm terminates because there is only a finite number of orbits. For example, if the orbit $5_2$ is present as well as all orbits with lower one-dimensional entropy, the basis set is $8_7R, 7_6, 7_4F, 8_6F, 8_8, 5_2$. As control parameters change, a strange attractor undergoes perestroikas that are quantitatively determined by changes in the basis sets of orbits.

## Bounding Tori

As experimental conditions or control parameters change, strange attractors can undergo "grosser" perestroikas than those that can be described by a change in the basis set of orbits. This occurs when new orbits are created that cannot be contained on the initial branched manifold – for example, when orbits are created that must be described by a new symbol. This is seen experimentally in the transition from horseshoe type dynamics to gateau roulé type dynamics. This involves the addition of a third branch to the branched manifold with two branches, as shown in Figures 7a and 7b. Strange attractors can undergo perestroikas described by the addition of new branches to, or deletion of old branches from, a branched manifold. These perestroikas are in a very real sense "grosser" than the perestroikas that can be described by changes in the basis sets of orbits on a fixed branched manifold.

There is a structure that provides constraints on the allowed bifurcations of branched manifolds (creation/annihilation of branches), which is analogous to the constraints that a branched manifold provides on the bifurcations and topological organization of the periodic orbits that can exist on it. This structure is called a bounding torus.

Bounding tori are constructed as follows. The semiflow on a branched manifold is "inflated" or "blown up" to a flow on a thin open set in $R^3$ containing this branched manifold. The boundary of this open set is a two-dimensional surface. Such surfaces have been classified. They are uniquely tori of genus $g$; $g=0$ (sphere), $g=1$ (tire tube), $g=2,3,\ldots$. The torus of genus $g$ has Euler characteristic $\chi=2-2g$. The flow is into this surface. The flow, restricted to the surface, exhibits a singularity wherever it is normal to the surface. At such singularities the stability is determined by the local Lyapunov exponents: $\lambda_1>0$ and $\lambda_3<0$, since the flow direction ($\lambda_2=0$) is normal to the surface. As a result, all singularities are saddles; so, by the Poincaré–Hopf theorem, the number of singularities is strongly related to the genus. The number is $2(g-1)$.

The flow, restricted to the genus-$g$ surface, can be put into canonical form and these canonical forms can be classified. The classification involves projection of the genus-$g$ torus onto a two-dimensional surface. The planar projection consists of a disk with outer boundary and $g$ interior holes. All singularities can be placed on the interior holes. The flow on the interior holes without singularities is in the same direction as the flow on the exterior boundary. Interior holes with singularities have an even number, $4,6,\ldots$. Some canonical forms are shown in Figure 9.

Poincaré sections have been used to simplify the study of flows in low-dimensional spaces by effectively reducing the dimension of the dynamics. In three dimensions, a Poincaré surface of section for a strange attractor is a minimal two-dimensional surface with the property that all points in the attractor intersect this surface transversally an infinite number of times under the flow. The Poincaré surface need not be connected and in fact is often not connected.

The Poincaré section for the flow in a genus-$g$ torus consists of the union of $g-1$ disjoint disks ($g\geq 3$) or is a single disk ($g=1$). The locations of the disks are determined algorithmically, as shown in Figure 9. The interior circles without singularities are labeled by capital letters $A,B,C,\ldots$ and those with singularities are labeled with lowercase letters $a,b,c,\ldots$ The components of the global Poincaré surface of section are numbered sequentially $1,2,\ldots,g-1$, in the order they are encountered when traversing the outer boundary in the direction of the flow, starting from any point on that boundary. Each component of the global Poincaré surface of section connects (in the projection) an interior circle without singularities to the exterior boundary. There is one component between each successive encounter of the flow with

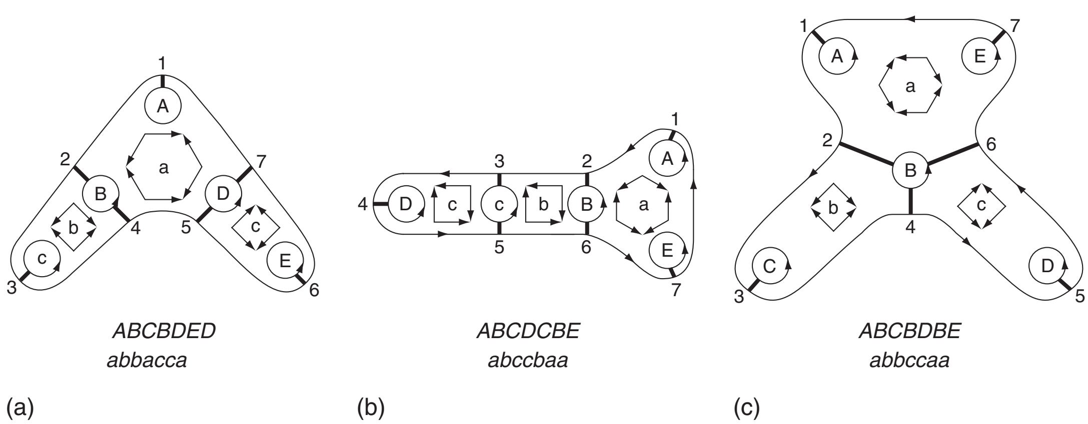

**Figure 9** Three inequivalent canonical forms of genus 8 are shown. Each is identified by a "period-7 orbit" and its dual. Reprinted figure with permission from *Physical Review E*, 69, 056206, 2004. Copyright (2004) by the American Physical Society.

holes that have singularities. Heavy lines are used to show the location of the seven components of the global Poincaré surface of section for each of the three inequivalent genus-8 canonical forms shown in Figure 9. The structure of the flow is summarized by a transition matrix. For the canonical form shown in Figure 9c the transition matrix is

$$T = \begin{bmatrix} 1 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix}$$

where $T_{i,j} = 1$ if the flow can proceed directly from component $i$ to component $j$, 0 otherwise.

Bounding tori, dressed with flows, can be labeled. In fact, two dual labeling schemes are possible. Following the outer boundary in the direction of the flow, one encounters the $g - 1$ components of the global Poincaré surface of section sequentially, the interior holes without singularities at least once each, and the interior holes with singularites at least twice each. The canonical form (genus-$g$ torus dressed with a flow) on the genus-8 bounding torus shown in Figure 9a can be labeled by the sequence in which the holes without singularities are encountered (*ABCBDED*) or the order in which the holes with singularities are encountered (*abbacca*). Both sequences contain $g - 1$ symbols. These labels are unique up to cyclic permutation.

Symbol sequences for canonical forms for bounding tori act in many ways like symbol sequences for periodic orbits on branched manifolds. Although there is a 1:1 correspondence between bounded closed two-dimensional surfaces in $R^3$ and genus $g$, the number of canonical forms grows rapidly with $g$, as shown in Table 4. In fact, the number, $N(g)$, grows exponentially and can even be assigned an entropy:

**Table 4** Number of canonical bounding tori as a function of genus $g$

| $g$ | $N(g)$ | $g$ | $N(g)$ | $g$ | $N(g)$ |
|---|---|---|---|---|---|
| 3 | 1 | 9 | 15 | 15 | 2 211 |
| 4 | 1 | 10 | 28 | 16 | 5 549 |
| 5 | 2 | 11 | 67 | 17 | 14 290 |
| 6 | 2 | 12 | 145 | 18 | 36 824 |
| 7 | 5 | 13 | 368 | 19 | 96 347 |
| 8 | 6 | 14 | 870 | 20 | 252 927 |

$$\lim_{g \to \infty} \frac{\ln(N(g))}{g - 1} = \ln 3 \qquad [5]$$

In some sense, canonical forms that constrain branched manifolds within them behave like branched manifolds that constrain periodic orbits on them.

Every strange attractor that has been studied in $R^3$ has been described by a canonical bounding torus that contains it. This classification is shown in Table 5.

Branched manifold perestroikas are constrained by bounding tori as follows. Each branch line of any branched manifold can be moved into one of the $g - 1$ components of the global Poincaré surface of section. Any branched manifold contained in a genus-$g$ bounding torus ($g \geq 3$) must have at least one branch between each pair of components of the global Poincaré surface of section between which the flow is allowed, as summarized by the canonical form's transition matrix. New branches can only be added in a way that is consistent with the canonical form's transition matrix, continuity requirements, and the no intersection condition.

**Table 5** All known strange attractors of dimension $d_L < 3$ are bounded by one of the standard dressed tori. Dual labels for the bounding tori depend on $g - 1$ symbols describing holes with or without singularities

| *Strange attractor* | *Holes w/o singularites* | *Holes with singularities* | *Genus* |
|---|---|---|---|
| Rossler, Duffing, Burke, and Shaw | $A$ | | 1 |
| Various lasers, gateau roulé | $A$ | | 1 |
| Neuron with subthreshold oscillations | $A$ | | 1 |
| Shaw–van der Pol | $A$ | | 1 |
| Lorenz, Shimizu–Morioka, Rikitake | $AB$ | $aa$ | 3 |
| $\mathcal{C}_2$ covers of Rossler | $AB$ | $a^2$ | 3 |
| $\mathcal{C}_2$ cover of Lorenz[a] | $ABCD$ | $a^4$ | 5 |
| $\mathcal{C}_2$ cover of Lorenz[b] | $ABCB$ | $abba$ | 5 |
| 2 → 1 Image of figure-8 branched manifold | $ABCB$ | $ab(ab)^{-1}$ | 5 |
| Figure-8 branched manifold | $AEBECEDE$ | $a^2b^2c^2d^2$ | 9 |
| $\mathcal{C}_n$ covers of Rossler | $AB \cdots N$ | $a^n$ | $n+1$ |
| $\mathcal{C}_n$ cover of Lorenz[a] | $AB \cdots (2N)$ | $a^{2n}$ | $2n+1$ |
| $\mathcal{C}_n$ cover of Lorenz[b] | $(AZ)(BZ) \cdots (NZ)$ | $a^2b^2 \cdots n^2$ | $2n+1$ |
| Multispiral attractors | $A(B \cdots M)N(B \cdots M)^{-1}$ | $(ab \cdots m)(ab \cdots m)^{-1}$ | $2m+1$ |

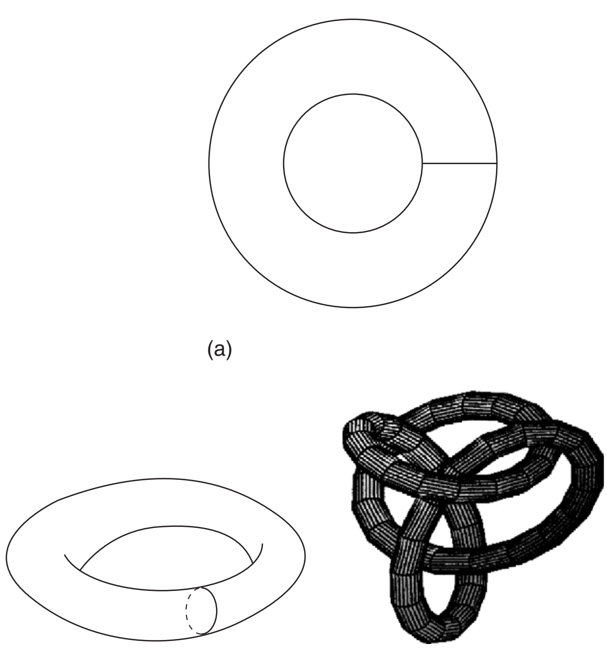
[a]Rotation axis through origin.
[b]Rotation axis through one focus.

In the simplest case, $g = 1$, a third branch can be added to a branched manifold with two branches only if its local torsion differs by $\pm 1$ from the adjacent branch. In addition, the ordering of the new branch must be consistent with the continuity and no intersection (ODE uniqueness theorem) requirements.

## Embeddings of Bounding Tori

The last level of topological structure needed for the classification of strange attractors in $R^3$ describes their embeddings in $R^3$. The classification using genus-$g$ bounding tori is intrinsic – that is, the canonical form shows how the flow looks from inside the torus. Strange attractors, and the tori that bound them, are actually embedded in $R^3$. For a complete classification, we must specify not only the canonical form but also how this form sits in $R^3$.

This program has not yet been completed, but we illustrate it with the genus-1 bounding torus in Figure 10. Figure 10a shows the canonical form, and two different embeddings of it in $R^3$. The embedding on the left is unknotted. The embedding on the right is knotted like a figure-8 knot. Extrinsic embeddings of genus-1 tori are described by tame knots in $R^3$, and tame knots can be used as "centerlines" for extrinsically embedded genus-1 tori. Higher-genus ($g \geq 3$) canonical forms – intrinsic genus-$g$ tori dressed with a canonical flow – have a larger (but discrete) variety of extrinsic embeddings in $R^3$.



(a) (b) (c)

**Figure 10** (a) Canonical form for genus-1 bounding torus. Extrinsic embeddings of the torus into $R^3$ that are (b) unknotted and (c) knotted like the figure-8 knot.

## The Embedding Question

The mechanism that nature uses to generate chaotic behavior in physical systems is not directly observable, and must be deduced by examining the data that are generated. Typically, the data consist of a single scalar time series that is discretely recorded: $x_i$, $i = 1, 2, \ldots$. In order to exhibit a strange attractor, a mapping of the data into $R^N$ must also be constructed. If the attractor is low dimensional ($d_L < 3$), one can hope that a mapping into $R^3$ can be constructed that exhibits no self-intersections or other degeneracies. Such a map is called an embedding. Once an embedding in $R^3$ is available, a topological analysis can be carried out. The analysis reveals the mechanism that underlies the creation of the embedded strange attractor.

But how do you know that the mechanism that generates the observed, embedded strange attractor has anything to do with the mechanism nature used to generate the experimental data?

If the embedding is contained in a genus-1 bounding torus, then the topological mechanism that generates the data, as defined by some unknown branched manifold $\mathcal{BM}_{\mathrm{EXP}}$, and the topological mechanism that is identified from the embedded strange attractor $\mathcal{BM}_{\mathrm{EMB}}$, are identical up to three degrees of freedom: parity, global torsion, and the knot type. As a result, in this case (genus-1) a topological analysis of embedded data does reveal nature's hidden secrets.

## Vector Bundles

Let $\mathrm{Vect}_k(M, \mathbb{F})$ be the set of isomorphism classes of real ($\mathbb{F} = \mathbb{R}$) or complex ($\mathbb{F} = \mathbb{C}$) vector bundles of rank $k$ over a smooth connected $m$-dimensional manifold $M$. Let

$$\mathrm{Vect}(M, \mathbb{F}) = \bigcup_k \mathrm{Vect}_k(M, \mathbb{F})$$

### Principal Bundles – Examples

Let $H$ be a Lie group. A fiber bundle

$$\rho : \mathcal{P} \to M$$

with fiber $H$ is said to be a principal bundle if there is a right action of $H$ on $\mathcal{P}$ which acts transitively on the fibers, that is, if $\mathcal{P}/H = M$. If $H$ is a closed subgroup of a Lie group $G$, then the natural projection $G \to G/H$ is a principal $H$ bundle over the homogeneous space $G/H$. Let $\mathrm{O}(k)$ and $\mathrm{U}(k)$ denote the orthogonal and unitary groups, respectively. Let $S^k$ denote the unit sphere in $\mathbb{R}^{k+1}$. Then we have natural principal bundles:

$$\mathrm{O}(k) \subset \mathrm{O}(k+1) \to S^k$$
$$\mathrm{U}(k) \subset \mathrm{U}(k+1) \to S^{2k+1}$$

Let $\mathbb{RP}^k$ and $\mathbb{CP}^k$ denote the real and complex projective spaces of lines through the origin in $\mathbb{R}^{k+1}$ and $\mathbb{C}^{k+1}$, respectively. Let

$$\mathbb{Z}_2 = \{\pm \mathrm{Id}\} \subset \mathrm{O}(k)$$
$$S^1 = \{\lambda \cdot \mathrm{Id} : |\lambda| = 1\} \subset \mathrm{U}(k)$$

One has $\mathbb{Z}_2$ and $S^1$ principal bundles:

$$\mathbb{Z}_2 \to S^{k-1} \to \mathbb{RP}^{k-1}$$
$$S^1 \to S^{2k-1} \to \mathbb{CP}^{k-1}$$

### Frames

A frame $\mathbf{s} := (s_1, \ldots, s_k)$ for $V \in \mathrm{Vect}_k(M, \mathbb{F})$ over an open set $\mathcal{O} \subset M$ is a collection of $k$ smooth sections to $V|_{\mathcal{O}}$ so that $\{s_1(P), \ldots, s_k(P)\}$ is a basis for the fiber $V_P$ of $V$ over any point $P \in \mathcal{O}$. Given such a frame $\mathbf{s}$, we can construct a local trivialization which identifies $\mathcal{O} \times \mathbb{F}^k$ with $V|_{\mathcal{O}}$ by the mapping

$$(P; \lambda_1, \ldots, \lambda_k) \to \lambda_1 s_1(P) + \cdots + \lambda_k s_k(P)$$

Conversely, given a local trivialization of $V$, we can take the coordinate frame

$$s_i(P) = P \times (0, \ldots, 0, 1, 0, \ldots, 0)$$

Thus, frames and local trivializations of $V$ are equivalent notions.

### Simple Covers

An open cover $\{\mathcal{O}_\alpha\}$ of $M$, where $\alpha$ ranges over some indexing set $A$, is said to be a simple cover if any finite intersection $\mathcal{O}_{\alpha_1} \cap \cdots \cap \mathcal{O}_{\alpha_k}$ is either empty or contractible.

Simple covers always exist. Put a Riemannian metric on $M$. If $M$ is compact, then there exists a uniform $\delta > 0$ so that any geodesic ball of radius $\delta$ is geodesically convex. The intersection of geodesically convex sets is either geodesically convex (and hence contractible) or empty. Thus, covering $M$ by a finite number of balls of radius $\delta$ yields a simple cover. The argument is similar even if $M$ is not compact where an infinite number of geodesic balls is used and the radii are allowed to shrink near $\infty$.

### Transition Cocycles

Let $\mathrm{Hom}(\mathbb{F}, k)$ be the set of linear transformations of $\mathbb{F}^k$ and let $\mathrm{GL}(\mathbb{F}, k) \subset \mathrm{Hom}(\mathbb{F}, k)$ be the group of all invertible linear transformations.

Let $\{\mathbf{s}_\alpha\}$ be frames for a vector bundle $V$ over some open cover $\{\mathcal{O}_\alpha\}$ of $M$. On the intersection $\mathcal{O}_\alpha \cap \mathcal{O}_\beta$, one may express $\mathbf{s}_\alpha = \psi_{\alpha\beta} \mathbf{s}_\beta$, that is

$$s_{\alpha,i}(P) = \sum_{1 \le j \le k} {\psi_{\alpha\beta,i}}^j(P) s_{\beta,j}(P)$$

## Vector Bundles

Let $\text{Vect}_k(M, \mathbb{F})$ be the set of isomorphism classes of real ($\mathbb{F} = \mathbb{R}$) or complex ($\mathbb{F} = \mathbb{C}$) vector bundles of rank $k$ over a smooth connected $m$-dimensional manifold $M$. Let

$$\text{Vect}(M, \mathbb{F}) = \bigcup_k \text{Vect}_k(M, \mathbb{F})$$

### Principal Bundles – Examples

Let $H$ be a Lie group. A fiber bundle

$$\rho : \mathcal{P} \to M$$

with fiber $H$ is said to be a principal bundle if there is a right action of $H$ on $\mathcal{P}$ which acts transitively on the fibers, that is, if $\mathcal{P}/H = M$. If $H$ is a closed subgroup of a Lie group $G$, then the natural projection $G \to G/H$ is a principal $H$ bundle over the homogeneous space $G/H$. Let $\text{O}(k)$ and $\text{U}(k)$ denote the orthogonal and unitary groups, respectively. Let $S^k$ denote the unit sphere in $\mathbb{R}^{k+1}$. Then we have natural principal bundles:

$$\text{O}(k) \subset \text{O}(k+1) \to S^k$$
$$\text{U}(k) \subset \text{U}(k+1) \to S^{2k+1}$$

Let $\mathbb{RP}^k$ and $\mathbb{CP}^k$ denote the real and complex projective spaces of lines through the origin in $\mathbb{R}^{k+1}$ and $\mathbb{C}^{k+1}$, respectively. Let

$$\mathbb{Z}_2 = \{\pm\text{Id}\} \subset \text{O}(k)$$
$$S^1 = \{\lambda \cdot \text{Id} : |\lambda| = 1\} \subset \text{U}(k)$$

One has $\mathbb{Z}_2$ and $S^1$ principal bundles:

$$\mathbb{Z}_2 \to S^{k-1} \to \mathbb{RP}^{k-1}$$
$$S^1 \to S^{2k-1} \to \mathbb{CP}^{k-1}$$

### Frames

A frame $s := (s_1, \ldots, s_k)$ for $V \in \text{Vect}_k(M, \mathbb{F})$ over an open set $\mathcal{O} \subset M$ is a collection of $k$ smooth sections to $V|_{\mathcal{O}}$ so that $\{s_1(P), \ldots, s_k(P)\}$ is a basis for the fiber $V_P$ of $V$ over any point $P \in \mathcal{O}$. Given such a frame $s$, we can construct a local trivialization which identifies $\mathcal{O} \times \mathbb{F}^k$ with $V|_{\mathcal{O}}$ by the mapping

$$(P; \lambda_1, \ldots, \lambda_k) \to \lambda_1 s_1(P) + \cdots + \lambda_k s_k(P)$$

Conversely, given a local trivialization of $V$, we can take the coordinate frame

$$s_i(P) = P \times (0, \ldots, 0, 1, 0, \ldots, 0)$$

Thus, frames and local trivializations of $V$ are equivalent notions.

### Simple Covers

An open cover $\{\mathcal{O}_\alpha\}$ of $M$, where $\alpha$ ranges over some indexing set $A$, is said to be a simple cover if any finite intersection $\mathcal{O}_{\alpha_1} \cap \cdots \cap \mathcal{O}_{\alpha_k}$ is either empty or contractible.

Simple covers always exist. Put a Riemannian metric on $M$. If $M$ is compact, then there exists a uniform $\delta > 0$ so that any geodesic ball of radius $\delta$ is geodesically convex. The intersection of geodesically convex sets is either geodesically convex (and hence contractible) or empty. Thus, covering $M$ by a finite number of balls of radius $\delta$ yields a simple cover. The argument is similar even if $M$ is not compact where an infinite number of geodesic balls is used and the radii are allowed to shrink near $\infty$.

### Transition Cocycles

Let $\text{Hom}(\mathbb{F}, k)$ be the set of linear transformations of $\mathbb{F}^k$ and let $\text{GL}(\mathbb{F}, k) \subset \text{Hom}(\mathbb{F}, k)$ be the group of all invertible linear transformations.

Let $\{s_\alpha\}$ be frames for a vector bundle $V$ over some open cover $\{\mathcal{O}_\alpha\}$ of $M$. On the intersection $\mathcal{O}_\alpha \cap \mathcal{O}_\beta$, one may express $s_\alpha = \psi_{\alpha\beta} s_\beta$, that is

$$s_{\alpha,i}(P) = \sum_{1 \le j \le k} \psi_{\alpha\beta,i}{}^j(P) s_{\beta,j}(P)$$

The maps $\psi_{\alpha\beta}: \mathcal{O}_\alpha \cap \mathcal{O}_\beta \to \mathrm{GL}(\mathbb{F}, k)$ satisfy

$$\begin{aligned} &\psi_{\alpha\alpha} = \mathrm{Id} \quad \text{on } \mathcal{O}_\alpha \\ &\psi_{\alpha\beta} = \psi_{\alpha\gamma}\psi_{\gamma\beta} \quad \text{on } \mathcal{O}_\alpha \cap \mathcal{O}_\beta \cap \mathcal{O}_\gamma \end{aligned} \qquad [1]$$

Let $G$ be a Lie group. Maps belonging to a collection $\{\psi_{\alpha\beta}\}$ of smooth maps from $\mathcal{O}_\alpha \cap \mathcal{O}_\beta$ to $G$ which satisfy eqn [1] are said to be transition cocycles with values in $G$; if $G \subset \mathrm{GL}(\mathbb{F}, k)$, they can be used to define a vector bundle by making appropriate identifications.

### Reducing the Structure Group

If $G$ is a subgroup of $\mathrm{GL}(\mathbb{F}, k)$, then $V$ is said to have a $G$-structure if we can choose frames so the transition cocycles belong to $G$; that is, we can reduce the structure group to $G$.

Denote the subgroup of orientation-preserving linear maps by

$$\mathrm{GL}^+(\mathbb{R}, k) := \{\psi \in \mathrm{GL}(\mathbb{R}, k): \det(\psi) > 0\}$$

If $V \in \mathrm{Vect}_k(M, \mathbb{R})$, then $V$ is said to be orientable if we can choose the frames so that

$$\psi_{\alpha\beta} \in \mathrm{GL}^+(\mathbb{R}, k)$$

Not every real vector bundle is orientable; the first Stiefel–Whitney class $sw_1(V) \in H^1(M; \mathbb{Z}_2)$, which is defined later, vanishes if and only if $V$ is orientable. In particular, the Möbius line bundle over the circle is not orientable.

Similarly, a real (resp. complex) bundle $V$ is said to be Riemannian (resp. Hermitian) if we can reduce the structure group to the orthogonal group $\mathrm{O}(k) \subset \mathrm{GL}(\mathbb{R}, k)$ (resp. to the unitary group $\mathrm{U}(k) \subset \mathrm{GL}(\mathbb{C}, k)$).

We can use a partition of unity to put a positive-definite symmetric (resp. Hermitian symmetric) fiber metric on $V$. Applying the Gram–Schmidt process then constructs orthonormal frames and shows that the structure group can always be reduced to $\mathrm{O}(k)$ (resp. to $\mathrm{U}(k)$); if $V$ is a real vector bundle, then the structure group can be reduced to the special orthogonal group $\mathrm{SO}(k)$ if and only if $V$ is orientable.

### Lifting the Structure Group

Let $\tau$ be a representation of a Lie group $H$ to $\mathrm{GL}(\mathbb{F}, k)$. One says that the structure group of $V$ can be lifted to $H$ if there exist frames $\{s_\alpha\}$ for $V$ and smooth maps $\phi_{\alpha\beta}: \mathcal{O}_\alpha \cap \mathcal{O}_\beta \to H$, so $\tau\phi_{\alpha\beta} = \psi_{\alpha\beta}$ where eqn [1] holds for $\phi$.

### Spin Structures

For $k \geq 3$, the fundamental group of $\mathrm{SO}(k)$ is $\mathbb{Z}_2$. Let $\mathrm{Spin}(k)$ be the universal cover of $\mathrm{SO}(k)$ and let

$$\tau : \mathrm{Spin}(k) \to \mathrm{SO}(k)$$

be the associated double cover; set $\mathrm{Spin}(2) = S^1$ and let $\tau(\lambda) = \lambda^2$. An oriented bundle $V$ is said to be spin if the transition functions can be lifted from $\mathrm{SO}(k)$ to $\mathrm{Spin}(k)$; this is possible if and only if the second Stiefel–Whitney class of $V$, which is defined later, vanishes. There can be inequivalent spin structures, which are parametrized by the cohomology group $H^1(M; \mathbb{Z}_2)$.

### The Tangent Bundle of Projective Space

The tangent bundle $T\mathbb{RP}^m$ of real projective space is orientable if and only if $m$ is odd; $T\mathbb{RP}^m$ is spin if and only if $m \equiv 3 \bmod 4$. If $m \equiv 3 \bmod 4$, there are two inequivalent spin structures on this bundle as $H^1(\mathbb{RP}^m; \mathbb{Z}_2) = \mathbb{Z}_2$.

The tangent bundle $T\mathbb{CP}^m$ of complex projective space is always orientable; $T\mathbb{CP}^m$ is spin if and only if $m$ is odd.

### Principal and Associated Bundles

Let $H$ be a Lie group and let

$$\phi_{\alpha\beta} : \mathcal{O}_\alpha \cap \mathcal{O}_\beta \to H$$

be a collection of smooth functions satisfying the compatibility conditions given in eqn [1]. We define a principal bundle $\mathcal{P}$ by gluing $\mathcal{O}_\alpha \times H$ to $\mathcal{O}_\beta \times H$ using $\phi$:

$$(P, h)_\alpha \sim (P, \phi_{\alpha\beta}(P)h)_\beta \quad \text{for } P \in \mathcal{O}_\alpha \cap \mathcal{O}_\beta$$

Because right multiplication and left multiplication commute, right multiplication gives a natural action of $H$ on $\mathcal{P}$:

$$(P, h)_\alpha \cdot \tilde{h} := (P, h \cdot \tilde{h})_\alpha$$

The natural projection $\mathcal{P} \to \mathcal{P}/H = M$ is an $H$ fiber bundle.

Let $\tau$ be a representation of $H$ to $\mathrm{GL}(\mathbb{F}, k)$. For $\xi \in \mathcal{P}, \lambda \in \mathbb{F}^k$, and $h \in H$, define a gluing

$$(\xi, \lambda) \sim (\xi \cdot h^{-1}, \tau(h)\lambda)$$

The associated vector bundle is then given by

$$\mathcal{P} \times_\tau \mathbb{F}^k := \mathcal{P} \times \mathbb{F}^k / \sim$$

Clearly, $\{\tau\phi_{\alpha\beta}\}$ are the transition cocycles of the vector bundle $\mathcal{P} \times_\tau \mathbb{F}^k$.

### Frame Bundles

If $V$ is a vector bundle, the associated principal $\mathrm{GL}(\mathbb{F}, k)$ bundle is the bundle of all frames; if $V$ is given an inner product on each fiber, then the associated principal $\mathrm{O}(k)$ or $\mathrm{U}(k)$ bundle is the bundle of orthonormal frames. If $V$ is an oriented Riemannian vector bundle, the associated principal $\mathrm{SO}(k)$ bundle is the bundle of oriented orthonormal frames.

### Direct Sum and Tensor Product

Fiber-wise direct sum (resp. tensor product) defines the direct sum (resp. tensor product) of vector bundles:

$$\begin{aligned} \oplus : &\mathrm{Vect}_k(M, \mathbb{F}) \times \mathrm{Vect}_n(M, \mathbb{F}) \\ &\to \mathrm{Vect}_{k+n}(M, \mathbb{F}) \\ \otimes : &\mathrm{Vect}_k(M, \mathbb{F}) \times \mathrm{Vect}_n(M, \mathbb{F}) \\ &\to \mathrm{Vect}_{kn}(M, \mathbb{F}) \end{aligned}$$

The transition cocycles of the direct sum (resp. tensor product) of two vector bundles are the direct sum (resp. tensor product) of the transition cocycles of the respective bundles.

The set of line bundles $\mathrm{Vect}_1(M, \mathbb{F})$ is a group under $\otimes$. The unit in the group is the trivial line bundle $\mathbb{1} := M \times \mathbb{F}$; the inverse of a line bundle $L$ is the dual line bundle $L^* := \mathrm{Hom}(L, \mathbb{F})$ since

$$L \otimes L^* = \mathbb{1}$$

### Pullback Bundle

Let $\rho : V \to M$ be the projection associated with $V \in \mathrm{Vect}_k(M, \mathbb{F})$. If $f$ is a smooth map from $N$ to $M$, then the pullback bundle $f^*V$ is the vector bundle over $N$ which is defined by setting

$$f^*V := \{(P, v) \in N \times V : f(P) = \rho(v)\}$$

The fiber of $f^*V$ over $P$ is the fiber of $V$ over $f(P)$.

Let $\{s_\alpha\}$ be local frames for $V$ over an open cover $\{\mathcal{O}_\alpha\}$ of $M$. For $P \in f^{-1}(\mathcal{O}_\alpha)$, define

$$\{f^* s_\alpha\}(P) := (P, s_\alpha(f(P)))$$

This gives a collection of frames for $f^*V$ over the open cover $\{f^{-1}(\mathcal{O}_\alpha)\}$ of $N$. Let

$$f^*\psi_{\alpha\beta} := \psi_{\alpha\beta} \circ f$$

be the pullback of the transition functions. Then

$$\begin{aligned} \{f^* s_\alpha\}(P) &= (P, \psi_{\alpha\beta}(f(P)) s_\beta(f(P))) \\ &= \{(f^*\psi_{\alpha\beta})(f^* s_\beta)\}(P) \end{aligned}$$

This shows that the pullback of the transition functions for $V$ are the transition functions of the pullback $f^*(V)$.

### Homotopy

Two smooth maps $f_0$ and $f_1$ from $N$ to $M$ are said to be homotopic if there exists a smooth map $F : N \times I \to M$ so that $f_0(P) = F(P, 0)$ and so that $f_1(P) = F(P, 1)$. If $f_0$ and $f_1$ are homotopic maps from $N$ to $M$, then $f_1^*V$ is isomorphic to $f_2^*V$.

Let $[N, M]$ be the set of all homotopy classes of smooth maps from $N$ to $M$. The association $V \to f^*V$ induces a natural map

$$[N, M] \times \mathrm{Vect}_k(M, \mathbb{F}) \to \mathrm{Vect}_k(N, \mathbb{F})$$

If $M$ is contractible, then the identity map is homotopic to the constant map $c$. Consequently, $V = \mathrm{Id}^*V$ is isomorphic to $c^*V = M \times \mathbb{F}^k$. Thus, any vector bundle over a contractible manifold is trivial. In particular, if $\{\mathcal{O}_\alpha\}$ is a simple cover of $M$ and if $V \in \mathrm{Vect}(M, \mathbb{F})$, then $V|_{\mathcal{O}_\alpha}$ is trivial for each $\alpha$. This shows that a simple cover is a trivializing cover for every $V \in \mathrm{Vect}(M, \mathbb{F})$.

### Stabilization

Let $\mathbb{1} \in \mathrm{Vect}_1(M, \mathbb{F})$ denote the isomorphism class of the trivial line bundle $M \times \mathbb{F}$ over an $m$-dimensional manifold $M$. The map $V \to V \oplus \mathbb{1}$ induces a stabilization map

$$s : \mathrm{Vect}_k(M, \mathbb{F}) \to \mathrm{Vect}_{k+1}(M, \mathbb{F})$$

which induces an isomorphism

$$\begin{aligned} &\mathrm{Vect}_k(M, \mathbb{R}) = \mathrm{Vect}_{k+1}(M, \mathbb{R}) \quad \text{for } k > m \\ &\mathrm{Vect}_k(M, \mathbb{C}) = \mathrm{Vect}_{k+1}(M, \mathbb{C}) \quad \text{for } 2k > m \end{aligned} \qquad [2]$$

These values of $k$ comprise the stable range.

### The *K*-Theory

The direct sum $\oplus$ and tensor product $\otimes$ make $\mathrm{Vect}(M, \mathbb{F})$ into a semiring; we denote the associated ring defined by the Grothendieck construction by $\mathrm{K}\mathbb{F}(M)$. If $V \in \mathrm{Vect}(M, \mathbb{F})$, let $[V] \in \mathrm{K}\mathbb{F}(M)$ be the corresponding element of $K$-theory; $\mathrm{K}\mathbb{F}(M)$ is generated by formal differences $[V_1] - [V_2]$; such formal differences are called virtual bundles.

The Grothendieck construction (*see* $K$-theory) introduces nontrivial relations. Let $S^m$ denote the standard sphere in $\mathbb{R}^{m+1}$. Since

$$T(S^m) \oplus \mathbb{1} = (m+1)\mathbb{1}$$

we can easily see that $[TS^m] = m[\mathbb{1}]$ in $\mathrm{K}\mathbb{R}(S^m)$, despite the fact that $T(S^m)$ is not isomorphic to $m\mathbb{1}$ for $m \neq 1, 3, 7$.

Let $L$ denote the nontrivial real line bundle over $\mathbb{RP}^k$. Then $T\mathbb{RP}^k \oplus \mathbb{1} = (k+1)L$, so

$$[T\mathbb{RP}^k] = (k+1)[L] - [\mathbb{1}]$$

The map $V \to \text{Rank}(V)$ extends to a surjective map from $\text{K}\mathbb{F}(M)$ to $\mathbb{Z}$. We denote the associated ideal of virtual bundles of virtual rank 0 by

$$\widetilde{\text{K}\mathbb{F}}(M) := \ker(\text{Rank})$$

In the stable range, $V \to [V] - k[\mathbb{1}]$ identifies

$$\begin{aligned} \text{Vect}_k(M,\mathbb{R}) &= \widetilde{\text{K}\mathbb{R}}(M) \quad \text{if } k > m \\ \text{Vect}_k(M,\mathbb{C}) &= \widetilde{\text{K}\mathbb{C}}(M) \quad \text{if } 2k > m \end{aligned} \qquad [3]$$

These groups contain nontrivial torsion. Let $L$ be the nontrivial real line bundle over $\mathbb{RP}^k$. Then

$$\widetilde{\text{K}\mathbb{R}}(\mathbb{RP}^k) = \mathbb{Z}\cdot\{[L]-[\mathbb{1}]\}/2^{\nu(k)}\mathbb{Z}\{[L]-[\mathbb{1}]\}$$

where $\nu(k)$ is the Adams number.

### Classifying Spaces

Let $\text{Gr}_k(\mathbb{F},n)$ be the Grassmannian of $k$-dimensional subspaces of $\mathbb{F}^n$. By mapping a $k$-plane $\pi$ in $\mathbb{F}^n$ to the corresponding orthogonal projection on $\pi$, we can identify $\text{Gr}_k(\mathbb{F},n)$ with the set of orthogonal projections of rank $k$:

$$\{\xi \in \text{Hom}(\mathbb{F}^n)\colon \xi^2 = \xi,\ \xi^* = \xi,\ \text{tr}(\xi) = k\}$$

There is a natural associated tautological $k$-plane bundle

$$V_k(\mathbb{F},n) \in \text{Vect}_k(\text{Gr}_k(\mathbb{F},n),\mathbb{F})$$

whose fiber over a $k$-plane $\pi$ is the $k$-plane itself:

$$V_k(\mathbb{F},n) := \{(\xi,x) \in \text{Hom}(\mathbb{F}^n)\times\mathbb{F}^n : \xi x = x\}$$

Let $[M,\text{Gr}_k(\mathbb{F},n)]$ denote the set of homotopy equivalence classes of smooth maps $f$ from $M$ to $\text{Gr}_k(\mathbb{F},n)$. Since $[f_1]=[f_2]$ implies that $f_1^*V$ is isomorphic to $f_2^*V$, the association

$$f \to f^*V_k(\mathbb{F},n) \in \text{Vect}_k(M,\mathbb{F})$$

induces a map

$$[M,\text{Gr}_k(\mathbb{F},n)] \to \text{Vect}_k(M,\mathbb{F})$$

This map defines a natural equivalence of functors in the stable range:

$$\begin{aligned} [M,\text{Gr}_k(\mathbb{R},\nu+k)] &= \text{Vect}_k(M,\mathbb{R}) \quad \text{for } \nu > m \\ [M,\text{Gr}_k(\mathbb{C},\nu+k)] &= \text{Vect}_k(M,\mathbb{C}) \quad \text{for } 2\nu > m \end{aligned} \qquad [4]$$

The natural inclusion of $\mathbb{F}^n$ in $\mathbb{F}^{n+1}$ induces natural inclusions

$$\begin{aligned} \text{Gr}_k(\mathbb{F},n) &\subset \text{Gr}_k(\mathbb{F},n+1) \\ V_k(\mathbb{F},n) &\subset V_k(\mathbb{F},n+1) \end{aligned} \qquad [5]$$

Let $\text{Gr}_k(\mathbb{F},\infty)$ and $V_k(\mathbb{F},\infty)$ be the direct limit spaces under these inclusions; these are the infinite-dimensional Grassmannians and classifying bundles, respectively. The topology on these spaces is the weak or inductive topology. The Grassmannians are called classifying spaces. The isomorphisms of eqn [4] are compatible with the inclusions of eqn [5] and we have

$$[M,\text{Gr}_k(\mathbb{F},\infty)] = \text{Vect}_k(M,\mathbb{F}) \qquad [6]$$

### Spaces with Finite Covering Dimension

A metric space $X$ is said to have a covering dimension at most m if, given any open cover $\{\mathcal{U}_\alpha\}$ of $X$, there exists a refinement $\{\mathcal{O}_\beta\}$ of the cover so that any intersection of more than $m+1$ of the $\{\mathcal{O}_\beta\}$ is empty. For example, any manifold of dimension $m$ has covering dimension at most $m$. More generally, any $m$-dimensional cell complex has covering dimension at most $m$.

The isomorphisms of [2]–[4], and [6] continue to hold under the weaker assumption that $M$ is a metric space with covering dimension at most $m$.

## Characteristic Classes of Vector Bundles

### The Cohomology of $\text{Gr}_k(\mathbb{F},\infty)$

The cohomology algebras of the Grassmannians are polynomial algebras on suitably chosen generators:

$$\begin{aligned} H^*(\text{Gr}_k(\mathbb{R},\infty);\mathbb{Z}_2) &= \mathbb{Z}_2[\text{sw}_1,\ldots,\text{sw}_k] \\ H^*(\text{Gr}_k(\mathbb{C},\infty);\mathbb{Z}) &= \mathbb{Z}[c_1,\ldots,c_k] \end{aligned} \qquad [7]$$

### The Stiefel–Whitney Classes

Let $V \in \text{Vect}_k(M,\mathbb{R})$. We use eqn [6] to find $\Psi : M \to \text{Gr}_k(\mathbb{R},\infty)$ which classifies $V$; the map $\Psi$ is uniquely determined up to homotopy and, using eqn [7], one sets

$$\text{sw}_i(V) := \Psi^*\text{sw}_i \in H^i(M;\mathbb{Z}_2)$$

The total Stiefel–Whitney class is then defined by

$$\text{sw}(V) = 1 + \text{sw}_1(V) + \cdots + \text{sw}_k(V)$$

The Stiefel–Whitney class has the properties:

1. If $f : X_1 \to X_2$, then $f^*(\text{sw}(V)) = \text{sw}(f^*V)$.
2. $\text{sw}(V \oplus W) = \text{sw}(V)\text{sw}(W)$.
3. If $L$ is the Möbius bundle over $S^1$, then $sw_1(L)$ generates $H^1(S^1;\mathbb{Z}_2) = \mathbb{Z}_2$.

The cohomology algebra of real projective space is a truncated polynomial algebra:

$$H^*(\mathbb{RP}^k;\mathbb{Z}_2) = \mathbb{Z}_2[x]/x^{k+1} = 0$$

Since $T\mathbb{RP}^k \oplus 1 = (k+1)L$, one has

$$\begin{aligned}\mathrm{sw}(T\mathbb{RP}^k) &= (1+x)^{k+1} \\ &= 1 + kx + \frac{(k+1)k}{2}x^2 + \cdots \end{aligned} \qquad [8]$$

### Orientability and Spin Structures

The Stiefel–Whitney classes have real geometric meaning. For example, $\mathrm{sw}_1(V) = 0$ if and only if $V$ is orientable; if $\mathrm{sw}_1(V) = 0$, then $\mathrm{sw}_2(V) = 0$ if and only if $V$ admits a spin structure. With reference to the discussion on the tangent bundle or projective space, eqn [8] yields

$$\mathrm{sw}_1(T\mathbb{RP}^k) = \begin{cases} 0 & \text{if } k \equiv 0 \bmod 2 \\ x & \text{if } k \equiv 1 \bmod 2 \end{cases}$$

Thus, $\mathbb{RP}^k$ is orientable if and only if $k$ is odd. Furthermore,

$$\mathrm{sw}_2(T\mathbb{RP}^k) = \begin{cases} 0 & \text{if } k \equiv 3 \bmod 4 \\ x & \text{if } k \equiv 1 \bmod 4 \end{cases}$$

Thus, $T\mathbb{RP}^k$ is spin if and only if $k \equiv 3 \bmod 4$.

### Chern Classes

Let $V \in \mathrm{Vect}_k(M, \mathbb{C})$. We use eqn [6] to find $\Psi : M \to \mathrm{Gr}_k(\mathbb{C}, \infty)$ which classifies $V$; the map $\Psi$ is uniquely determined up to homotopy and, using eqn [7], one sets

$$c_i(V) := \Psi^* c_i \in H^{2i}(M; \mathbb{Z})$$

The total Chern class is then defined by

$$c(V) := 1 + c_1(V) + \cdots + c_k(V)$$

The Chern class has the properties:

1. If $f : X_1 \to X_2$, then $f^*(c(V)) = c(f^*V)$.
2. $c(V \oplus W) = c(V)c(W)$.
3. Let $L$ be the classifying line bundle over $S^2 = \mathbb{CP}^1$. Then $\int_{S^2} c_1(L) = -1$.

The cohomology algebra of complex projective space also is a truncated polynomial algebra

$$H^*(\mathbb{CP}^k; \mathbb{Z}) = \mathbb{Z}[x]/x^{k+1}$$

where $x = c_1(L)$ and $L$ is the complex classifying line bundle over $\mathbb{CP}^k = \mathrm{Gr}_1(\mathbb{C}, k+1)$. If $T_c\mathbb{CP}^k$ is the complex tangent bundle, then

$$c(T_c\mathbb{CP}^k) = (1+x)^{k+1}$$

### The Pontrjagin Classes

Let $V$ be a real vector bundle over a topological space $X$ of rank $r = 2k$ or $r = 2k+1$. The Pontrjagin classes $p_i(V) \in H^{4i}(X; \mathbb{Z})$ are characterized by the properties:

1. $p(V) = 1 + p_1(V) + \cdots + p_k(V)$.
2. If $f : X_1 \to X_2$, then $f^*(p(V)) = p(f^*V)$.
3. $p(V \oplus W) = p(V)p(W)$ mod elements of order 2.
4. $\int_{\mathbb{CP}^2} p_1(T\mathbb{CP}^2) = 3$.

We can complexify a real vector bundle $V$ to construct an associated complex vector bundle $V_{\mathbb{C}}$. We have

$$p_i(V) := (-1)^i c_{2i}(V_{\mathbb{C}})$$

Conversely, if $V$ is a complex vector bundle, we can construct an underlying real vector bundle $V_{\mathbb{R}}$ by forgetting the underlying complex structure. Modulo elements of order 2, we have

$$p(V_{\mathbb{R}}) = c(V)c(V^*)$$

Let $T\mathbb{CP}^k$ be the real tangent bundle of complex projective space. Then

$$p(T\mathbb{CP}^k) = (1 - x^2)^{k+1}$$

### Line Bundles

Tensor product makes $\mathrm{Vect}_1(M, \mathbb{F})$ into an abelian group. One has natural equivalences of functors which are group homomorphisms:

$$\begin{aligned} \mathrm{sw}_1 &: \mathrm{Vect}_1(M, \mathbb{R}) \to H^1(M; \mathbb{Z}_2) \\ c_1 &: \mathrm{Vect}_1(M, \mathbb{C}) \to H^2(M; \mathbb{Z}) \end{aligned}$$

A real line bundle $L$ is trivial if and only if it is orientable or, equivalently, if $\mathrm{sw}_1(L)$ vanishes. A complex line bundle $L$ is trivial if and only if $c_1(L) = 0$. There are nontrivial vector bundles with vanishing Stiefel–Whitney classes of rank $k > 1$. For example, $\mathrm{sw}_i(TS^k) = 0$ for $i > 0$ despite the fact that $TS^k$ is trivial if and only if $k = 1, 3, 7$.

## Curvature and Characteristic Classes

### de Rham Cohomology

We can replace the coefficient group $\mathbb{Z}$ by $\mathbb{C}$ at the cost of losing information concerning torsion. Thus, we may regard $p_i(V) \in H^{4i}(M; \mathbb{C})$ if $V$ is real or $c_i(V) \in H^{2i}(M; \mathbb{C})$ if $V$ is complex. Let $M$ be a smooth manifold. Let $C^\infty \Lambda^p M$ be the space of smooth $p$-forms and let

$$d : C^\infty \Lambda^p M \to C^\infty \Lambda^{p+1} M$$

be the exterior derivative. The de Rham cohomology groups are then defined by

$$H^p_{\mathrm{deR}}(M) := \frac{\ker(d : C^\infty\Lambda^p M \to C^\infty\Lambda^{p+1}M)}{\mathrm{im}(d : C^\infty\Lambda^{p-1}M \to C^\infty\Lambda^p M)}$$

The de Rham theorem identifies the topological cohomology groups $H^p(M;\mathbb{C})$ with the de Rham cohomology groups $H^p_{\mathrm{deR}}(M)$ which are given differential geometrically.

Given a connection on $V$, the Chern–Weyl theory enables us to compute Pontrjagin and Chern classes in de Rham cohomology in terms of curvature.

### Connections

Let $V$ be a vector bundle over $M$. A connection

$$\nabla : C^\infty(V) \to C^\infty(T^*M \otimes V)$$

on $V$ is a first-order partial differential operator which satisfies the Leibnitz rule, that is, if $s$ is a smooth section to $V$ and if $f$ is a smooth function on $M$,

$$\nabla(fs) = \mathrm{d}f \otimes s + f\nabla s$$

If $X$ is a tangent vector field, we define

$$\nabla_X s = \langle X, \nabla s\rangle$$

where $\langle\cdot,\cdot\rangle$ denotes the natural pairing between the tangent and cotangent spaces. This generalizes to the bundle setting the notion of a directional derivative and has the properties:

1. $\nabla_{fX}s = f\nabla_X s$.
2. $\nabla_X(fs) = X(f)s + f\nabla_X s$.
3. $\nabla_{X_1+X_2}s = \nabla_{X_1}s + \nabla_{X_2}s$.
4. $\nabla_X(s_1 + s_2) = \nabla_X s_1 + \nabla_X s_2$.

### The Curvature 2-Form

Let $\omega_p$ be a smooth $p$-form. Then

$$\nabla : C^\infty(\Lambda^p M \otimes V) \to C^\infty(\Lambda^{p+1}M \otimes V)$$

can be extended by defining

$$\nabla(\omega_p \otimes s) = \mathrm{d}\omega_p \otimes s + (-1)^p\omega_p \wedge \nabla s$$

In contrast to ordinary exterior differentiation, $\nabla^2$ need not vanish. We set

$$\Omega(s) := \nabla^2 s$$

This is not a second-order partial differential operator; it is a zeroth-order operator, that is,

$$\begin{aligned}\Omega(fs) &= \mathrm{dd}f \otimes s - \mathrm{d}f \wedge \nabla s + \mathrm{d}f \wedge \nabla s + f\nabla^2 s\\ &= f\Omega(s)\end{aligned}$$

The curvature operator $\Omega$ can also be computed locally. Let $(s_i)$ be a local frame. Expand

$$\nabla s_i = \sum_j \omega_i^j \otimes s_j$$

to define the connection 1-form $\omega$. One then has

$$\nabla^2 s_i = \left(\mathrm{d}\omega_i^j - \omega_i^k \wedge \omega_k^j\right) \otimes s_k$$

and so

$$\Omega_i^j = \mathrm{d}\omega_i^j - \omega_i^k \wedge \omega_k^j$$

If $\tilde{s} = \psi_i^{js} j$ is another local frame, we compute

$$\tilde{\omega} = \mathrm{d}gg^{-1} + g\omega g^{-1} \quad \text{and} \quad \tilde{\Omega} = g\Omega g^{-1}$$

Although the connection 1-form $\omega$ is not tensorial, the curvature is an invariantly defined 2-form-valued endomorphism of $V$.

### Unitary Connections

Let $(\cdot\,,\cdot)$ be a nondegenerate Hermitian inner product on $V$. We say that $\nabla$ is a unitary connection if

$$(\nabla s_1, s_2) + (s_1, \nabla s_2) = d(s_1, s_2)$$

Such connections always exist and, relative to a local orthonormal frame, the curvature is skew-symmetric, that is,

$$\Omega + \Omega^* = 0$$

Thus, $\Omega$ can be regarded as a 2-form-valued element of the Lie algebra of the structure group, $\mathrm{O}(V)$ in the real setting or $\mathrm{U}(V)$ in the complex setting.

### Projections

We can always embed $V$ in a trivial bundle $1^\nu$ of dimension $\nu$; let $\pi_V$ be the orthogonal projection on $V$. We project the flat connection to $V$ to define a natural connection on $V$. For example, if $M$ is embedded isometrically in the Euclidean space $\mathbb{R}^\nu$, this construction gives the Levi-Civita connection on the tangent bundle $TM$. The curvature of this connection is then given by

$$\Omega = \pi_V\ \mathrm{d}\pi_V\ \mathrm{d}\pi_V$$

Let $V_P$ be the fiber of $V$ over a point $P \in M$. The inclusion $i : V \subset \mathbb{R}^n$ defines the classifying map $f : P \to Gr_k(\mathbb{R}, n)$ where we set

$$f(P) = i(V_P)$$

### Chern–Weyl Theory

Let $\nabla$ be a Riemannian connection on a real vector bundle $V$ of rank $k$. We set

$$p(\Omega) := \det\left(I + \frac{1}{2\pi}\Omega\right)$$

Let $\Omega^{\mathrm{T}}$ denote the transpose matrix of differential form. Since $\Omega + \Omega^{\mathrm{T}} = 0$, the polynomials of odd degree in $\Omega$ vanish and we may expand

$$p(\Omega) = 1 + p_1(\Omega) + \cdots + p_r(\Omega)$$

where $k = 2r$ or $k = 2r + 1$ and the differential forms $p_i(\Omega) \in C^\infty\Lambda^{4i}(M)$ are forms of degree $4i$.

Changing the gauge (i.e., the local frame) replaces $\Omega$ by $g\Omega g^{-1}$ and hence $p(\Omega)$ is independent of the local frame chosen. One can show that $\mathrm{d}p_i(\Omega) = 0$; let $[p_i(\Omega)]$ denote the corresponding element of de Rham cohomology. This is independent of the particular connection chosen and $[p_i(\Omega)]$ represents $p_i(V)$ in $H^{4i}(M;\mathbb{C})$.

Similarly, let $V$ be a complex vector bundle of rank $k$ with a Hermitian connection $\nabla$. Set

$$c(\Omega) := \det\left(I + \frac{\sqrt{-1}}{2\pi}\Omega\right) = 1 + c_1(\Omega) + \cdots + c_k(\Omega)$$

Again $c_i(\Omega)$ is independent of the local gauge and $\mathrm{d}c_i(\Omega) = 0$. The de Rham cohomology class $[c_i(\Omega)]$ represents $c_i(V)$ in $H^{2i}(M;\mathbb{C})$.

### The Chern Character

The total Chern character is defined by the formal sum

$$\begin{aligned}\mathrm{ch}(\Omega) &:= \mathrm{tr}(\mathrm{e}^{\sqrt{-1}\Omega/2\pi}) \\ &= \sum_\nu \frac{(\sqrt{-1})^\nu}{(2\pi)^\nu \nu!}\mathrm{tr}(\Omega^\nu) \\ &= \mathrm{ch}_0(\Omega) + \mathrm{ch}_1(\Omega) + \cdots\end{aligned}$$

Let $\mathrm{ch}(V) = [\mathrm{ch}(\Omega)]$ denote the associated de Rham cohomology class; it is independent of the particular connection chosen. We then have the relations

$$\mathrm{ch}(V \oplus W) = \mathrm{ch}(V) + \mathrm{ch}(W)$$
$$\mathrm{ch}(V \otimes W) = \mathrm{ch}(V)\mathrm{ch}(W)$$

The Chern character extends to a ring isomorphism from $KU(M) \otimes \mathbb{Q}$ to $H^e(M;\mathbb{Q})$, which is a natural equivalence of functors; modulo torsion, $K$ theory and cohomology are the same functors.

### Other Characteristic Classes

The Chern character is defined by the exponential function. There are other characteristic classes which appear in the index theorem that are defined using other generating functions that appear in index theory. Let $\boldsymbol{x} := (x_1, \ldots)$ be a collection of indeterminates. Let $s_\nu(\boldsymbol{x})$ be the $\nu$th elementary symmetric function;

$$\prod_\nu (1 + x_\nu) = 1 + s_1(\boldsymbol{x}) + s_2(\boldsymbol{x}) + \cdots$$

For a diagonal matrix $A := \mathrm{diag}(\lambda_1, \ldots)$, denote the normalized eigenvalues by $x_j := \sqrt{-1}\lambda_j/2\pi$. Then

$$c(A) = \det\left(1 + \frac{\sqrt{-1}}{2\pi}A\right) = 1 + s_1(\boldsymbol{x}) + \cdots$$

Thus, the Chern class corresponds in a certain sense to the elementary symmetric functions.

Let $f(\boldsymbol{x})$ be a symmetric polynomial or more generally a formal power series which is symmetric. We can express $f(\boldsymbol{x}) = F(s_1(\boldsymbol{x}), \ldots)$ in terms of the elementary symmetric functions and define $f(\Omega) = F(c_1(\Omega), \ldots)$ by substitution. For example, the Chern character is defined by the generating function

$$f(\boldsymbol{x}) := \sum_{\nu=1}^{k} \mathrm{e}^{x_\nu}$$

The Todd class is defined using a different generating function:

$$\begin{aligned}\mathrm{td}(\boldsymbol{x}) &:= \prod_\nu x_\nu(1 - \mathrm{e}^{-x_\nu})^{-1} \\ &= 1 + \mathrm{td}_1(\boldsymbol{x}) + \cdots\end{aligned}$$

If $V$ is a real vector bundle, we can define some additional characteristic classes similarly. Let $\{\pm\sqrt{-1}\lambda_1, \ldots\}$ be the nonzero eigenvalues of a skew-symmetric matrix $A$. We set $x_j = -\lambda_j/2\pi$ and define the Hirzebruch polynomial $L$ and the $\hat{A}$ genus by

$$\begin{aligned}L(\boldsymbol{x}) &:= \prod_\nu \frac{x_\nu}{\tanh(x_\nu)} \\ &= 1 + L_1(\boldsymbol{x}) + L_2(\boldsymbol{x}) + \cdots \\ \hat{A}(\boldsymbol{x}) &:= \prod_\nu \frac{x_\nu}{2\sinh((1/2)x_\nu)} \\ &= 1 + \hat{A}_1(\boldsymbol{x}) + \hat{A}_2(\boldsymbol{x}) + \cdots\end{aligned}$$

The generating functions

$$\frac{x}{\tanh(x)} \quad \text{and} \quad \frac{x}{2\sinh((1/2)x)}$$

are even functions of $x$, so the ambiguity in the choice of sign in the eigenvalues plays no role. This defines characteristic classes

$$L_i(V) \in H^{4i}(M;\mathbb{C}) \quad \text{and} \quad \hat{A}_i(V) \in H^{4i}(M;\mathbb{C})$$

### Summary of Formulas

We summarize below some of the formulas in terms of characteristic classes:

1. $c_1(\Omega) = \dfrac{\sqrt{-1}\mathrm{tr}(\Omega)}{2\pi}$,
2. $c_2(\Omega) = \dfrac{1}{8\pi^2}\{\mathrm{tr}(\Omega^2) - \mathrm{tr}(\Omega)^2\}$,
3. $p_1(\Omega) = -\dfrac{1}{8\pi^2}\mathrm{tr}(\Omega^2)$,
4. $\mathrm{ch}(V) = k + \left\{c_1 + \dfrac{c_1^2 - 2c_2}{2} + \cdots\right\}(V)$,
5. $\mathrm{td}(V) = \left\{1 + \dfrac{c_1}{2} + \dfrac{(c_1^2 + c_2)}{12} + \dfrac{c_1 c_2}{24} + \cdots\right\}(V)$,
6. $\hat{A}(V) = \left\{1 - \dfrac{p_1}{24} + \dfrac{7p_1^2 - 4p_2}{5760} + \cdots\right\}(V)$,
7. $L(V) = \left\{1 + \dfrac{p_1}{3} + \dfrac{7p_2 - p_1^2}{45} + \cdots\right\}(V)$,
8. $\mathrm{td}(V \oplus W) = \mathrm{td}(V)\mathrm{td}(W)$,
9. $\hat{A}(V \oplus W) = \hat{A}(V)\hat{A}(W)$,
10. $L(V \oplus W) = L(V)L(W)$.

### The Euler Form

So far, this article has dealt with the structure groups $\mathrm{O}(k)$ in the real setting and $\mathrm{U}(k)$ in the complex setting. There is one final characteristic class which arises from the structure group $\mathrm{SO}(k)$. Suppose $k = 2n$ is even. While a real antisymmetric matrix $A$ of shape $2n \times 2n$ cannot be diagonalized, it can be put in block off 2-diagonal form with blocks,

$$\begin{pmatrix} 0 & \lambda_\nu \\ -\lambda_\nu & 0 \end{pmatrix}$$

The top Pontrjagin class $p_n(A) = x_1^2 \cdots x_n^2$ is a perfect square. The Euler class

$$e_{2n}(A) := x_1 \cdots x_n$$

is the square root of $p_n$. If $V$ is an oriented vector bundle of dimension $2n$, then

$$e_{2n}(V) \in H^{2n}(M;\mathbb{C})$$

is a well-defined characteristic class satisfying $e_{2n}(V)^2 = p_n(V)$.

If $V$ is the underlying real oriented vector bundle of a complex vector bundle $W$,

$$e_{2n}(V) = c_n(W)$$

If $M$ is an even-dimensional manifold, let $e_m(M) := e_m(TM)$. If we reverse the local orientation of $M$, then $e_m(M)$ changes sign. Consequently, $e_m(M)$ is a measure rather than an $m$-form; we can use the Riemannian measure on $M$ to regard $e_m(M)$ as a scalar. Let $R_{ijkl}$ be the components of the curvature of the Levi-Civita connection with respect to some local orthonormal frame field; we adopt the convention that $R_{1221} = 1$ on the standard sphere $S^2$ in $\mathbb{R}^3$. If $\varepsilon^{I,J} := (e^I, e^J)$ is the totally antisymmetric tensor, then

$$e_{2n} := \sum_{I,J} \frac{\varepsilon^{I,J} R_{i_1 i_2 j_2 j_1} \cdots R_{i_{m-1} i_m j_m j_{m-1}}}{(8\pi)^n n!}$$

Let $\mathcal{R} := R_{ijji}$ and $\rho_{ij} := R_{ikkj}$ be the scalar curvature and the Ricci tensor, respectively. Then

$$e_2 = \frac{1}{4\pi}\mathcal{R}$$
$$e_4 = \frac{1}{32\pi^2}(\mathcal{R}^2 - 4|\rho|^2 + |R|^2)$$

## Characteristic Classes of Principal Bundles

Let $\mathfrak{g}$ be the Lie algebra of a compact Lie group $G$. Let $\pi : \mathcal{P} \to M$ be a principal $G$ bundle over $M$. For $\xi \in \mathcal{P}$, let

$$\mathcal{V}_\xi := \ker \pi_* : T_\xi\mathcal{P} \to T_{\pi\xi}M \quad \text{and} \quad \mathcal{H}_\xi := \mathcal{V}_\xi^\perp$$

be the vertical and horizontal distributions of the projection $\pi$, respectively. We assume that the metric on $\mathcal{P}$ is chosen to be $G$-invariant and such that $\pi_* : \mathcal{H}_\xi \to T_{\pi\xi}M$ is an isometry; thus, $\pi$ is a Riemannian submersion. If $F$ is a tangent vector field on $M$, let $\mathcal{H}F$ be the corresponding vertical lift. Let $\rho_\mathcal{V}$ be orthogonal projection on the distribution $\mathcal{V}$. The curvature is defined by

$$\Omega(F_1, F_2) = \rho_\mathcal{V}[\mathcal{H}(F_1), \mathcal{H}(F_2)]$$

the horizontal distribution $\mathcal{H}$ is integrable if and only if the curvature vanishes. Since the metric is $G$-invariant, $\Omega(F_1, F_2)$ is invariant under the group action. We may use a local section $s$ to $P$ over a contractible coordinate chart $\mathcal{O}$ to split $\pi^{-1}\mathcal{O} = \mathcal{O} \times G$. This permits us to identify $\mathcal{V}$ with $TG$ and to regard $\Omega$ as a $\mathfrak{g}$-valued 2-form. If we replace the section $s$ by a section $\tilde{s}$, then $\tilde{\Omega} = g\Omega g^{-1}$ changes by the adjoint action of $G$ on $\mathfrak{g}$.

If $V$ is a real or complex vector bundle over $M$, we can put a fiber metric on $V$ to reduce the structure group to the orthogonal group $\mathrm{O}(r)$ in the real setting or the unitary group $\mathrm{U}(r)$ in the complex setting. Let $\mathcal{P}_V$ be the associated frame bundle. A Riemannian connection $\nabla$ on $V$ induces an invariant splitting of $T\mathcal{P}_V = \mathcal{V} \oplus \mathcal{H}$ and defines a natural

metric on $\mathcal{P}_V$; the curvature $\Omega$ of the connection $\nabla$ defined here agrees with the definition previously.

Let $\mathcal{Q}(G)$ be the algebra of all polynomials on $\mathfrak{g}$ which are invariant under the adjoint action. If $Q \in \mathcal{Q}(G)$, then $Q(\Omega)$ is well defined. One has $dQ(\Omega) = 0$. Furthermore, the de Rham cohomology class $Q(P) := [Q(\Omega)]$ is independent of the particular connection chosen. We have

$$\begin{aligned}\mathcal{Q}(\mathrm{U}(k)) &= \mathbb{C}[c_1, \ldots, c_k]\\ \mathcal{Q}(\mathrm{SU}(k)) &= \mathbb{C}[c_2, \ldots, c_k]\\ \mathcal{Q}(\mathrm{O}(2k)) &= \mathbb{C}[p_1, \ldots, p_k]\\ \mathcal{Q}(\mathrm{O}(2k+1)) &= \mathbb{C}[p_1, \ldots, p_k]\\ \mathcal{Q}(\mathrm{SO}(2k)) &= \mathbb{C}[p_1, \ldots, p_k, e_k]/e_k^2 = p_k\\ \mathcal{Q}(\mathrm{SO}(2k+1)) &= \mathbb{C}[p_1, \ldots, p_k]\end{aligned}$$

Thus, for this category of groups, no new characteristic classes ensue. Since the invariants are Lie-algebra theoretic in nature,

$$\mathcal{Q}(\mathrm{Spin}(k)) = \mathcal{Q}(\mathrm{SO}(k))$$

Other groups, of course, give rise to different characteristic rings of invariants.

# Chern–Simons Models: Rigorous Results

**A N Sengupta**, Louisiana State University, Baton Rouge, LA, USA

## Introduction

The relationship between topological invariants and functional integrals from quantum Chern–Simons theory discovered by Witten (1989) raised several challenges for mathematicians. Most of the tremendous amount of mathematical activity generated by Witten's discovery has been concerned primarily with issues that arise after one has accepted the functional integral as a formal object. This has left, as an important challenge, the task of giving rigorous meaning to the functional integrals themselves and to rigorously derive their relation to topological invariants. The present article will discuss efforts to put the functional integral itself on a rigorous basis.

## Chern–Simons Functional Integrals

We shall describe here the typical Chern–Simons functional integral. For the purposes of this article, we will confine ourselves to a simpler setting rather than the most general possible one. In fact, we shall work with fields over three-dimensional Euclidean space $\mathbb{R}^3$ (instead of a general 3-manifold).

The typical Chern–Simons functional integral is of the form

$$\int_{\mathcal{A}} e^{i(k/4\pi)S_{CS}(A)} W_{C_1,R_1}(A) \ldots W_{C_n,R_n}(A) DA \qquad [1]$$

Our objective in this section will be to specify what the terms in this formal integral mean. Very briefly, the integration is with respect to a formal "Lebesgue measure" on $\mathcal{A}$, an infinite-dimensional space of geometric objects $A$ called connections over $\mathbb{R}^3$ with values in the Lie algebra $LG$ of a group $G$. In the first term in the integrand, in the exponent, $k$ is a real number, and $S_{CS}(A)$ is the Chern–Simons action for the connection $A$. Each term $W_{C_i,R_i}(A)$ is a Wilson loop observable, the trace in some representation $R_i$ of the holonomy of the connection $A$ around the loop $C_i$. The entire integral, formal though it may be, provides an invariant associated with the system of loops $C_1, \ldots, C_n$.

Let $G$ be a compact Lie group; for ease of exposition, let us take $G$ to be a closed, connected subgroup of $U(n)$. Thus, each element of $G$ is an $n \times n$ complex matrix $g$ with $g^*g = I$, the identity. The Lie algebra $LG$ consists of all $n \times n$ matrices $A$ which are skew-Hermitian, that is, satisfy $A^* = -A$, and for which $e^{tA} \in G$ for all real numbers $t$. On $LG$ there is a convenient inner product given by

$$\langle A, B \rangle = \mathrm{tr}(AB^*)$$

This inner product is invariant under the conjugation action of the group $G$ on its Lie algebra $LG$.

By a connection over $\mathbb{R}^3$ we shall mean a $C^\infty$ 1-form with values in $LG$. The set of all connections is an affine (in our case, actually a linear) space $\mathcal{A}$. If $A \in \mathcal{A}$, then define

$$S_{CS}(A) = \int_{\mathbb{R}^3} \mathrm{tr}(A \wedge dA + \tfrac{2}{3} A \wedge A \wedge A) \qquad [2]$$

This is, up to constant multiple, the Chern–Simons action functional.

Let $A$ be a connection and consider a piecewise smooth path

$$C : [0, 1] \to \mathbb{R}^3$$

With this one can associate a $G$-valued path $[0,1] \to G : t \mapsto g(t) \in G$ satisfying the differential equation

$$g'(t)g(t)^{-1} = -A(C'(t))$$

subject to the initial condition $g(0) = I$, the identity. The path $t \mapsto g(t)$ describes parallel transport along $C$ by the connection $A$. If $C$ is a loop then the final value $g(1)$ is the holonomy of $A$ around $C$. If $R$ is a representation of $G$ on some finite-dimensional vector space then the trace of $R(g(1))$ is the Wilson loop observable:

$$W_{C,R}(A) = \mathrm{tr}(R(g(1))) \qquad [3]$$

Thus, we have specified the meaning of the terms appearing in the formal integral [1], where $C_1, \ldots, C_n$ of eqn [1] form a link (a family of nonintersecting, imbedded loops) in $\mathbb{R}^3$ and $R_1, \ldots, R_n$ are finite-dimensional representations of $G$. Witten showed that, at least for suitable values of $k$, integrals of this form ought to produce topological invariants, which he identified, for the link.

The integral [1] is problematic for several reasons. First, there is no reasonable and useful analog of Lebesgue measure on an infinite-dimensional space. Even if one were to regularize this measure in some simple way, one would run into the problem that the measure would not live on the space of smooth connections, and so the integrand would become meaningless.

There are several different approaches to a mathematical interpretation of [1]. The approach that is often taken in practice is to simply ignore the analytical problem and define the value of the integral [1] to be what Witten's calculations have given. One approach, used, for instance, by Bar-Natan (1995) is to expand the integrand in a series and relate each individual integral in this expansion separately to topological invariants. Discrete approximation procedures to the continuum integral have also been explored. In the abelian case, infinite-dimensional oscillatory integral techniques have been used to understand the functional integral. Fröhlich and King (1999) showed the possibility of interpreting parallel transport using ideas from stochastic differential equations. Such an approach has been used successfully in the case of two-dimensional Yang–Mills theory, where the functional integral actually corresponds to integration with respect to a measure. In this article, we focus on a method of understanding the normalized Chern–Simons functional integral in terms of infinite-dimensional distribution theory and examining some ideas for understanding Wilson loop expectation values in this setting.

## Infinite Dimensional Distributions

Let $(x^0, x^1, x^2)$ denote the usual coordinates on $\mathbb{R}^3$. Gauge symmetry, an issue which will not be examined here, may be used to simplify the problem of the Chern–Simons integral. In particular, one

need only focus on connections which vanish in the $x^2$-direction, that is, connections of the form $A = A_0 dx^0 + A_1 dx^1$. For such $A$, the triple wedge-product term in the Chern–Simons action disappears, and we are left with the quadratic expression:

$$S_{CS}(A) = \int_{\mathbb{R}^3} \mathrm{tr}(A \wedge dA) \qquad [4]$$

This is good, since the functional integral now involves a quadratic exponent and so stands a good chance of rigorous realization, just as Gaussian measure can be given rigorous meaning in infinite dimensions. However, in the Chern–Simons situation, there is no hope of actually getting a measure, not even a complex measure.

The next best thing to a measure is a distribution or "generalized function." A distribution over a space $Y$ is a continuous linear functional on a topological vector space of functions on $Y$. Thus, the objective is to realize the Chern–Simons functional integral as a continuous linear functional on some space of test functions over $\mathcal{A}$ (more precisely, on an extension of $\mathcal{A}$). Before turning to the specific case of the Chern–Simons integral, let us examine some elements of the theory of infinite-dimensional distributions, in as much as they are relevant to our needs.

Let us consider a Hilbert space $\mathcal{E}_0$, and a positive Hilbert–Schmidt operator $T$ on $\mathcal{E}_0$. For each integer $p \geq 0$, let $\mathcal{E}_p = T^p(\mathcal{E}_0)$, which is a Hilbert space with the inner product $\langle x, y\rangle_p = \langle T^{-p}x, T^{-p}y\rangle$. Then we have the chain of inclusions

$$\mathcal{E} = \bigcap_{p\geq 1} \mathcal{E}_p \subset \cdots \mathcal{E}_2 \subset \mathcal{E}_1 \subset \mathcal{E}_0 \qquad [5]$$

with each inclusion $\mathcal{E}_{p+1} \to \mathcal{E}_p$ being Hilbert–Schmidt. Let $\mathcal{E}_{-p} = \mathcal{E}'_p$ be the topological dual of $\mathcal{E}_p$, the space of continuous linear functionals on $\mathcal{E}_p$, and let $\mathcal{E}'$ be the topological dual of $\mathcal{E}$, where the latter is given the topology generated by all the norms $\|\cdot\|_p$. Then we have the inclusions

$$\mathcal{E}_0 \simeq \mathcal{E}'_0 \subset \mathcal{E}_{-1} \subset \mathcal{E}_{-2} \subset \cdots \subset \mathcal{E}' = \bigcup_{p\geq 0} \mathcal{E}_{-p} \qquad [6]$$

For each $x \in \mathcal{E}$ there is the evaluation map $\hat{x} : \mathcal{E}' \to \mathbb{R} : \phi \mapsto \phi(x)$. A very special case of a general theorem of Minlos guarantees that on the dual $\mathcal{E}'$ there is a measure $\mu$ on the sigma algebra generated by all the functions $\hat{x}$ such that each $\hat{x}$ is a Gaussian random variable of mean zero and variance $|x|_0^2$, that is,

$$\int_{\mathcal{E}'} e^{it\hat{x}}\, d\mu = e^{-t^2|x|_0^2/2}$$

for all $x \in \mathcal{E}$ and $t \in \mathbb{R}$. This measure $\mu$ is the standard Gaussian measure on $\mathcal{E}'$ for the infinite-dimensional nuclear space $\mathcal{E}$.

The inner products $\langle\cdot,\cdot\rangle_p$ give rise to a nuclear space structure on function spaces over $\mathcal{E}$. Let $\mathcal{U}$ be the algebra of functions on $\mathcal{E}'$ generated by the exponentials $e^{\lambda\hat{x}}$, with $x$ running over $\mathcal{E}$ and $\lambda$ over $\mathbb{C}$. For each $p \geq 0$, there is an inner product $\langle\langle\cdot,\cdot\rangle\rangle_p$ on $\mathcal{U}$ such that

$$\left\langle\left\langle e^{\lambda\hat{x}-\lambda^2|x|_p^2/2}, e^{\mu\hat{y}-\mu^2|y|_p^2/2}\right\rangle\right\rangle_p = e^{\lambda\bar{\mu}\langle x,y\rangle_p} \qquad [7]$$

For $p = 0$ the left-hand side coincides with the $L^2(\mu)$ inner product. Let $[\mathcal{E}]_p$ be the Hilbert space completion of $\mathcal{U}$ in the $\langle\langle\cdot,\cdot\rangle\rangle_p$ inner product. Then

$$\cdots [\mathcal{E}]_3 \subset [\mathcal{E}]_2 \subset [\mathcal{E}]_1 \subset [\mathcal{E}]_0 = L^2(\mathcal{E}', \mu) \qquad [8]$$

Let $[\mathcal{E}] = \cap_{p\geq 0} [\mathcal{E}]_p$, equipped with topology from all the norms $\|\cdot\|_p$, and $[\mathcal{E}]'$ its topological dual. Elements of $[\mathcal{E}]'$, being continuous linear functionals on the "test function space" $[\mathcal{E}]$, are called distributions over $\mathcal{E}$, in the language of white-noise analysis.

A fundamental tool in the study of infinite-dimensional distributions is the $S$-transform. This generalizes the traditional Segal–Bargmann transform from the $L^2$-setting to the context of distributions. Let $\mathcal{E}_c$ be the complexification of $\mathcal{E}$. The inner product $\langle\cdot,\cdot\rangle_0$ on $\mathcal{E}$ extends to a complex-bilinear pairing $\mathcal{E}_c \times \mathcal{E}_c \to \mathbb{C} : (z, w) \mapsto z \cdot w$. The evaluation pairing $\mathcal{E}' \times \mathcal{E} \to \mathbb{R}$ also extends naturally to the complexifications. For $\Phi$ a distribution belonging to $[\mathcal{E}]'$, define a function $S\Phi$ on $\mathcal{E}$ by

$$S\Phi(z) = \Phi(c_z)$$

for all $z \in \mathcal{E}_c$. Here $c_z$ is the coherent state function on $\mathcal{E}'$ given by $c_z(\phi) = e^{\phi(z)-(1/2)z\cdot z}$. A fundamental and useful result in white-noise analysis, due originally to Potthoff and Streit, specifies the range of the transform $S$ and allows reconstruction of a distribution $\Phi$ from the function $S\Phi$. Briefly, the range of $S$ consists of functions which are holomorphic, in an appropriate sense, and have at most quadratic exponential growth. In particular, this theorem implies that a function of the form $z \mapsto e^{az\cdot z}$, for any constant $a$, is in the range of $\Phi$.

## Rigorous Realization of Chern–Simons Integrals

We return to the Chern–Simons context. As mentioned earlier, gauge symmetry may be invoked to reduce the space of connections to the smaller space:

$$\mathcal{E} = X \oplus X \qquad [9]$$

where $X = \mathcal{S}(\mathbb{R}^3) \otimes LG$ is the space of rapidly decreasing functions with values in the Lie algebra $LG$. Let

$$T_1 = \left(-\frac{d^2}{dx^2} + \frac{x^2}{4}\right)^{-1}$$

as a linear operator on $L^2(\mathbb{R}^3), T_2 = T_1^{\otimes 3} \otimes I$ the induced operator on $L^2(\mathbb{R}^3) \otimes LG$, and $T = T_2 \oplus T_2$. Then, as described in the preceding section, we have the space $\mathcal{E}$ and its dual $\mathcal{E}'$. There is then the standard Gaussian measure $\mu$ on $\mathcal{E}'$, and the space $[\mathcal{E}]'$ of distributions over $\mathcal{E}'$.

The normalized Chern–Simons integral may be viewed as a linear functional

$$\Phi_{\text{CS}} : F \mapsto \frac{1}{N} \int_{\mathcal{E}} e^{i(k/4\pi)S_{\text{CS}}(A)} F(A) D\mathcal{A} \qquad [10]$$

where $N$ is a "normalizing" factor. Rigorous meaning can be given to this by first formally working out what the $S$-transform of $\Phi_{\text{CS}}$ ought to be. Calculation shows that $S\Phi$ is indeed a holomorphic function on $\mathcal{E}_c$ of quadratic growth. The Potthoff–Streit theorem then implies that $\Phi_{\text{CS}}$ does exist as a distribution in the space $[\mathcal{E}]'$. Let us examine this in some more detail.

As before, we take $A$ to be of the form $A = A_0 dx^0 + A_1 dx^1$, with the component $A_2$ equal to 0. Integration by parts shows that

$$\frac{k}{4\pi} S_{\text{CS}}(A) = -\frac{k}{2\pi} \int_{\mathbb{R}^3} \text{tr}(A_0 \partial_2 A_1)\, \text{dvol} \qquad [11]$$

A formal computation reveals that $S(\Phi_{\text{CS}})(j)$ should be given by

$$\exp\left(\frac{2\pi i}{k} \text{tr}\left(j_0 \partial_2^{-1} j_1\right)\right) \qquad [12]$$

where $j = (j_0, j_1)$, and

$$\partial_2^{-1} f(x) = \frac{1}{2} \int ds [1_{(-\infty, x_2]}(s) - 1_{[x_2, \infty)}(s)]\, f(x^0, x^1, s)$$

The Potthoff–Streit criterion implies the existence of a distribution $\Phi_{\text{CS}}$, whose $S$-transform is given by the above expression.

The distribution $\Phi_{\text{CS}}$ is, however, not a sufficiently powerful object to allow determination of the Wilson loop expectations that one would really like to have. For instance, $\Phi_{\text{CS}}$ does not live on the space of smooth connections and so the meaning of parallel transport needs to be defined. The state of knowledge, at the rigorous level, at this point is still evolving, with progress reported by A. Hahn. We describe some ideas for the Wilson loop expectations in the following.

The strategy for defining parallel transport along a path is to smear out the path by means of bump functions and essentially replace the path by a path of test functions in $\mathcal{E}$. The description given here is mainly for the case of abelian $G$. Choose first a $C^\infty$ non-negative bump function $\psi$ on $\mathbb{R}^3$, vanishing outside the unit ball and having $L^1$ norm equal to 1. For $\epsilon > 0$, let $\psi^\epsilon$ be the scaled bump function given by $\psi^\epsilon(x) = \epsilon^{-3}\psi(x/\epsilon)$. Next, for a smooth loop $[0,1] \to l(t) = (l_0(t), l_1(t), l_2(t))$, let $l^\epsilon(t) = \psi^\epsilon(\cdot - l(t))$, the scaled bump function centered now at the path point $l(t)$. Now consider a generalized connection $A = (A_0, A_1) \in \mathcal{E}'$. Set

$$B_A^{l^\epsilon}(t) = A_0(l^\epsilon(t)) l'(t)_0 + A_1(l^\epsilon(t)) l'(t)_1 \qquad [13]$$

The equation of parallel transport can be reformulated as a differential equation for a matrix-valued path $t \mapsto P_A^{l^\epsilon}(t)$ satisfying

$$\frac{d}{dt} P_A^{l^\epsilon}(t) + B_A^{l^\epsilon}(t) P_A^{l^\epsilon}(t) = 0 \qquad [14]$$

and the initial condition $P_A^{l^\epsilon}(t) = I$. With this smearing, one can consider functions of the form

$$W_\epsilon(L; A) = \prod_{i=1}^{n} \text{tr}(P^{l_i^\epsilon}(A)) \qquad [15]$$

for a link $L$ consisting of loops $l_1, \ldots, l_n$, instead of the classical Wilson loop variable.

At this stage, it would be natural to consider taking $\epsilon \downarrow 0$ in $\Phi(W_\epsilon(L))$. However, this is still problematic. A further regularization is needed, roughly corresponding to the geometric notion of framing. In the definition of $\Phi_{\text{CS}}$, alteration is made to the quadratic form $Q(j, j)$ in the exponent which appears in the expression for $S(\Phi_{\text{CS}})$, replacing it with $Q(j, \phi_s^* j)$, where $\{\phi_s\}_{s>0}$ is a family of suitable diffeomorphisms of $\mathbb{R}^3$, with $\phi_0$ being the identity. In a sense, this splits a single loop $l$ into $l$ and a neighboring loop $\phi_s \circ l$. At the end, one has to take $s \downarrow 0$. The resulting limiting value is the expected link-invariant. We shall not go into the case of nonabelian $G$, which is more complex, for which work continues to be in progress.

Infinite-dimensional distributions can be used to formulate a rigorous theory for normalized Chern–Simons functional integrals. The more specific questions raised by the Wilson-loop integrals in this setting opens up new problems for further developments in the distribution theory, connecting geometry, topology, and infinite-dimensional analysis.

# Classical Groups and Homogeneous Spaces

**S Gindikin**, Rutgers University, Piscataway, NJ, USA

Classical groups are Lie groups corresponding to three classical geometries – linear, metric, and symplectic. Let us start with the complex field $\mathbb{C}$. We consider the linear space $\mathbb{C}^n$ and the group $GL(n;\mathbb{C})$ of its automorphisms – nondegenerate (invertible) linear transformations. The complex linear metric space is the space $\mathbb{C}^n$ endowed by a nondegenerate symmetric bilinear form; the orthogonal group $O(n;\mathbb{C})$ is the subgroup in $GL(n;\mathbb{C})$ of automorphisms of this structure. If, for $n = 2l$, we replace the symmetric form by a nondegenerate skew-symmetric form, we obtain the linear symplectic space and the group $Sp(l;\mathbb{C})$ of its automorphisms – the symplectic group.

A fundamental observation of nineteenth century geometry was that the transfer from the complex field to the real one, gives not only three corresponding groups for $\mathbb{R}$ but a much reacher collection of real forms of complex classical groups: unitary, pseudounitary, pseudoorthogonal, etc. (see below). Classical geometries correspond to homogeneous manifolds with classical groups of transformations. Geometers understood that this produces a very reach world of non-Euclidean geometries, including the first example of non-Euclidean geometry – hyperbolic geometry. Some classical algebraic theories through such an approach obtain a geometrical interpretation (see below the consideration of the cone of symmetric positive forms). Between classical manifolds there are Minkowski space, Grassmannians, and multidimensional analogs of the disk and the half-plane. A substantial part of this theory is a matrix geometry, which serves as a background for matrix analysis. A rich geometry on classical manifolds with many symmetries is a background for a rich multidimensional analysis with many explicit formulas. Classical geometries, starting with Minkowski geometry, have appeared in some problems of mathematical physics.

A crucial technical fact is the embedding of the classical groups in the class of semisimple Lie groups; it gives a very strong unified method to work with semisimple groups and corresponding geometries – the method of roots. Nevertheless, some special realizations and constructions for classical groups can also be very useful. A very impressive example is the twistors of Penrose, where an initial construction is the realization of points of four-dimensional Minkowski space as lines in three-dimensional complex projective space. We mention below some general facts about semisimple groups and homogeneous manifolds, but the focus will be on special possibilities for the classical groups. The class of simple Lie groups contains, besides the classical groups, only a finite number of exceptional groups which are also very interesting and are connected, in particular, with noncommutative and nonassociative geometries; they have applications to mathematical physics.

## Complex Groups and Homogeneous Manifolds

### Complex Classical Groups

The complete linear group $\mathrm{GL}(n;\mathbb{C})$ is the group of nongenerate matrices $g$ of order $n$ ($\det g \neq 0$) and the special linear group $\mathrm{SL}(n;\mathbb{C})$ is its subgroup of matrices with the determinant equal 1 (unimodular condition). The unimodular condition kills the one-dimensional center, perhaps, leaving only a finite center. We realize the direct products of several copies of complete linear groups with different dimensions, for example, $\mathrm{GL}(k;\mathbb{C}) \times \mathrm{GL}(l;\mathbb{C})$, as the groups of the blockdiagonal nondegenerate matrices. The letter S always means that we take matrices with determinant 1. So the notation $\mathrm{S}(\mathrm{L}(k;\mathbb{C}) \times \mathrm{L}(l;\mathbb{C}))$ means that we take blockdiagonal matrices with blocks of sizes $k$, $l$ and with the determinant 1.

Let $I$ be a nondegenerate symmetric matrix of order $n$; then the orthogonal group $\mathrm{O}(n;\mathbb{C})$ is the subgroup in $\mathrm{GL}(n;\mathbb{C})$ of matrices preserving the corresponding symmetric form so that

$$g^{\top} I g = I$$

These matrices can have the determinant $\pm 1$. The special orthogonal group $\mathrm{SO}(n;\mathbb{C})$ is the subgroup of orthogonal matrices with determinant 1. Different $I$'s give isomorphic orthogonal groups since they are all linearly equivalent. If we take as $I$ the unit matrix $E = E_n$, then we receive the group of orthogonal matrices in the classical sense: $g^{\top} g = E$.

If $n = 2l$ and we replace in this definition the symmetric matrix $I$ by a nondegenerate skew-symmetric matrix $J$, we obtain the symplectic group $\mathrm{Sp}(l;\mathbb{C})$. Again, different $J$'s give isomorphic groups. The typical example of $J$ is

$$J = \begin{pmatrix} 0 & E_l \\ -E_l & 0 \end{pmatrix}$$

It is convenient then to represent matrices $g$ as

$$g = \begin{pmatrix} A & B \\ C & D \end{pmatrix}$$

where the blocks $A$, $B$, $C$, $D$ are matrices of order $l$. Then the symplectic condition is that $A^{\top} D - C^{\top} A = E$ and matrices $A^{\top} C$ and $D^{\top} B$ are symmetric. If $C = 0$ then $D = (A^{\top})^{-1}$ and $A^{-1} B$ is a symmetric matrix. In this way, we have in $\mathrm{Sp}(l;\mathbb{C})$ a subgroup $P$ of blocktriangular matrices of a very simple structure; it is an example of subgroups which are called parabolic.

There are two principal classes of homogeneous spaces with complex semisimple Lie groups: flag manifolds and Stein manifolds.

#### Flag Manifolds

These homogeneous spaces $F = G/P$ with semisimple (in our case with classical) groups $G$ have parabolic subgroups $P$ as the isotropy subgroups. The group $G = \mathrm{GL}(n;\mathbb{C})$ transitively acts on the flag manifolds $F(n_1, \ldots, n_r), 0 < n_1 < \cdots < n_r < n$, whose elements are $(n_1, \ldots, n_r)$-flags – sequences of embedded subspaces in $\mathbb{C}^n$ of the dimensions $(n_1, \ldots, n_r)$. The isotropy subgroup $P = P(n_1, \ldots, n_r)$ is the subgroup of blocktriangle matrices with the diagonal blocks of sizes $k_1, \ldots, k_{r+1}, k_j = (n_j - n_{j-1}), n_0 = 0, n_{r+1} = n$. The flag manifolds are compact complex manifolds. The matrices proportional to the unit matrix $E_n$ act trivially and we can consider instead of the action of $G = \mathrm{GL}(n;\,\mathbb{C})$ the transitive action of $G = \mathrm{SL}(n;\mathbb{C})$.

Let us pay particular attention to two extremal cases. The first one is the case of the maximal flag manifold when we have the sequence of all integers $(1, 2, 3, \ldots, n-1)$ – complete flags; the subgroup $P$ in this case is called Borelian. Another case is minimal flag manifolds with $r = 1$ (for them the unipotent radical of the parabolic subgroups is commutative). Then in the case of $\mathrm{SL}(n;\mathbb{C})$ the sequence has only one element $n_1 = k < n$ and we have Grassmannian manifolds $\mathrm{Gr}_{\mathbb{C}}(k;n) = F(k)$ of $k$-dimensional subspaces in $\mathbb{C}^n$. If $k = 1$ or $k = n-1$, we obtain the dual realizations of the complex projective space $\mathbb{C}\mathrm{P}^{n-1}$. We can interpret points of $\mathrm{Gr}_{\mathbb{C}}(k;n)$ also as $(k-1)$-dimensional planes in $\mathbb{C}P^{n-1}$.

We can define points of the projective space $\mathbb{C}\mathrm{P}^{n-1}$ by homogeneous coordinates – as the equivalency classes $(z \sim cz, z \in \mathbb{C}^n \setminus \{0\}, c \in \mathbb{C} \setminus 0)$. For the Grassmannians we can similarly use matrix homogeneous coordinates (Stiefel's coordinates): classes of $(k \times n)$-matrices $Z \in \mathrm{Mat}(k, n)$ of the maximal rank $k$ relative to the equivalency

$$Z \sim uZ, \quad u \in \mathrm{GL}(k;\mathbb{C})$$

The rows of a matrix $Z$ correspond to a base in subspace with the homogeneous coordinate $Z$; the left multiplication on a matrix $u$ replaces this base, but does not change the subspace. The group $\mathrm{GL}(n;\mathbb{C})$ acts by right multiplications:

$$Z \mapsto Zg$$

and this action preserves the equivalency classes. Suppose $k \leq n-k$ and the left $k$-minor of $Z$ is not zero. Such matrices give the dense coordinate chart $\mathbb{C}^{k(n-k)}$: we can pick in the equivalency classes the representatives $(E_k, z), z \in \mathrm{Mat}(k, n-k)$, and consider the matrices $z$ as (inhomogeneous) local coordinates. In the inhomogeneous coordinates the

action of the group has a matrix fractional linear form: let

$$g = \begin{pmatrix} A & B \\ C & D \end{pmatrix}$$
$$A \in \mathrm{Mat}(k), \qquad D \in \mathrm{Mat}(n-k),$$
$$B \in \mathrm{Mat}(k, n-k), \qquad C \in \mathrm{Mat}(n-k, k)$$

Then we have the transformation in inhomogeneous coordinates:

$$z \mapsto (A + zC)^{-1}(B + zD)$$

The condition $C = 0$ defines the parabolic subgroup which has affine action in inhomogeneous coordinates which is transitive in the coordinate chart. In such a way the Grassmannian is a compactification of $\mathbb{C}^{k(n-k)}$ (realized as a space of $k \times (n-k)$ matrices). If $n = 2k$, we can consider it as the compactification of the space of square matrices $z$ of order $k$ with the flat generalized conformal structure defined by translations of the isotropy cone $\{\det z = 0\}$.

There are similar constructions of flag manifolds for other classical groups. We will consider only the minimal flag manifolds. For $O(2k; \mathbb{C})$ we consider the isotropic Grassmannian $\mathrm{Gr}^I_{\mathbb{C}}(2k; \mathbb{C})$ of isotropic $k$-subspaces relative to the symmetric form $I$. We take the matrix realization of $\mathrm{Gr}_{\mathbb{C}}(k; 2k)$, using Stiefel's homogeneous coordinates, and add the matrix equation

$$ZIZ^{\top} = 0$$

which is well defined in the homogeneous coordinates (compatible with the equivalency classes) and defines isotropic subspaces relative to $I$. This matrix cone is preserved by the subgroup $O(2k; \mathbb{C}) \subset GL(2k; \mathbb{C})$ corresponding to the matrix $I$. If we take the symmetric matrix

$$I = \begin{pmatrix} 0 & E_k \\ E_k & 0 \end{pmatrix}$$

then in inhomogeneous coordinates ($z$ is a square $k$-matrix) this equation is transformed into the condition that the matrix $z$ is skew-symmetric. So, in a natural sense, the isotropic Grassmannian is the compactification of the linear space of skew-symmetric matrices $\mathrm{Alt}(k) = \mathbb{C}^N, N = k(k-1)/2$.

A similar construction makes sense for the symplectic group: if we replace the symmetric form $I$ with the skew-symmetric form $J$, we obtain the equation of the matrix cone representing the Lagrangian Grassmannian $\mathrm{Gr}^L_{\mathbb{C}}(k; 2k)$ of Lagrangian subspaces in $2k$-dimensional linear symplectic space. If we were to choose $J$ as above, then in the (inhomogeneous) coordinate chart we obtain the condition that the matrix $z$ is symmetric. Thus, we have the (dense) coordinate chart on the Lagrangian Grassmannian $\mathbb{C}^N = \mathrm{Sym}(k), N = k(k+1)/2$ – the linear space of symmetric matrices.

There is one more type of minimal flag manifolds for the orthogonal group $SO(n; \mathbb{C})$ – the quadric $Q$ in the projective space:

$$I(z) = zIz^{\top} = 0$$

where rows $z \in \mathbb{C}^n \setminus \{0\}$ represent, in homogeneous coordinates, points in $\mathbb{C}P^{n-1}$. If $I = E_n$ we have the equation $(z_1)^2 + \cdots + (z_n)^2 = 0$. This quadric is the complex compact conformal flat manifold $\mathbb{C}C^N, N = n-2$; it is the compactification of $\mathbb{C}^N$ endowed with the flat conformal structure corresponding to the quadratic isotropic cone. The parabolic group is generated by linear conformal transformations and translations. On the quadric $Q$ the conformal structure is defined by intersections of tangent spaces with $Q$. Apparently, this structure is invariant relative to the natural action of $SO(n; \mathbb{C})$.

### Classical Stein Manifolds

Such homogeneous complex manifolds $X = G/H$ have complex reductive isotropy subgroups $H$. Contrary to the flag manifolds which are compact, these manifolds are Stein ones and there are many holomorphic functions on them. The typical examples for $G = GL(n; \mathbb{C})$ are homogeneous spaces $S(k_1, \ldots, k_{r+1}), n = k_1 + \cdots + k_{r+1}$, for which the isotropy subgroups are blockdiagonal matrices with the blocks of sizes $k_1, \ldots, k_{r+1}$. Then points of the manifold can be realized as generic sets of subspaces $L_j \subset \mathbb{C}^n$, $\dim L_j = k_j, 1 \le j \le r+1$ or, what is equivalent, generic sets of $(k_j - 1)$-dimensional planes in $\mathbb{C}P^{n-1}$. Since the isotropy subgroup of such a homogeneous space is a subgroup of the parabolic subgroup $P(n_1, \ldots, n_r)$, $k_j = n_j - n_{j-1}$, we have the natural fibering $S(k_1, \ldots, k_{r+1}) \to F(n_1, \ldots, n_r)$ (it is simple to see this geometrically: the $i$th subspace of a flag in the base is the direct sum of first $i$ subspaces representing a point in the fiber). This is a convenient tool to apply complex analysis on $S$ to the compact manifold $F$ where there are no nontrivial holomorphic functions. Let us emphasize that such a connection exists only for special classes of classical Stein manifolds.

Let us pay special attention to the subclass of symmetric Stein manifolds. For such manifolds $X$, the isotropy subgroup $H$ is fixed relative to a holomorphic involutive automorphism of $G$. Complex semisimple Lie groups $G$ (including classical ones) are symmetric Stein manifolds relative to the action of their square $G \times G$ by left and right multiplications.

Classical Stein manifolds for $\mathrm{SL}(n;\mathbb{C})$ considered above are symmetric if $r=1$ and we have the manifold of pairs of subspaces of complimentary dimensions intersecting only on $\{0\}$. The simplest example is the manifold of pairs of different points of the projective line $\mathbb{C}\mathrm{P}^1$. Let us point out again that the transition to the generic pairs of points transforms the compact complex manifold without nonconstant holomorphic functions into a Stein manifold with a large collection of holomorphic functions.

Some other examples of symmetric Stein manifolds are connected with classical geometry and linear algebra. The affine hyperboloid in $\mathbb{C}^n$,

$$Q(z)=1$$

is a symmetric space for $G=\mathrm{O}(n;\mathbb{C}), H=\mathrm{O}(n-1;\mathbb{C})$. We can compare it with the projective quadric $Q(z)=0$ which is a minimal flag manifold. Let us remark that there is a duality here: it is possible to interpret points of the hyperboloid of dimension $n$ as generic hyperplane sections of the projective quadric of dimension $n-1$.

The space $X$ of complex symmetric matrices of order $n$ with determinant 1 is symmetric for the group $\mathrm{SL}(n;\mathbb{C})$ which acts by the changes of variables in the corresponding quadratic forms:

$$z\mapsto g^{\top}zg,\ g\in \mathrm{SL}(n;\mathbb{C})$$

The transitive action reflects the possibility of transforming such a form into a sum of squares. The isotropy subgroup is $\mathrm{SO}(n;\mathbb{C})$.

The Stein symmetric manifold $X=\mathrm{SO}(n;\mathbb{C})/\mathrm{S}(\mathrm{O}(k;\mathbb{C})\times \mathrm{O}(n-k;\mathbb{C}))$ is realized as the manifold of $k$-dimensional subspaces in $\mathbb{C}^n$ on which the restriction of the principal symmetric form $I$ is nondegenerate.

#### Isomorphisms in Small Dimensions

Isomorphisms of classical groups in small dimensions produce isomorphisms of some classical homogeneous manifolds. Such isomorphisms were very important in the history of geometry; below are a few examples. We will consider local isomorphisms (up to a finite center). We have $\mathrm{SL}(2;\mathbb{C})\cong \mathrm{SO}(3;\mathbb{C})$. Let us realize $\mathbb{C}^3$ as the space of symmetric matrices $z$ of order 2. Then, as we remarked above, the two-dimensional submanifold $X$ of matrices with determinant 1 is the symmetric Stein manifold for the group $\mathrm{SL}(2;\mathbb{C})$. On the other hand, we can take $\det z$ as the quadratic symmetric form $I$ in $\mathbb{C}^3$; then $X$ is the hyperboloid for this form and the action of $\mathrm{SL}(2;\mathbb{C})$ on symmetric matrices gives the orthogonal transformations relative to this form $I$.

Similarly, we can interpret the local isomorphism $\mathrm{SO}(4;\mathbb{C})\cong \mathrm{SL}(2;\mathbb{C})\times \mathrm{SL}(2;\mathbb{C})$. We realize $\mathbb{C}^4$ as the space of square matrices $z$ of order 2 with the symmetric quadratic form $I(z,z)=\det(z)$. Then left and right multiplications of $z$ on unimodular matrices ($z\mapsto uzv, u,v\in \mathrm{SL}(2;\mathbb{C})$) induce orthogonal transforms for the form $I$ and any orthogonal transform can be represented in such a form (one can see it by the calculation of dimensions).

The local isomorphism $\mathrm{SL}(4;\mathbb{C})\cong \mathrm{SO}(6;\mathbb{C})$ has a slightly more complicated nature. Let us consider the Grassmannian $\mathrm{Gr}_{\mathbb{C}}(2;4)$ of lines in the projective space $\mathbb{C}P^3$ with $2\times 4$ matrices $Z$ as matrix homogeneous coordinates. Let $p_{ij}, i<j$, be the minors of $Z$ with $i$th and $j$th columns. They are called Plücker coordinates on $\mathrm{Gr}_{\mathbb{C}}(2;4)$: the equivalency class of $Z$ is defined by the sequence of six numbers $p=(p_{ij}, 1\le i<j\le j)\ne(0,\ldots,0)$ up to a constant factor. Thus, we have an imbedding of $\mathrm{Gr}_{\mathbb{C}}(2;4)$ in the projective space $\mathbb{C}P^5$. The image will be the quadric

$$p_{12}p_{34}-p_{13}p_{24}+p_{14}p_{24}=0$$

Thus, we have the isomorphism of two flag manifolds and the action of $\mathrm{SL}(4;\mathbb{C})$ on the Grassmannian transforms in orthogonal transformations of four-dimensional quadric in $\mathbb{C}P^5$. The Plücker coordinates can be defined for any Grassmannian, but they do not produce in other cases some isomorphisms with other flag manifolds; nevertheless, they realize them as intersections of quadrics in projective spaces.

## Compact Classical Homogeneous Manifolds

Compact classical groups $\mathrm{U}(n), \mathrm{SU}(n), \mathrm{O}(n), \mathrm{SO}(n), \mathrm{Sp}(l)$ are maximal compact subgroups in the corresponding classical complex groups $\mathrm{GL}(n;\mathbb{C}), \mathrm{SL}(n;\mathbb{C}), \mathrm{O}(n;\mathbb{C}), \mathrm{SO}(n;\mathbb{C}), \mathrm{Sp}(l;\mathbb{C})$. This condition defines them up to an isomorphism. They are fixed subgroups of some antiholomorphic involutive automorphisms. The unitary groups $\mathrm{U}(n)$ and $\mathrm{SU}(n)$ are the groups of unitary matrices ($g^*g=E$,) correspondingly, of unitary matrices with determinant 1. As the compact orthogonal group we can take the intersection $\mathrm{U}(n)\cap \mathrm{O}(n;\mathbb{C})$. For the standard form $I$, it will be the group of real orthogonal matrices: $g^{\top}g=E$ (so the involution in $\mathrm{O}(n;\mathbb{C})$ is the conjugation $g\mapsto \bar{g}$). Similarly, we can take $\mathrm{Sp}(l)=\mathrm{SU}(2l)\cap \mathrm{Sp}(l;\mathbb{C})$ (then the involution is $g\mapsto -J\bar{g}J$).

Compact classical groups act on compact homogeneous Riemann manifolds. There are two mechanisms connecting compact and complex homogeneous manifolds. We observe the first possibility in the case of flag manifolds which are

compact. We considered them so far relative to the action of complex (noncompact) groups. It turns out that on the flag manifold $F = G/P$ the maximal compact subgroup $U \subset G$ continues to be transitive: so we can consider flag manifolds also as being homogeneous with compact groups. Then $F = U/C$, where $C$ is the centralizer of a torus in $U$. There is a Kähler metric on $F$, invariant relative to $U$. Thus, $G$ is the group of all automorphisms of $F$ as the complex manifold, but $U$ is the group of its automorphisms as the Kähler manifold. It defines two sides of geometry of flag manifolds: complex and Kähler. Flag manifolds are the only compact homogeneous Kähler manifolds with semisimple Lie groups (the class of all compact Kähler manifolds also contains locally flat compact manifolds – toruses). In the example considered above we have $F(n_1, \ldots, n_r) = \mathrm{SU}(n)/\mathrm{S}(\mathrm{U}(k_0) \times \cdots \mathrm{U}(k_r))$. In the language of Stiefel (homogeneous) coordinates, we fix a positive Hermitian form in $\mathbb{C}^n$ and characterize subspaces by orthonormal bases. For $r = 1$ we have Grassmannians $\mathrm{Gr}_{\mathbb{C}}(k; n)$, in particular the projective space $\mathbb{C}\mathrm{P}^{n-1}$ which we consider relative to the action of the unitary groups. Relative to this action they are Hermitian symmetric spaces. In the case of minimal flag manifolds for other groups the action of maximal compact subgroups also defines on them the structure of compact Hermitian symmetric spaces. Let us emphasize that relative to noncompact groups of biholomorphic automorphisms $G$, the minimal flag manifolds (including the Grassmannians) are not symmetric.

In the case of homogeneous Stein manifolds $X = G/H$, the picture is different: the maximal compact subgroups have no open orbits. There are totally real orbits which are the compact forms of $X$: $X_{\mathbb{R}} = G_{\mathbb{R}}/H_{\mathbb{R}}$, where $G_{\mathbb{R}}$ and $H_{\mathbb{R}}$ are compact forms of $G$ and $H$, respectively. It is the canonical embedding of compact homogeneous manifolds in their complexifications. The important special case is the embedding of compact symmetric manifolds in the Stein symmetric manifolds – their complexifications.

For compact symmetric manifolds $X = U/K$ the groups $U, K$ are compact Lie groups and elements of $K$ are fixed for an involutive automorphism $\sigma$ such that $K$ contains the connected component of the subgroup of all fixed elements of $\sigma$. This possibility to connect several symmetric manifolds with one involution is illustrated by the next example. The sphere $\mathrm{S}^{n-1} \subset \mathbb{R}^n$ is the symmetric space $\mathrm{SO}(n)/\mathrm{SO}(n-1)$; the real projective space $\mathbb{R}\mathrm{P}^{n-1}$ is $\mathrm{SO}(n)/\mathrm{O}(n-1)$. Here $\mathrm{SO}(n-1)$ is the connected component of $O(n-1)$ and $S^{n-1}$ is a double covering of $\mathbb{R}\mathrm{P}^{n-1}$. A few more examples, the real Grassmannian $\mathrm{Gr}_{\mathbb{R}}(k; n)$ of $k$-subspaces in $\mathbb{R}^n$ can be defined as $\mathrm{SO}(n)/\mathrm{S}(\mathrm{O}(k) \times \mathrm{O}(n-k))$. This representation corresponds to the characterization of subspaces by orthonormal bases. The consideration of arbitrary bases defines the action of the larger group $GL(n; \mathbb{R})$ on $\mathrm{Gr}_{\mathbb{R}}(k; n)$. Relative to this action, the real Grassmannian is not symmetric since the isotropy subgroup is parabolic and is not involutive. Such a possibility to extend the group is typical for a class of compact symmetric manifolds called symmetric $R$-spaces. They are real forms of Hermitian compact symmetric manifolds (minimal flag manifolds). Let us also mention compact symmetric spaces $\mathrm{SU}(n)/\mathrm{SO}(n)$, which is the compact form of the space of unimodular symmetric matrices and can be presented by the submanifold of unitary matrices in it. Also, all compact Lie groups $G$ are symmetric spaces relative to the action of $G \times G$.

## Noncompact Riemannian Symmetric Manifolds

This class of symmetric manifolds has the strongest connections with classical mathematics. Let us consider noncompact real semisimple Lie groups – real forms of complex semisimple Lie groups. They correspond to antiholomorphic involutions in complex groups.

Between real forms of $\mathrm{SL}(\mathbb{C}, n)$ there are real and quaternionic unimodular groups $\mathrm{SL}(\mathbb{R}, n), \mathrm{SL}(\mathbb{H}, n)$ and pseudounitary groups $\mathrm{SU}(p, q)$ of complex matrices preserving a Hermitian form $H$ of the signature $(p, q)$. The complex orthogonal group has as real forms, in particular, pseudoorthogonal groups $\mathrm{SO}(p, q)$ of real matrices preserving a quadratic form of the signature $(p, q)$.

Let $G$ be a real simple Lie group and $K$ be its maximal compact subgroup. Then $X = G/K$ is a Riemann symmetric manifold of noncompact type; $K$ is defined by an involutive automorphism of $G$. Therefore, in irreducible situation there is a correspondence between noncompact Riemann symmetric manifolds and real simple noncompact Lie groups. $K$-orbits on $X$ are parametrized by points of the orbit on $X$ of a maximal abelian subgroup $A$ – the Cartan subgroup of the symmetric space $X$. Its dimension $l$ is the important invariant of $X$ – its rank. The algebraic base for geometry of $X$ is the Iwasawa decomposition

$$G = KAN$$

where $N$ is a maximal unipotent subgroup (in a natural sense compatible with $A$). Then the parabolic subgroup $P = AN$ is transitive on $X$.

### Symmetric Cones

Let us start with $X = \mathrm{GL}(n, \mathbb{R})/\mathrm{O}(n)$. This manifold corresponds to the classical theory of quadratic forms: $X$ can be realized as the manifold $\mathrm{Sym}_+(n)$ of symmetric positive matrices $x \gg 0$ of order $n$ (corresponding to positive quadratic forms). Then the transitivity of $\mathrm{GL}(n; \mathbb{R})$ on $X$ corresponds to the possibility to transform positive forms to a sum of squares. The sufficiency of triangle matrices for such transformations corresponds to the transitivity on $X = \mathrm{Sym}_+(n)$ of the parabolic subgroup $P$ of (upper) triangle matrices with positive diagonal elements. So $A$ is the group of diagonal matrices with positive elements and the submanifold of diagonal matrices in $X$ parametrizes $K$-orbits. The general fact about $A$-parametrization in this example is the classical fact about the reduction of quadratic forms to diagonal form by orthogonal transformations.

There are complex and quaternionic versions of this picture. The symmetric manifold $X = \mathrm{GL}(n; \mathbb{C})/\mathrm{U}(n)$ is realized as the manifold $\mathrm{Herm}_+(n)$ of positive complex Hermitian matrices (forms) and similarly classical facts of linear algebra on Hermitian quadratic forms are transformed into geometrical statements on symmetric spaces. Let us emphasize that we consider here the group $\mathrm{GL}(n; \mathbb{C})$ as the real group. The same situation exists with the manifold $\mathrm{Herm}_+(\mathbb{H}, n)$ of positive quaternionic Hermitian matrices, which is the symmetric manifold for the real group $\mathrm{GL}(n; \mathbb{H})$.

These three manifolds can be included in an impressive geometrical structure. They all are convex homogeneous cones $V$ in linear spaces $\mathbb{R}^N$ which are self-dual ($V = V^*$) relative to a bilinear form $\langle \cdot, \cdot \rangle$. Let us recall that

$$V^* = \{x; \langle x, y \rangle > 0, y \in \overline{V} \setminus 0\}$$

Here $\overline{V}$ is the closure of $V$. So these three symmetric manifolds are linear homogeneous self-dual cones.

There is only one more type of classical homogeneous self-dual cones – quadratic (Lorentzian) cones

$$L_n = \{x \in \mathbb{R}^{n+1};\ x_1^2 - x_2^2 - \cdots - x_{n+1}^2 > 0, x_1 > 0\}$$

which is also called the future light cone (the condition $x_1 < 0$ defines the past light cone). The group of linear automorphisms of this cone is $\mathrm{SO}(1, n) \times \mathbb{R}^+$; the first factor is the Lorentz group.

There is also one exceptional 27-dimensional cone; it is possible to interpret this cone as the cone of positive Hermitian matrices of third order over Cayley numbers. There is a very nice structural theory of homogeneous self-dual cones; it is convenient to develop this theory in the language of Jordan algebras (Faraut and Koranyi 1994). Such cones participate as elements of explicit constructions of other classes of symmetric spaces (see below).

Following Siegel, it is possible to connect with homogeneous self-dual cones multidimensional versions of Euler integrals ($\Gamma$- and $B$-functions) (Faraut and Koranyi 1994). They have many applications, including those to integral formulas for complex symmetric domains.

### Riemann Symmetric Manifolds of Rank 1

The first example of non-Euclidean geometry is connected with the Riemann symmetric manifolds of rank 1 – hyperbolic spaces; $X = \mathrm{SO}(1, n)/\mathrm{O}(n)$ is the hyperbolic space of dimension $n$. It can be realized as the upper sheet of the two-sheeted hyperboloid:

$$x_0^2 - x_1^2 - \cdots - x_n^2 = 1, x_0 > 0$$

Pseudoorthogonal linear transformations from $\mathrm{SO}(1, n)$ preserve this surface; they play the role of hyperbolic motions. The equivalent realization is in the real ball $x_1^2 - \cdots - x_n^2 < 1$ relative to the projective transformations preserving this ball.

Another example of a Riemann symmetric manifold of rank 1 is the complex hyperbolic symmetric space $X = \mathrm{SU}(1; n)/U(n)$. It can similarly be realized either as the hyperboloid

$$|z_0|^2 - |z_1|^2 - \cdots - |z_n|^2 = 1$$

in $\mathbb{C}^{n+1}$ relative to pseudounitary linear transformations or as the complex ball $|z_1|^2 + \cdots + |z_n|^2 < 1$ relative to complex projective transformations preserving it. There are also quaternionic hyperbolic spaces which are realized as the quaternionic balls in the quaternionic projective spaces. These three series exhaust all classical Riemann symmetric manifolds of rank 1 of noncompact type. There is only one exceptional symmetric manifold of rank 1: it has the dimension 16 and can be interpreted as a two-dimensional ball for Cayley numbers.

### Classical Symmetric Domains in $\mathbb{C}^n$ (Cartan Domains)

Riemann symmetric manifolds of noncompact type which admit an invariant complex structure also have an invariant Hermitian form corresponding to the Riemann metrics. For this reason, we will call them noncompact Hermitian symmetric manifolds (we considered above the compact Hermitian symmetric manifolds). They are Stein manifolds, but as opposed to symmetric Stein manifolds, which we considered above, they are homogeneous relative to real groups. The condition for a Riemann symmetric

manifold $X = G/K$ to be Hermitian is that $K$ has an one-dimensional center. All Hermitian symmetric manifolds of noncompact type can be realized as bounded domains in $\mathbb{C}^n$ (but, of course, not all their holomorphic automorphisms extend in $\mathbb{C}^n$). In the case of classical manifolds, these domains are called Cartan's domains: Cartan gave their explicit matrix realizations.

The nature of groups of holomorphic automorphisms of symmetric domains $X = G/K \subset \mathbb{C}^N$ is explained by Cartan's duality. Each such domain (Hermitian symmetric manifold of noncompact type) admits an embedding in a Hermitian symmetric manifold of compact type $X_{\mathbb{C}}$ such that the complexification $G_{\mathbb{C}}$ of $G$ is the group of holomorphic automorphisms of $X_{\mathbb{C}}$ (correspondingly, $D$ is an open $G$-orbit on $X_{\mathbb{C}}$). Moreover, $X$ lies inside a (Zariski open) coordinate chart $\mathbb{C}^N$, which is an orbit of a parabolic subgroup.

The simplest example is the complex ball $\mathbb{C}B^n$ (complex hyperbolic space) imbedded in the complex projective space $\mathbb{C}P^n$. The affine chart $\mathbb{C}^n$ is the orbit of the parabolic subgroup of affine transformations. Let us consider more complicated examples.

Let $X_{\mathbb{C}}$ be the Grassmannian $\mathrm{Gr}_{\mathbb{C}}(k;n), q = n - k \geq p$; we will use matrix homogeneous coordinates $Z$ – $k \times n$ matrices – for the description of the symmetric domain. Then $G_{\mathbb{C}} = \mathrm{SL}(n;\mathbb{C})$. Let us take its real form $G = \mathrm{SU}(k;q), k + q = n$. We fix a Hermitian form $H$ of the signature $(k, q)$ and realize $G$ as the group of matrices preserving $H$:

$$gHg^* = H$$

Then $X = X_{k,q} = \mathrm{SU}(k,q)/\mathrm{S}(\mathrm{U}(k) \times \mathrm{U}(q))$ can be realized as the domain in the Grassmannian

$$ZHZ^* \gg 0$$

so that this Hermitian matrix of order $k$ must be positive. It is essential that this condition is invariant relative to multiplications of $Z$ on nondegenerate matrices $u$ on the left and, therefore, it is a well-defined condition in homogeneous coordinates.

Let us specify the choice of $H$:

$$H_1 = \begin{pmatrix} E_k & 0 \\ 0 & -E_q \end{pmatrix}$$

Then the corresponding domain $X_1$ is defined in inhomogeneous coordinates $Z = (E_k, z), z \in \mathrm{Mat}(k, q)$, by the condition

$$E_k - zz^* \gg 0$$

This matrix ball lies completely in the coordinate chart $\mathbb{C}^{kq}$. Its rank is equal to $\min(k, q)$. Thus, we have the realization of this Hermitian symmetric space as a bounded domain in $\mathbb{C}^N, N = kq$. In the case $k = 1$, we have the usual (scalar) complex ball. Let us remark that the edge of the boundary (Shilov's boundary) is the compact symmetric space

$$zz^* = E_k$$

with the group of automorphisms $\mathrm{S}(\mathrm{U}(k) \times \mathrm{U}(q))$ (the isotropy subgroup of $X$). For $k = q$ the edge coincides with the set of unitary matrix $\mathrm{U}(k)$.

Different forms $H$ of the signature $(k, q)$ are linearly equivalent and they correspond to different (biholomorphically equivalent) realizations of this Hermitian symmetric spaces. Let us, in the beginning, set $k = q$; the inhomogeneous matrix coordinates are square matrices of order $k$. Let us take the form

$$H_2 = \begin{pmatrix} 0 & \mathrm{i}E_k \\ -\mathrm{i}E_k & 0 \end{pmatrix}$$

Then, in inhomogeneous matrix coordinates, we have the domain $X_2$:

$$\frac{1}{\mathrm{i}}(z - z^*) \gg 0$$

(complex matrices with positive skew-Hermitian parts). This domain (but not its boundary) lies in the chart. It has the structure of the tube domain $T = \mathbb{R}^n + \mathrm{i}V, n = k^2$, corresponding to the symmetric cone of positive Hermitian matrices (we take the space of such matrices as a real form of $\mathbb{C}^n$). The group of affine transformations of the tube domain:

$$z \mapsto uzu^* + a, \quad u \in \mathrm{GL}(k;\mathbb{C}), a \in \mathrm{Herm}(k)$$

is transitive on $X_2$; it is the parabolic subgroup in $\mathrm{SU}(k, q)$.

The biholomorphic equivalency of the realizations of $X$ corresponding to different $H$ is induced by the equivalency of these forms. We have

$$H_2 = \lambda H_1 \lambda^*, \quad \lambda = \frac{\sqrt{2}}{2}\begin{pmatrix} E_k & -\mathrm{i}E_k \\ -\mathrm{i}E_k & E_k \end{pmatrix}$$

Then the transform $Z \mapsto Z\lambda$ transforms $X_2$ in $X_1$. In inhomogeneous coordinates it is the fractional linear matrix transform

$$z \mapsto \mathrm{i}(z + \mathrm{i}E_k)^{-1}(z - \mathrm{i}E_k)$$

It is the matrix version of the classical Cayley transform. Similarly, we can write down the inverse transform.

If $q \neq k$, then there is also an analog of the tube realization. Let $r = q - k > 0$ and

$$H_2 = \begin{pmatrix} 0 & \mathrm{i}E_k & 0 \\ -\mathrm{i}E_k & 0 & 0 \\ 0 & 0 & -E_r \end{pmatrix}$$

Let us represent the inhomogeneous coordinates as $z = (E_k, w, u), w \in \mathrm{Mat}(k), u \in \mathrm{Mat}(k, r)$. Then the domain $X_2$ is defined by the condition

$$\frac{1}{\mathrm{i}}(w - w^*) - uu^* \gg 0$$

This is an example of Siegel domains of the second kind (Pyatetskii-Shapiro 1969). This domain has a transitive group of affine transformations:

$$\begin{gathered}(w, u) \mapsto (w + a + 2ub^* + bb^*, u + b)\\ a \in \mathrm{Herm}(k), \quad b \in \mathrm{Mat}(k, r)\\ (w, u) \mapsto (cwc^*, cu) \quad c \in \mathrm{GL}\,(k; \mathbb{C})\end{gathered}$$

This class of symmetric domains in Grassmannians is called Cartan's domains of the first class. There are similar constructions for minimal flag domains (compact Hermitian symmetric spaces) with other groups. Let us consider the Lagrangian Grassmannian $\mathrm{Gr}^L_{\mathbb{C}}(k; 2k)$ corresponding to the form $J$ above. Here $G_{\mathbb{C}} = \mathrm{Sp}(k, \mathbb{C})$. Its real form $G = \mathrm{Sp}(k; \mathbb{R})$ can be realized as the subgroup of complex symplectic matrices preserving a Hermitian form $H$ of the signature $(k, k)$. In other words, we intersect the domains from the last example with the Lagrangian Grassmannians. We consider the coordinate chart with inhomogeneous coordinates – symmetric matrices $z \in \mathrm{Sym}(k)$. For $H_1$ we have the domain of symmetric matrices $z$ with the condition

$$E_k - z\bar{z} \gg 0, z = z^\top$$

This bounded realization is called Siegel's disk. For $H_2$ the real form is the group of real symplectic matrices and $X_2$ is the domain

$$\Im z = \frac{1}{2\mathrm{i}}(z - \bar{z}) \gg 0, \quad z = z^\top$$

of complex symmetric matrices with positive imaginary parts; it is called Siegel's half-plane. This is the third class of Cartan's domains. There are Siegel domains of second kind connecting with the cones of positive symmetric matrices; some of them are homogeneous, but they are never symmetric.

There are two more series of classical minimal flag manifolds: the isotropic Grassmannians and quadrics. They both contain the dual bounded symmetric domains (Cartan's domains of second and fourth classes correspondingly). Some of these domains in the isotropic Grassmannians admit the realizations as tubes with the cone of positive Hermitian quaternionic matrices and others as Siegel domains of the second kind corresponding to the same cones.

Symmetric domains in quadrics can be realized as tube domains with the Lorentzian (light) cones. The corresponding tubes are called the future (past) tube, depending on which light cone was taken. Let us consider this construction. The group of holomorphic automorphisms of these domains is $G = \mathrm{SO}(2; n)$ – the conformal extension of the Lorentz group. To realize this group, let us fix a real symmetric matrix $Q$ of signature $(2, n)$ and the group is the group of linear transformations preserving simultaneously the quadratic symmetric and Hermitian forms with this matrix $Q$:

$$g^\top Qg = Q, \qquad g^* Qg = Q$$

The standard realization corresponds to the diagonal matrix $Q$ with the diagonal $(1, 1, -1, \ldots, -1)$. Cartan's domains of the fourth class are connected components of the manifold

$$ZQZ^\top = 0, \qquad ZQZ^* > 0$$

where rows $Z$ are homogeneous coordinates in the projective space $\mathbb{C}\mathrm{P}^{n+1}$. In other words, we consider a domain on the quadric in the projective space (which is the complex flat conformal space $\mathbb{C}\mathrm{C}^n$). For the standard $Q$ the domain will lie in the coordinate chart; thus it is the bounded realization. For the tube realization, we take

$$Q = \begin{pmatrix} 0 & 1 & 0\\ 1 & 0 & 0\\ 0 & 0 & E_n \end{pmatrix}$$

Let $Z = (z_0, z_1, w_1, \ldots, w_n)$, $w = u + \mathrm{i}v$, $q(s, t) = s_1t_1 - s_2t_2 - \cdots - \cdots - s_nt_n$ and we consider the affine chart $\mathbb{C}^{n+1} = \{z_0 = 1\}$. We have

$$\begin{gathered}ZQZ^\top = 2z_1 + q(w, w) = 0\\ ZQZ^* = 2\Re z_1 + q(w, \bar{w}) > 0\end{gathered}$$

The first condition gives $2\Re z_1 = q(v, v) - q(u, u)$ and then the second condition gives the final description of the considered set in $\mathbb{C}^n_w$:

$$q(v, v) = v_1^2 - v_2^2 - \cdots - v_n^2 > 0, \quad w = u + \mathrm{i}v$$

as the union of the future and the past tubes ($T_\pm = \{v_1 \gtrless 0\}$). The edge $\mathbb{R}^n$ of these tubes ($v = 0$) has the structure of the Minkowski space corresponding to the form $q$. The parabolic subgroup is the affine conformal group of the Minkowski space. It includes the Poincaré group and is transitive on tubes. The complete group of holomorphic automorphisms of tubes $G = \mathrm{SO}(2, n)$ is the group of all (not only affine) conformal transformations of the Minkowski space. The complete edge of these symmetric domains in the quadric $\mathbb{C}\mathrm{C}^n$ is the conformal compactification of the Minkowski space (a compact symmetric $R$-space with the compact group $\mathrm{S}(\mathrm{O}(2) \times \mathrm{O}(n))$ on which the noncompact group $\mathrm{SO}(2, n)$ also acts).

In addition to four Cartan's classes of classical domains there are two exceptional symmetric domains in the dimensions 27 and 16 (dual to two exceptional compact Hermitian symmetric spaces of these dimensions). The first of them can be realized as the tube domain corresponding to the exceptional cone of positive Hermitian matrices with Cayley numbers of order 3 (the dimension 27) and another can be realized as a Siegel domain of the second kind associated with the eight-dimensional future tube. It is possible, using Γ-function of self-dual homogeneous cones, to write explicit Bergman and Cauchy–Szego integral formulas.

## Noncompact Symmetric *R*-Spaces

There are several other interesting noncompact symmetric manifolds. Let us mention the noncompact symmetric $R$-spaces which are real forms of complex symmetric domains. The typical example is the domain of real square matrices $x \in \mathrm{Mat}(k)$:

$$E_k - xx^\top \gg 0$$

The condition is that this symmetric matrix is positive. It is the Riemann symmetric space with the group $G = \mathrm{SO}(k,k)$. It can be embedded in the real Grassmannian $\mathrm{Gr}_{\mathbb{R}}(k;2k)$ with the matrix homogeneous coordinates $X \in \mathrm{Mat}_{\mathbb{R}}(k,2k)$ and the group $\mathrm{SL}(2k;\mathbb{R})$ acting of $X$ by right multiplications. Let

$$I_1 = \begin{pmatrix} E_k & 0 \\ 0 & -E_k \end{pmatrix}$$

and $\mathrm{SO}(k,k)$ be the subgroup of matrices preserving the quadratic form $I_1$: $gI_1g^\top = I_1$. This group will preserve the domain $XI_1X^\top \gg 0$ and, in the inhomogeneous coordinates $X = (E_k, x), x \in \mathrm{Mat}_{\mathbb{R}}(k)$, it will be exactly the same as the domain above. The group $\mathrm{SO}(k,k)$ acts by matrix fractional linear transformations. This domain is the real form on Siegel's ball. If we replace the form on

$$I_2 = \begin{pmatrix} 0 & E_k \\ E_k & 0 \end{pmatrix}$$

then we realize our symmetric manifold as the domain

$$x + x^\top \gg 0$$

So, the symmetric part of the matrix $x$ must be positive. This realization is homogeneous relative to the linear automorphisms: $x \mapsto axa^\top + b$, $a \in \mathrm{GL}(k;\mathbb{R})$, $b = -b^\top$. A similar construction exists for rectangular matrices.

## Geometry of Isomorphisms in Small Dimensions

We connected above several local isomorphisms of complex classical groups with some geometrical facts. Let us mention now several similar examples for real groups. We start from isomorphisms of symmetric cones. The cone $\mathrm{Sym}_+(2)$ of symmetric positive matrices of second order is (linearly) isomorphic to the future light cone $L(2)$. The comparison of the groups of automorphisms gives the local isomorphism

$$\mathrm{SL}(2;\mathbb{R}) \cong SO(1;2)$$

This isomorphism corresponds also to the isomorphism of two classical realizations of hyperbolic plane – of Poincaré and Klein. Let us also mention that the isomorphism $\mathrm{SL}(2,\mathbb{R}) \cong \mathrm{SU}(1,1)$ corresponds to the holomorphic equivalency of the disk and the upper half-plane. The isomorphism $\mathrm{Herm}_+(2) = L(3)$ corresponds to the presentation of any Hermitian matrix of the order 2 in Pauli's coordinates,

$$z = \begin{pmatrix} t - x_1 & x_2 + ix_3 \\ x_2 - ix_3 & t + x_1 \end{pmatrix}$$

Then, $\det z = t^2 - x_1^2 - x_2^2 - x_3^2$. To compare the groups of automorphisms, we receive

$$\mathrm{SL}(2,\mathbb{C}) \cong SO(1,3)$$

Similarly, in the quaternionic case, the isomorphism of the cones $\mathrm{Herm}_+(2,\mathbb{H})$ gives the isomorphism

$$\mathrm{SL}(2,\mathbb{H}) \cong \mathrm{SO}(1,5)$$

The linear isomorphism of cones produces the holomorphic isomorphism of corresponding tubes and their groups of holomorphic automorphisms. So each of these three isomorphisms gives automatically one more isomorphism. Let us give it for the first two cones:

$$\mathrm{Sp}(2,\mathbb{R}) \cong \mathrm{SO}(2,2), \qquad \mathrm{SU}(2,2) \cong \mathrm{SO}(2,3)$$

We just compared the descriptions of automorphisms of classical tubes from above.

Considering $\det(x)$ as the quadratic form of signature $(2,2)$ on $\mathrm{Mat}(2) \simeq \mathbb{R}^4$, we obtain

$$\mathrm{SO}(2,2) \cong \mathrm{SL}(2,\mathbb{R}) \times \mathrm{SL}(2,\mathbb{R})$$

Each of local isomorphisms in the complex case has different real forms which admit some geometrical interpretations. We mentioned above two real forms of the isomorphism $\mathrm{SL}(4;\mathbb{C}) \cong \mathrm{SO}(6;\mathbb{C})$. The isomorphism for $\mathrm{SO}(2,2)$ admits another interpretation in the language of Plücker's coordinates: points of the quadric in $\mathbb{R}P^5$ of the signature $(2,3)$ can be interpreted as (complex) lines in $\mathbb{C}P^3$ which lie on a Hermitian quadric of the signature $(2,2)$ (Gindikin

1983). The isomorphism above for the group $SL(2, \mathbb{H})$ also corresponds to Hopf's fibering of $\mathbb{C}P^3$ on complex lines over the sphere $S^4$ or the isomorphism $S^4$ and the quaternionic projective line $\mathbb{H}P^1$. In all these cases, isomorphisms of homogeneous manifolds intertwine the actions of locally isomorphic groups.

## Pseudo-Riemann Symmetric Manifolds

We obtain the next broad class of homogeneous manifolds if we preserve conditions that the group $G$ is a real semisimple one, the isotropy subgroup $H$ is involutive, but we remove the restriction that $H$ must be (maximal) compact. Such symmetric manifolds are often called semisimple pseudo-Riemann symmetric manifolds (since there are also pseudo-Riemann symmetric manifolds whose groups are not semisimple). This class of spaces contains symmetric Stein manifolds $X_{\mathbb{C}} = G_{\mathbb{C}}/H_{\mathbb{C}}$. Each semisimple symmetric manifold $X = G/H$ admits complexification as a symmetric Stein manifold. Each real semisimple Lie group $G$ is symmetric relative to the group $G \times G$.

The simplest family of semisimple symmetric manifolds is the family of all hyperboloids of all signatures

$$H_{p,q} = \{x_1^2 + \cdots + x_p^2 - x_{p+1}^2 - \cdots - x_n^2 = 1\}$$

with the groups $SO(p, q)$. Their complexifications are complex hyperboloids. There are two types of Riemann manifolds in these families: compact ones – spheres and noncompact ones – two-sheeted hyperboloids; all others are pseudo-Riemann.

The Cartan duality holds for pseudo-Hermitian symmetric manifolds: they are domains in compact Hermitian symmetric manifolds (minimal flag manifolds) $Z = G_{\mathbb{C}}/P_{\mathbb{C}}$. They are open orbits of real forms $G$ of the groups of holomorphic automorphisms $G_{\mathbb{G}}$. We construct examples of such manifolds if we consider one of the above-described realizations of noncompact Hermitian symmetric manifolds (through matrix homogeneous coordinates) and replace the condition of positivity with the condition that the symmetric (Hermitian) matrix in the definition has a fixed nondegenerate signature $(\mathrm{i}, k - \mathrm{i})$. We can call such pseudo-Hermitian symmetric manifolds satellites of Hermitian ones. Correspondingly, we can consider nonconvex tubes, for example, the set $T$ of such symmetric matrices whose imaginary parts have the signature $(\mathrm{i}, n - \mathrm{i})$. This domain is linear homogeneous, but it is not symmetric; to receive the symmetric manifold we need to extend the nonconvex tube by a manifold of smaller dimension (which plays a role of infinity).

There are pseudo-Hermitian symmetric manifolds which are not satellites of Hermitian ones. Let us give an interesting example. The group $SL(2p, \mathbb{R})$ has two open orbits on the Grassmannian $\mathrm{Gr}_{\mathbb{C}}(p; 2p)$ which are both pseudo-Hermitian symmetric spaces. Let us consider as above the Stiefel coordinates $Z \in \mathrm{Mat}_{\mathbb{C}}(p, 2p)$ and let $Z = X + \mathrm{i}Y$. Then the orbits are defined by the conditions

$$\det \begin{pmatrix} X \\ Y \end{pmatrix} \gtrless 0$$

In the intersection with the coordinate chart $Z = (E, z), z \in \mathrm{Mat}_{\mathbb{C}}(p), z = x + \mathrm{i}y$, we have the conditions

$$\det y \gtrless 0$$

Therefore, we obtain (nonconvex) tube domains in $\mathbb{C}^N = \mathrm{Mat}_{\mathbb{C}}(p), N = p^2$, corresponding to nonconvex homogeneous cones $V_{\pm}$ of real matrices with positive (negative) determinants. These tubes do not coincide with the symmetric manifolds which include also some sets of small dimensions outside of the coordinate chart (on "infinity"). There are other homogeneous nonconvex cones such that corresponding tube domains are Zariski open parts of pseudo-Hermitian symmetric spaces (D'Atri and Gindikin 1993). Between these cones are cones of nondegenerate skew-symmetric matrices, of skew-Hermitian quaternionic matrices. We again observe strong connections with classical mathematics. Not all pseudo-Hermitian symmetric manifolds admit such tube realizations of dense parts. Analysis in pseudo-Hermitian symmetric manifolds is very interesting: we consider there instead of holomorphic functions $\bar{\partial}$-cohomology of some degree.

Geometric relations between different symmetric manifolds are usually important for analytic applications since they can produce some nontrivial integral transformations. In a broad sense, such transforms are considered in integral geometry (Gelfand *et al.* 2003). An important example is duality between some compact Hermitian symmetric manifolds (when points in one of them are interpreted as submanifolds in another one). The simplest example is the projective duality between dual copies of projective spaces or, more generally, the realization of points of Grassmannians as projective planes. Such a duality can induce a duality between orbits of real forms of groups. In a special case, it can be a duality between Hermitian and pseudo-Hermitian symmetric manifolds.

Here is one important example. Let us consider in the projective space $\mathbb{C}\mathrm{P}^{2k-1}$ the domain $D$ which in

homogeneous coordinates – rows $z = (z_0, z_1, \ldots, z_n)$ are defined by the equation $zHz^* > 0$, where $H$ is a Hermitian form of the signature $(k, k)$, for example,

$$|z_0|^2 + \cdots + |z_k|^2 - |z_{k+1}|^2 - \cdots - |z_n|^2 > 0$$

This domain is $(k-1)$-pseudoconcave and it contains $(k-1)$-dimensional complex compact cycles, namely $(k-1)$-dimensional planes. The manifold of these planes is exactly the domain $X$ in the Grassmannian $\mathrm{Gr}_{\mathbb{C}}(k; 2k)$ (of projective $(k-1)$-planes) which is the noncompact Hermitian symmetric space – the orbit of the group $\mathrm{SU}(k, k)$ (see above). This picture is the geometrical basis for a deep analytic construction. In the domain $D$ the spaces of $(k-1)$-dimensional $\bar{\partial}$-cohomology are infinite dimensional for some coefficients. Their integration on $(k-1)$-planes (the Penrose transform) gives sections of corresponding vector bundles on $X$. The images are described by differential equations – generalized massless equations. The basic twistor theory corresponds to $k = 2$ when $X$ is isomorphic to four-dimensional future tube (see above).

Similar dual realizations of Hermitian symmetric manifolds exist only in special cases. The twistor realization of four-dimensional future tube was possible since the Grassmannian $\mathrm{Gr}_{\mathbb{C}}(2; 4)$ is isomorphic to the quadric in $\mathbb{C}P^5$. This does not work for the future tubes of bigger dimensions but there is another possibility (Gindikin 1998). Let us have the quadric $Q_{n-1} \subset \mathbb{C}P^n$ be defined in the homogeneous coordinates by the equation

$$\square(z) = (z_0)^2 - (z_1)^2 - \cdots - (z_n)^2 = 0$$

and $z \cdot \zeta$ is the bilinear form. As already mentioned, the set of (nondegenerate) hyperplane sections

$$\zeta \cdot z = 0, \quad \zeta \in \mathbb{C}^{n+1}, \ \square(\zeta) = 1$$

of $Q_{n-1}$ is the corresponding hyperboloid $H_n$. Thus, we have the duality between a flag manifold (the quadric $Q_{n-1}$) and a symmetric Stein manifold (the hyperboloid $H_n$) with the same group $\mathrm{SO}(n+1, \mathbb{C})$; they have different dimensions.

The group $\mathrm{SO}(1, n)$ has two orbits on $Q_{n-1}$: the real quadric $Q_{\mathbb{R}} = \{z \in Q_{n-1}; \Im(z) = 0\}$ and its complement $X = Q_{n-1} \backslash Q_{\mathbb{R}}$. Hyperplane sections which do not intersect $Q_{\mathbb{R}}$ (lie at $X$) correspond such $\zeta \in H_n$ that

$$\square(\Re(z)) > 0$$

This set has two connected components $D_\pm$ which are biholomorphically equivalent to the future and past tubes $T_\pm$ of the dimension $n$. Let us emphasize that their group of automorphisms is $\mathrm{SO}(2, n)$ in spite of the fact that this group acts neither on $X$ nor on $H_n$. Such an extension of the symmetry group is a very interesting phenomenon. It happens for several other symmetric manifolds, but is not a general fact. This geometrical construction gives a possibility to construct a multidimensional version of the Penrose transform from $(n-2)$-dimensional $\bar{\partial}$-cohomology with different coefficients into solutions of massless equations on the future (past) tubes.

The last duality is connected with some general geometrical construction. We mentioned that each of the Riemann symmetric manifolds $X = G/K$ admits a canonical embedding in the symmetric Stein manifold $X_{\mathbb{C}} = G_{\mathbb{C}}/K_{\mathbb{C}}$. It turns out that $X$ has in $X_{\mathbb{C}}$ a canonical Stein neighborhood – the complex crown $\Omega(X)$ such that many analytic objects on $X$ can be holomorphically extended on the crown (Gindikin 2002). For example, all solutions of all invariant differential equations on $X$ (which are elliptic) admit such holomorphic extension. In the last example, $D_+$ is the crown of the Riemann symmetric space which is defined, in $H_n$, by the condition $\Im(\zeta) = 0, \Re(\zeta_0) > 0$.

Symmetric manifolds are distinguished from most other homogeneous manifolds by a very rich geometry which is a background for deep analytic considerations. There are several important nonsymmetric homogeneous manifolds. We already mentioned flag manifolds and Stein homogeneous manifolds with complex semisimple Lie groups which can be nonsymmetric. Pseudo-Riemann symmetric manifolds are open orbits of real groups on compact Hermitian symmetric spaces. It turns out that open orbits on other flag manifolds also produce interesting homogeneous manifolds. Let $F = G_{\mathbb{C}}/P_{\mathbb{C}}$ be a flag manifold. Flag domains are open orbits of a real form $G$ on $F$. Of course, pseudo-Hermitian symmetric manifolds are a special case of this construction. Let us consider a simple example with $G_{\mathbb{C}} = \mathrm{SL}(3; \mathbb{C})$ and $P$ – the triangle group. Then points of $F$ are pairs {a point $z$ and a line $l$ passing through it}. Let $G = \mathrm{SU}(2; 1)$; it has two open orbits on $\mathbb{C}\mathrm{P}^2$: the complex ball $D$ and its complementary $D^{\mathrm{C}}$. On $F$, the group $G$ has three open orbits (flag domains): in the first $z \in D$, $l$ is arbitrary; in the second $l \subset D^{\mathrm{C}}$; in the third $z \in D^{\mathrm{C}}, l$ intersects $D$. They are all 1-pseudoconcave. In one-dimensional $\bar{\partial}$-cohomology of these flag domains with coefficients in line bundles, are realized all three discrete series of unitary representations of $\mathrm{SU}(2, 1)$. For arbitrary semisimple Lie groups, all discrete series of representations can also be realized in $\bar{\partial}$-cohomology of flag domains. Crowns of Riemann symmetric spaces which we just mentioned parametrize cycles (complex compact submanifolds)

in flag domains. Some general version of the Penrose transform connects through the integration along cycles cohomology in flag domains with holomorphic solutions of some differential equations in crowns (generalized massless equations).

# Classical *r*-Matrices, Lie Bialgebras, and Poisson Lie Groups

**M A Semenov-Tian-Shansky**, Steklov Institute of Mathematics, St. Petersburg, Russia, and Université de Bourgogne, Dijon, France

## Introduction

The notion of "classical *r*-matrices" has emerged as a by-product of the quantum inverse scattering method (which was developed mainly by L D Faddeev and his team in their work at the Steklov Mathematical Institute in Leningrad); it has given a new insight into the study of Hamiltonian structures associated with classical integrable systems solvable by the classical inverse scattering method and its generalizations. Important classification results for classical *r*-matrices are due to Belavin and Drinfeld. Based on the initial results of Sklyanin, Drinfeld introduced the important concepts of "Poisson Lie groups" and "Lie bialgebras" which arise as a semiclassical approximation in the study of quantum groups.

A Poisson group is a Lie group $G$ equipped with a Poisson bracket such that the multiplication $m: G \times G \to G$ is a Poisson mapping. A Poisson bracket on $G$ with this property is called multiplicative. More explicitly, let $\lambda_x, \rho_x$ be the left and right translation operators in $C^\infty(G)$ by an element $x \in G, \lambda_x\varphi(y) = \varphi(xy), \rho_x\varphi(y) = \varphi(yx)$. Multiplication in $G$ is a Poisson mapping, if for any $\varphi, \psi \in C^\infty(G)$, we have

$$\{\varphi, \psi\}(xy) = \{\lambda_x\varphi, \lambda_x\psi\}(y) + \{\rho_y\varphi, \rho_y\psi\}(x) \qquad [1]$$

Note that in general, multiplicative brackets are neither left nor right invariant; in other words, for fixed $x$ translation operators $\lambda_x, \rho_x$ do not preserve Poisson brackets.

Multiplicative Poisson brackets naturally arise in the study of integrable systems which admit the so-called "zero-curvature representation." The study of zero-curvature equations, and in particular, of the Poisson properties of the associated monodromy map, was the main source of nontrivial examples (associated with classical *r*-matrices, classical Yang–Baxter equations, and factorizable Lie bialgebras). The special class of multiplicative Poisson brackets encountered in this context is closely related to factorization problems in Lie groups (in particular, the matrix Riemann problem); these problems represent the key tools in constructing solutions of zero-curvature equations.

The equivalent definition of Poisson Lie groups uses the dual language of "Hopf algebras." Let $A = F(G)$ be the commutative algebra of (smooth) functions on a Lie group $G$ equipped with the standard coproduct $\Delta: A \to A \otimes A$

$$\Delta\varphi(x, y) = \varphi(xy), \qquad \varphi \in F(G), \quad x, y \in G$$

as usual, we identify the (topological) tensor product $F(G) \otimes F(G)$ with $F(G \times G)$. The multiplicative

Poisson bracket on $G$ equips $F(G)$ with the structure of a Poisson–Hopf algebra, that is

$$\Delta\{\varphi, \psi\} = \{\Delta\varphi, \Delta\psi\} \qquad [2]$$

Equation [2] is the starting point for the study of relations between Poisson groups and quantum groups. Following the general philosophy of deformation quantization, we can look for a deformation $A_h$ of the commutative Hopf algebra $A$ with the deformation germ determined by the Poisson structure on $A$ satisfying eqn [2]. The fundamental theorem (conjectured by Drinfeld and proved by Etingof and Kazhdan) asserts that any Poisson algebra associated with a Poisson group admits a formal quantization (in the category of Hopf algebras).

## Poisson Groups and Lie Bialgebras

Let $G$ be a Lie group with Lie algebra $\mathfrak{g}$ equipped with a multiplicative Poisson bracket. Any Poisson bracket is bilinear in differentials of functions; it is convenient to express it by means of right- or left-invariant differentials. For $\varphi \in F(G)$ set

$$\langle \nabla\varphi(x), X\rangle = (\mathrm{d}/\mathrm{d}t)_{t=0}\varphi(\mathrm{e}^{tX}x),$$
$$\langle \nabla'\varphi(x), X\rangle = (\mathrm{d}/\mathrm{d}t)_{t=0}\varphi(x\mathrm{e}^{tX}),$$
$$X \in \mathfrak{g}, \nabla\varphi(x), \nabla'\varphi(x) \in \mathfrak{g}^*$$

Let us define the Poisson operator $\eta : G \to \mathrm{Hom}(\mathfrak{g}^*, \mathfrak{g})$ by setting

$$\{\varphi, \psi\}(x) = \langle \eta(x)\nabla\varphi(x), \nabla\psi\rangle \qquad [3]$$

For a finite-dimensional Lie algebra, we can identify $\mathrm{Hom}(\mathfrak{g}^*, \mathfrak{g})$ with $\mathfrak{g}\otimes\mathfrak{g}$; the skew symmetry of Poisson bracket implies that $\eta \in \mathfrak{g}\wedge\mathfrak{g}$. By an abuse of language, the same identification is traditionally used for infinite-dimensional algebras (e.g., for loop algebras) as well. Of course, in the latter case, the corresponding Poisson tensors are represented by singular kernels which do not lie in the algebraic tensor product and should be regarded as distributions.

Multiplicativity of Poisson bracket on $G$ implies a functional equation for $\eta$

$$\eta(xy) = (\mathrm{Ad}\, x \otimes \mathrm{Ad}\, x)\cdot\eta(y) + \eta(x) \qquad [4]$$

which means that $\eta$ is a 1-cocycle on $G$ (with values in $\mathfrak{g}\wedge\mathfrak{g}$). By setting

$$\delta(X) = \left(\frac{\mathrm{d}}{\mathrm{d}t}\right)_{t=0}\eta(\mathrm{e}^{tX}), \quad X \in \mathfrak{g}$$

we conclude from eqn [4] that $\delta : \mathfrak{g} \to \mathfrak{g}\wedge\mathfrak{g}$ is a 1-cocycle on $\mathfrak{g}$, that is,

$$\begin{aligned}\delta([X, Y]) = {}& [X\otimes I + I\otimes X, \delta(Y)] \\ & - [Y\otimes I + I\otimes Y, \delta(X)]\end{aligned}$$

Equation [4] implies that $\eta(e) = 0$, that is, a multiplicative Poisson structure is identically zero at the unit element. Its linearization at this point induces the structure of a Lie algebra on the cotangent space $T_e^*G \simeq \mathfrak{g}^*$; namely, for any $\xi, \xi' \in \mathfrak{g}^*$, choose $\varphi, \varphi' \in F(G)$ in such a way that $\nabla_e\varphi = \xi, \nabla_e\varphi' = \xi'$, and set

$$[\xi, \xi']_* = \nabla_e\{\varphi, \varphi'\} \qquad [5]$$

It is easy to see that $\langle [\xi, \xi']_*, X\rangle = \langle \xi\wedge\xi', \delta(X)\rangle$, which proves that the bracket is well defined, while eqn [5] implies the Jacobi identity.

**Definition 1** Let $\mathfrak{g}, \mathfrak{g}^*$ be a pair of linear spaces set in duality; $(\mathfrak{g}, \mathfrak{g}^*)$ is called a Lie bialgebra if both $\mathfrak{g}$ and $\mathfrak{g}^*$ are Lie algebras and the mapping $\delta : \mathfrak{g} \to \mathfrak{g}\otimes\mathfrak{g}$ which is dual to the commutator map $[\,,]_* : \mathfrak{g}^*\otimes\mathfrak{g}^* \to \mathfrak{g}^*$ is a 1-cocycle on $\mathfrak{g}$.

Thus if $G$ is a Poisson–Lie group, the pair $(\mathfrak{g}, \mathfrak{g}^*)$ is a Lie bialgebra (called the "tangent Lie bialgebra" of $G$). Poisson–Lie groups form a category in which the morphisms are Lie group homomorphisms, which are also Poisson mappings. A morphism $(\mathfrak{g}, \mathfrak{g}^*) \rightsquigarrow (\mathfrak{h}, \mathfrak{h}^*)$ in the category of Lie bialgebras is a Lie algebra homomorphism $\mathfrak{g} \to \mathfrak{h}$ such that the dual map $\mathfrak{h}^* \to \mathfrak{g}^*$ is again a Lie algebra homomorphism. It is easy to see that morphisms of Poisson groups induce morphisms of their tangent bialgebras. The converse is also true.

**Theorem 1**

(*i*) *Let* $(\mathfrak{g}, \mathfrak{g}^*)$ *be a Lie bialgebra,* $G$ *a connected, simply connected Lie group with Lie algebra* $\mathfrak{g}$. *There is a unique multiplicative Poisson bracket on G such that* $(\mathfrak{g}, \mathfrak{g}^*)$ *is its tangent Lie bialgebra.*
(*ii*) *Morphisms of Lie bialgebras induce Poisson mappings of the corresponding Poisson groups.*

Basically, the theorem asserts that a Poisson tensor is uniquely restored from the infinitesimal cocycle on the corresponding Lie algebra; moreover, the obstruction for the Jacobi identity vanishes globally if this is true for its infinitesimal part at the unit element of the group.

It is important to observe that Lie bialgebras possess a remarkable symmetry: if $(\mathfrak{g}, \mathfrak{g}^*)$ is a Lie bialgebra, the same is true for $(\mathfrak{g}^*, \mathfrak{g})$. Hence, the dual group $G^*$ (which corresponds to $\mathfrak{g}^*$) also carries a multiplicative Poisson bracket. The duality theory for Lie bialgebras, based on the key notion of the Drinfeld double, is discussed in the next section.

## Classical *r*-Matrices and Special Classes of Lie Bialgebras

The general classification problem for Lie bialgebras is unfeasible (e.g., classification of abelian Lie bialgebras includes classification of all Lie algebras). In applications, one mainly deals with important special classes of Lie bialgebras, of which factorizable Lie bialgebras are probably the most important. In a sense, this class may be regarded as exhaustive, since (as explained below) any Lie bialgebra is canonically embedded into a factorizable one. Various other special classes discussed in literature are "coboundary bialgebras," "triangular bialgebras," and "quasitriangular bialgebras."

The Lie bialgebra $(\mathfrak{g}, \mathfrak{g}^*, \delta)$ is called a coboundary bialgebra if the cobracket $\delta$ is a trivial 1-cocycle on $\mathfrak{g}$, that is,

$$\delta(X) = [X \otimes I + I \otimes X, r] \quad \text{for all } X \in \mathfrak{g} \qquad [6]$$

the constant element $r \in \mathfrak{g} \wedge \mathfrak{g}$ is called the "classical $r$-matrix." If $\mathfrak{g}$ is semisimple, $H^1(\mathfrak{g}, V) = 0$ for any $\mathfrak{g}$-module $V$ by the classical Whitehead theorem, and hence all Lie bialgebra structures on $\mathfrak{g}$ are of coboundary type. The associated Lie bracket on $\mathfrak{g}^*$ is given by the formula

$$[\xi, \xi']_* = \mathrm{ad}^*_{\mathfrak{g}}\, r\xi \cdot \xi' - \mathrm{ad}^*_{\mathfrak{g}}\, r\xi' \cdot \xi \qquad [7]$$

where we identified $r \in \mathfrak{g} \wedge \mathfrak{g}$ with a skew-symmetric linear operator $r : \mathfrak{g}^* \to \mathfrak{g}$. The restrictions imposed on $r$ by the Jacobi identity are formulated in terms of the so-called "Yang–Baxter tensor" $[[r, r]] \in \mathfrak{g} \wedge \mathfrak{g} \wedge \mathfrak{g}$, which is a quadratic expression in $r$. To define it, let us mark different factors in tensor products, for example, $\mathfrak{g} \otimes \mathfrak{g} \otimes \mathfrak{g}$, by fixed numbers 1, 2, 3, ... which indicate their place; for simplicity, we assume that $\mathfrak{g}$ is embedded in an associative algebra $\mathcal{A}$ with a unit. The embeddings are defined as

$$i_{12}, i_{23}, i_{13} : \mathfrak{g} \otimes \mathfrak{g} \longrightarrow \mathcal{A} \otimes \mathcal{A} \otimes \mathcal{A}$$

by setting $i_{12}(X \otimes Y) = X \otimes Y \otimes I$, and similarly in other cases. For $a \in \mathfrak{g} \otimes \mathfrak{g}$, we put $i_{12}(a) = a_{12}$, etc. Set

$$[[r, r]] = [r_{12}, r_{13}] + [r_{12}, r_{23}] + [r_{13}, r_{23}] \qquad [8]$$

The commutators in the RHS are computed in the associative algebra $\mathcal{A} \otimes \mathcal{A} \otimes \mathcal{A}$; it is easy to check that the result does not depend on the choice of the embedding $\mathfrak{g} \hookrightarrow \mathcal{A}$.

**Proposition 1** *The Jacobi identity for* $[\,,\,]_*$ *is valid if and only if* $[[r, r]]$ *is* $\mathrm{ad}\,\mathfrak{g}$*-invariant, that is, if*

$$[X \otimes I \otimes I + I \otimes X \otimes I + I \otimes I \otimes X, [[r]]] = 0 \quad \text{for all } X \in \mathfrak{g}$$

A coboundary Lie bialgebra with $[[r, r]] \in (\overset{3}{\wedge}\mathfrak{g})^{\mathfrak{g}}$ is called "quasitriangular"; it is called "triangular" if $r$ satisfies the classical Yang–Baxter equation $[[r, r]] = 0$. (Both terms come from another name of the classical Yang–Baxter equation, the "classical triangle equation.")

When a Lie algebra $\mathfrak{g}$ admits a nondegenerate invariant inner product, the class of quasitriangular Lie bialgebra structures on $\mathfrak{g}$ admits an important specialization. Let $\mathfrak{g} \otimes \mathfrak{g}^* \simeq \mathfrak{g} \otimes \mathfrak{g}$ be the natural isomorphism induced by the inner product. Let $I \in \mathfrak{g} \otimes \mathfrak{g}^*$ be the canonical element; its image $t \in \mathfrak{g} \otimes \mathfrak{g}$ under this isomorphism is called the "tensor Casimir element." Clearly, $t \in (S^2\mathfrak{g})^{\mathfrak{g}}$ and, moreover, $[t_{12}, t_{23}] \in (\overset{3}{\wedge}\mathfrak{g})^{\mathfrak{g}}$. When $\mathfrak{g}$ is semisimple, the mapping $(S^2\mathfrak{g})^{\mathfrak{g}} \to (\overset{3}{\wedge}\mathfrak{g})^{\mathfrak{g}} : s \mapsto [s_{12}, s_{23}]$ is an isomorphism; in particular, if $\mathfrak{g}$ is simple, both spaces are one dimensional and generated by a tensor Casimir (which is unique up to a scalar multiple). A Lie bialgebra $(\mathfrak{g}, r)$ is called factorizable if $r \in \mathfrak{g} \wedge \mathfrak{g}$ satisfies the modified classical Yang–Baxter equation

$$[r, r] = c[t_{12}, t_{23}], \quad c = \text{const} \neq 0 \qquad [9]$$

The convenient normalization is $c = -1/4$ (it can be achieved by an appropriate normalization of $r$). Instead of dealing with the modified Yang–Baxter equation, we may relax the antisymmetry condition imposed on $r$. Set $r_\pm = r \pm (1/2)t \in \mathfrak{g} \otimes \mathfrak{g}$. Since $t$ is $\mathrm{ad}\,\mathfrak{g}$-invariant, the symmetric part of $r_\pm$ drops out from the cobracket; on the other hand, one has $[[r_\pm, r_\pm]] = 0$. Regarding $r_\pm$ as a linear operator, $r_\pm \in \mathrm{Hom}(\mathfrak{g}^*, \mathfrak{g})$, we get the following important result:

**Proposition 2** *Let* $(\mathfrak{g}, \mathfrak{g}^*)$ *be a factorizable Lie bialgebra.*

(*i*) *The mappings* $r_\pm \in \mathrm{Hom}(\mathfrak{g}^*, \mathfrak{g})$ *are Lie algebra homomorphisms*; *moreover*, $r_+^* = -r_-$.
(*ii*) *The combined mapping*

$$i_r : \mathfrak{g}^* \to \mathfrak{g} \oplus \mathfrak{g} : X \mapsto (r_+X, r_-X)$$

*is a Lie algebra embedding.*
(*iii*) *Any* $X \in \mathfrak{g}$ *admits a unique decomposition* $X = X_+ - X_-$ *with* $(X_+, X_-) \in \mathrm{Im}\, i_r$.

The additive decomposition in a factorizable Lie bialgebra gives rise to a multiplicative factorization problem in the associated Lie group. Namely, $i_r$ may be extended to a Lie group embedding $i_r : G^* \to G \times G$ and any $x \in G$, which is sufficiently close to the unit element, admits a decomposition $x = x_+ x_-^{-1}$ with $(x_+, x_-) \in \mathrm{Im}\; i_r$.

Any Lie bialgebra $(\mathfrak{g}, \mathfrak{g}^*)$ admits a canonical embedding into a larger Lie bialgebra (called its

"double") which is already factorizable. Namely, set $\mathfrak{d} = \mathfrak{g} \oplus \mathfrak{g}^*$ as a linear space and equip it with the natural inner product,

$$\langle\langle (X, F), (X', F') \rangle\rangle = \langle F, X' \rangle + \langle F', X \rangle \qquad [10]$$

**Theorem 2**

(*i*) *There exists a unique structure of the Lie algebra on* $\mathfrak{d}$ *such that*: (*a*) $\mathfrak{g}, \mathfrak{g}^* \subset \mathfrak{d}$ *are Lie subalgebras.* (*b*) *The inner product* [10] *is invariant.*

(*ii*) *Let* $P_{\mathfrak{g}}, P_{\mathfrak{g}^*}$ *be the projection operators onto* $\mathfrak{g}, \mathfrak{g}^* \subset \mathfrak{d}$ *parallel to the complementary subalgebra. Set* $r_+^{\mathfrak{d}} = P_{\mathfrak{g}}, r_-^{\mathfrak{d}} = -P_{\mathfrak{g}^*}$; *then* $(\mathfrak{d}, r_\pm^{\mathfrak{d}})$ *is a factorizable Lie bialgebra.*

(*iii*) *The inclusion map* $(\mathfrak{g}, \mathfrak{g}^*) \rightsquigarrow (\mathfrak{d}, \mathfrak{d}^*)$ *is a homomorphism of Lie bialgebras and the dual inclusion map* $(\mathfrak{g}^*, \mathfrak{g}) \rightsquigarrow (\mathfrak{d}, \mathfrak{d}^*)$ *is an antihomomorphism.*

Conversely, let $\mathfrak{a}$ be a Lie algebra equipped with a nondegenerate invariant inner product, $\mathfrak{a}_\pm \subset \mathfrak{a}$ its Lie subalgebras such that (*i*) $\mathfrak{a}_\pm$ are isotropic with respect to inner product, (*ii*) $\mathfrak{a} = \mathfrak{a}_+ \dot{+} \mathfrak{a}_-$ as a linear space. The triple $(\mathfrak{a}, \mathfrak{a}_+, \mathfrak{a}_-)$ is called a "Manin triple." Let $P_\pm$ be the projection operators onto $\mathfrak{a}_\pm$ in this decomposition. Set $r_\pm = \pm P_\pm$. Then $(\mathfrak{a}, r_\pm)$ is a factorizable Lie bialgebra; moreover, $\mathfrak{a}_+$ and $\mathfrak{a}_-$ are set into duality by the inner product in $\mathfrak{a}$ and inherit the structure of a Lie bialgebra, and $\mathfrak{a}$ is their double.

If $(\mathfrak{g}, \mathfrak{g}^*)$ is itself a factorizable Lie bialgebra, its double admits a simple explicit description. Set $\mathfrak{d} = \mathfrak{g} \oplus \mathfrak{g}$ (direct sum of Lie algebras); let us equip $\mathfrak{d}$ with the inner product

$$\langle\langle (X, X'), (Y, Y') \rangle\rangle = \langle X, Y \rangle - \langle Y, Y' \rangle$$

Let $\mathfrak{g}^\delta \subset \mathfrak{d}$ be the diagonal subalgebra; we identify $\mathfrak{g}^*$ with the embedded subalgebra $i_r(\mathfrak{g}^*) \subset \mathfrak{d}$.

**Proposition 3**

(*i*) $(\mathfrak{d}, \mathfrak{g}^\delta, i_r(\mathfrak{g}^*))$ *is a Manin triple.*

(*ii*) *As a Lie algebra,* $\mathfrak{d} = \mathfrak{g} \oplus \mathfrak{g}$ *is isomorphic to the double of* $\mathfrak{g}$.

Key examples of factorizable Lie bialgebras are associated with semisimple Lie algebras and their loop algebras.

1. Let $\mathfrak{k}$ be a compact semisimple Lie algebra: $\mathfrak{g} = \mathfrak{k}_{\mathbb{C}}$ its complexification regarded as a real Lie algebra, $\sigma \in \operatorname{Aut} \mathfrak{g}$ the Cartan involution which fixes $\mathfrak{k}$, and $\mathfrak{g} = \mathfrak{k} \oplus \mathfrak{p}$ the associated Cartan decomposition. Fix a real split Cartan subalgebra $\mathfrak{a} \subset \mathfrak{p}$ and the associated Iwasawa decomposition $\mathfrak{g} = \mathfrak{k} \dot{+} \mathfrak{a} \dot{+} \mathfrak{n}$; put $\mathfrak{s} = \mathfrak{a} \dot{+} \mathfrak{n}$. Let $B$ be the complex Killing form on $\mathfrak{g}$; let us equip $\mathfrak{g}$ with the real inner product $(X, Y) = \operatorname{Im} B(X, Y)$, then $(\mathfrak{g}, \mathfrak{k}, \mathfrak{s})$ is a Manin triple. Hence, any compact semisimple Lie group $K$ carries a natural Poisson structure; its double $G = D(K)$ is the complex group $G = K_{\mathbb{C}}$ (regarded as a real Lie group). The associated factorization problem in $G$ is the Iwasawa decomposition $G = KAN$, which exists globally.
2. Let $\mathfrak{g}$ be a real split semisimple Lie algebra, $\mathfrak{h}$ its Cartan subalgebra, and $\Delta_+$ a system of positive roots. Fix an invariant inner product on $\mathfrak{g}$ which is positive on $\mathfrak{h}$, and let $\{e_\alpha; \alpha \in \pm\Delta_+\}$ be the root vectors normalized in such a way that $(e_\alpha, e_{-\alpha}) = 1$. Let
$$\mathfrak{n}_\pm = \bigoplus_{\alpha \in \Delta_+} \mathbb{R} \cdot e_{\pm\alpha}$$
Fix an orthonormal basis $\{H_i\}$ in $\mathfrak{h}$; let $P_\pm, P_0$ be the projection operators onto $\mathfrak{n}_\pm, \mathfrak{h}$ in the Bruhat decomposition $\mathfrak{g} = \mathfrak{n}_- \dot{+} \mathfrak{h} \dot{+} \mathfrak{n}_+$. The standard Lie bialgebra structure on $\mathfrak{g}$ is given by the *r*-matrices $r_\pm = \pm P_\pm \pm \frac{1}{2} P_0$. In tensor notation,
$$r_\pm = \pm \sum_{\alpha \in \Delta_+} e_\alpha \wedge e_{-\alpha} \pm \frac{1}{2} \sum_i H_i \otimes H_i \qquad [11]$$
Let $\mathfrak{b}_\pm = \mathfrak{h} \dot{+} \mathfrak{n}_\pm$ be the opposite Borel subalgebras; the inner product in $\mathfrak{g}$ sets them into duality, and $(\mathfrak{b}_+, \mathfrak{b}_-)$ is a Lie sub-bialgebra in $(\mathfrak{g}, \mathfrak{g}^*)$. Let $G$ be the connected, simply connected Lie group associated with $\mathfrak{g}, B_\pm = HN_\pm$ its opposite Borel subgroups which correspond to $\mathfrak{b}_\pm$. Let $p: B_\pm \to B_\pm / N_\pm \simeq H$ be the canonical projection. The associated factorization problem in $G$, $g = b_+ b_-^{-1}$, $(b_+, b_-) \in B_+ \times B_-, p(b_+) = p(b_-)^{-1}$, is closely related to the Bruhat decomposition; it is solvable for all $g$ in the open Bruhat cell $B_+ N_- \subset G$.
3. Let $L\mathfrak{g} = \mathfrak{g} \otimes \mathbb{C}((z))$ be the loop algebra of a finite dimensional semisimple Lie algebra $\mathfrak{g}$, as usual we denote the ring of formal Laurent series by $\mathbb{C}((z))$. Put $L\mathfrak{g}_+ = \mathfrak{g} \otimes \mathbb{C}[[z]]$, $L\mathfrak{g}_- = \mathfrak{g} \otimes z^{-1}\mathbb{C}[z^{-1}]$. Fix an invariant inner product on $\mathfrak{g}$ and equip $L\mathfrak{g}$ with the inner product
$$\langle\langle X, Y \rangle\rangle = \operatorname{Res}_{z=0} \langle X(z), Y(z) \rangle \, dz$$
Then $(L\mathfrak{g}, L\mathfrak{g}_+, L\mathfrak{g}_-)$ is a Manin triple. The associated classical *r*-matrix is called "rational *r*-matrix"; in tensor notation, it is represented by a singular kernel
$$r(z, z') = \frac{t}{z - z'}$$
where $t \in \mathfrak{g} \otimes \mathfrak{g}$ is the tensor Casimir, which is essentially the Cauchy kernel.
4. Let us assume that $\mathfrak{g} = \mathfrak{sl}(n)$; in this case, the loop algebra $L\mathfrak{g}$ admits a nontrivial decomposition

associated with the so-called "elliptic *r*-matrix." Set

$$I_1 = \mathrm{diag}(1, \varepsilon, \ldots, \varepsilon^{n-1}),$$

$$I_2 = \begin{pmatrix} 0 & 1 & & \ldots & 0 \\ & 0 & 1 & & \\ \vdots & & & \ddots & \vdots \\ & & & \ddots & 1 \\ 1 & 0 & \ldots & & 0 \end{pmatrix}, \quad \varepsilon = e^{2\pi i/n} \qquad [12]$$

Put $\mathbb{Z}_n^2 = \mathbb{Z}/n\mathbb{Z} \times \mathbb{Z}/n\mathbb{Z}$; for $a = (a_1, a_2) \in \mathbb{Z}_n^2$, set $I_a = I_1^{a_1} I_2^{a_2}$; matrices $I_a$ define an irreducible projective representation of $\mathbb{Z}_n^2$ (they form the so-called "finite Heisenberg group)". Let us denote the elliptic curve of modulus $\tau$ by $\mathcal{E} = \mathbb{C}/\mathbb{Z} + \tau\mathbb{Z}$ and let $P \to \mathcal{E}$ be the *n*-dimensional holomorphic vector bundle with flat connection and with monodromies given by

$$z \mapsto z + 1 : h_1 = \mathrm{Ad}\, I_1, \qquad z \mapsto z + \tau : h_2 = \mathrm{Ad}\, I_2$$

Let $\mathcal{G}_{\mathcal{E}} \subset L\mathfrak{g}$ be the subspace of Laurent expansions at zero of the global meromorphic sections of $P$ with a unique pole at $0 \in \mathcal{E}$. Then $(L\mathfrak{g}, L\mathfrak{g}_+, \mathcal{G}_{\mathcal{E}})$ is again a Manin triple. The associated classical *r*-matrix is the kernel of a singular integral operator which associates a meromorphic section of $P$ to its principal part at 0. Explicitly, it is given by

$$r(z - z') = \frac{1}{n} \sum_{a,b=0}^{n-1} \zeta\left(\frac{z - z'}{n} - a - b\tau\right) \times (\mathrm{Ad}\, I_{a,b} \otimes I) \cdot t \qquad [13]$$

where $\zeta$ is the Weierstrass zeta function.

5. Let $\mathfrak{g}$ be an arbitrary semisimple Lie algebra again. Let us equip the loop algebra $L\mathfrak{g}$ with the inner product

$$\langle\langle X, Y \rangle\rangle_0 = \mathrm{Res}_{z=0} \langle X(z), Y(z) \rangle z^{-1}\, dz$$

Set $\mathcal{N}_+ = \mathfrak{n}_+ \dot{+} \mathfrak{g} \otimes z\mathbb{C}[[z]]$, $\mathcal{N}_- = \mathfrak{n}_- \dot{+} \mathfrak{g} \otimes z^{-1}\mathbb{C}[z^{-1}]$. We have $L\mathfrak{g} = \mathcal{N}_+ \dot{+} \mathfrak{h} \dot{+} \mathcal{N}_-$, where we identify $\mathfrak{h}, \mathfrak{n}_\pm \subset \mathfrak{g}$ with the corresponding subalgebras of constant loops in $L\mathfrak{g}$. Let $P_\pm$, $P_0$ be the projection operators onto $\mathcal{N}_\pm, \mathfrak{h}$ in this decomposition and $r_\pm = \pm P_\pm \pm (1/2)P_0$. The classical *r*-matrices $r_\pm$ define on $L\mathfrak{g}$ the structure of a factorizable Lie bialgebra. The associated tensor kernels are called the trigonometric classical *r*-matrices.

Classical *r*-matrices described above are associated with factorization problems in the infinite-dimensional loop groups: matrix Riemann problems or matrix Cousin problems (in the elliptic case). Belavin and Drinfeld have given a complete classification of factorizable Lie bialgebra structures for semisimple Lie algebras; in the loop algebra case, the problem they solved consists of classification of all meromorphic solutions of the classical Yang–Baxter equation. In other words, we assume that the distribution kernel associated with the classical *r*-matrix is represented by a meromorphic function (of two complex variables). Up to an equivalence, any such solution depends only on one variable and belongs to the rational, trigonometric, or elliptic type (in the latter case, the underlying Lie algebra is necessarily $\mathfrak{sl}(n)$). Classification of solutions in the elliptic case is completely rigid; in the trigonometric case, the moduli space is finite dimensional and admits an explicit description. In the rational case, the classification is somewhat less explicit (it has been completed by A Stolin under some nondegeneracy condition). Contrary to to the popular belief, there are many other structures of a factorizable Lie bialgebra on loop algebras, for which the associated *r*-matrices are given by more singular distribution kernels.

## Poisson Lie Groups

If the tangent Lie bialgebra of a Poisson Lie group is of coboundary type, the cocycle $\eta$ is also trivial, $\eta(\mathfrak{g}) = r - \mathrm{Ad}\,\mathfrak{g} \otimes \mathrm{Ad}\,\mathfrak{g} \cdot r$. Hence, the Poisson bracket on $G$ is given by

$$\{\varphi, \psi\} = \langle r, \nabla'\varphi \wedge \nabla'\psi \rangle - \langle r, \nabla\varphi \wedge \nabla\psi \rangle, \quad r \in \mathfrak{g} \wedge \mathfrak{g}$$

where $\nabla\varphi, \nabla'\varphi \in \mathfrak{g}^*$ are left and right differentials of $\varphi \in C^\infty(G)$. This is the so-called "Sklyanin bracket". Let us assume that $G$ is a matrix group; its affine ring generated by evaluation functions $\phi_{ij}$ which assign to $L \in G$ its matrix coefficients, $\phi_{ij}(L) = L_{ij}$. The Poisson bracket on $G$ is completely determined by its values on $\phi_{ij}$. Explicitly, we get

$$\{\phi_{ij}, \phi_{km}\}(L) = [r, L \otimes L]_{ikjm} \qquad [14]$$

the commutator in the RHS is in $\mathrm{Mat}(n^2)$. By a variation of language, evaluating functions and their values on a generic element $L \in G$ are denoted by the same letter; using tensor notation to suppress matrix indices, we get

$$\{L_1, L_2\} = [r, L_1 L_2], \quad L_1 = L \otimes I,\ L_2 = I \otimes L \quad [15]$$

In the case of loop algebras, these Poisson bracket relations take the form

$$\{L_1(\lambda), L_2(\mu)\} = [r(\lambda, \mu), L_1(\lambda) L_2(\mu)]$$

Let us assume that $G$ is factorizable and the associated factorization problem is globally solvable. The Poisson bracket on the dual group $G^* \simeq$

$i_r(G^*) \subset G \times G$ may be characterized in terms of the matrix coefficients of $(h_+, h_-) = i_r(h)$, or of their quotient $h = h_+ h_-^{-1}$. Explicitly, we get

$$\{h_\pm^1, h_\pm^2\}_* = [r, h_\pm^1 h_\pm^2], \quad \{h_+^1, h_-^2\}_* = [r_+, h_+^1 h_-^2] \quad [16]$$

$$\{h_1, h_2\}_* = r h_1 h_2 + h_1 h_2 r - h_2 r_+ h_1 - h_1 r_- h_2, \quad r = \tfrac{1}{2}(r_+ + r_-) \quad [17]$$

The key question in the geometry of Poisson groups consists in description of symplectic leaves in $G, G^*$. This question is already nontrivial when $G^*$ is abelian (and hence may be identified with the dual of the Lie algebra $\mathfrak{g} = \mathrm{Lie}(G)$). The Poisson bracket on $\mathfrak{g}^*$ is linear; this is the well-known Lie–Poisson (alias, Beresin–Kirillov–Kostant) bracket. Its symplectic leaves coincide with the orbits of the coadjoint representation of $G$ in $\mathfrak{g}^*$. The natural way to prove this fundamental result (which goes back to Lie) is to consider first the natural action of $G$ on the cotangent bundle $T^*G \simeq G \times \mathfrak{g}^*$; this action is Hamiltonian, and the coadjoint orbits arise as a result of Hamiltonian reduction associated with this action. The generalization of the theory of coadjoint orbits to the case of arbitrary Poisson groups starts with the notion of symplectic double, which is the nonlinear analog of the cotangent bundle.

Let $D$ be the double of $(G, G^*)$; assume for simplicity that $D = G \cdot G^*$ globally and hence the associated factorization problem is always solvable. Let $r_\mathfrak{d} = (1/2)(P_\mathfrak{g} - P_{\mathfrak{g}^*})$. Set

$$\{\varphi, \psi\}_\pm = \langle r_\mathfrak{d} \nabla\varphi, \nabla\psi \rangle \pm \langle r_\mathfrak{d} \nabla'\varphi, \nabla'\psi \rangle \quad [18]$$

The bracket $\{\,,\}_-$ is the usual Sklyanin bracket which defines the structure of a Poisson group on $D$, while $\{\,,\}_+$ is nondegenerate and defines a symplectic structure on $D$. Let us denote the copies of $D$ equipped with the bracket $\{\,,\}_\pm$ by $D_\pm$. The bracket on $D_+$ is not multiplicative, but it is covariant with respect to the action of $D_-$ by left and right translations; in other words, the natural mappings $D_- \times D_+ \to D_+$ and $D_+ \times D_- \to D_+$, associated with multiplication in $D$, preserve Poisson brackets. Since $G, G^* \subset D_-$ are Poisson subgroups, natural actions $G \times D_+ \to D_+$ and $G^* \times D_+ \to D_+$ by left and right translations are Poisson mappings. Consider the natural projections

$$\begin{array}{ccc} & D_+ & \\ {}^{\pi}\swarrow & & \searrow^{\pi'} \\ G^* \simeq D/G & & G\backslash D \simeq G^* \end{array} \qquad \begin{array}{ccc} & D_+ & \\ {}^{p}\swarrow & & \searrow^{p'} \\ G \simeq D/G^* & & G^*\backslash D \simeq G \end{array}$$

onto the space of left and right coset classes. It is easy to see that functions on $D_+$ which are constant on each projection fiber are closed with respect to the Poisson bracket. This means that the quotient spaces inherit the Poisson structure. Moreover, the maps $\pi, \pi'$ and $p, p'$ form the so-called "dual pairs", that is, the algebras of functions which are constant on the fibers of $\pi$ and $\pi'$ (or of $p$ and $p'$) are mutual centralizers of one another in the big Poisson algebra $F(D_+)$. Since $D = G \cdot G^* = G^* \cdot G$, we have $G^*/D \simeq G$, $G/D \simeq G^*$; it is easy to check that the quotient Poisson structure induced on $G, G^*$ coincides with the original one. Applying the fundamental theorem on dual pairs of Poisson mappings (going back to S. Lie), we conclude that symplectic leaves in $G$ and $G^*$, respectively, coincide with the orbits of $G^*$ (respectively, $G$) in these quotient spaces. The actions $G \times G^* \to G^*$, $G^* \times G \to G$ are called "dressing transformations". Unit elements in $G$ and $G^*$ are fixed points of dressing transformations; their linearizations at the tangent spaces $T_eG^* \simeq \mathfrak{g}^*$, $T_eG \simeq \mathfrak{g}$ coincide with the coadjoint actions of $G$ and $G^*$, respectively.

When $D \neq G \cdot G^*$ (i.e., the factorization problem in $D$ is not always solvable), dressing actions are still well defined as global transformations of the quotient spaces; in this case $G$, $G^*$ may be identified with open cells in $D/G^*$, $D/G$, respectively, which means that dressing action on $G$, $G^*$ is, in general, incomplete.

If the group $G$ is factorizable, symplectic leaves in the dual group $G^*$ admit a nice uniform description: since in this case $D = G \times G$ and $G \subset D$ is the diagonal subgroup, the quotient $D/G$ may be modeled on $G$ itself. The quotient Poisson bracket in this realization coincides with [17], while the dressing action coincides with conjugation in $G$ (and is independent of $r$). Hence, symplectic leaves in $D/G$ coincide with conjugacy classes in $G$; the equivalence of this model with $G^*$ (equipped with the bracket [16]) is provided by the factorization map. The description of symplectic leaves in $G$ is more subtle (and already crucially depends on the choice of $r$!); for semisimple Lie groups with the standard Poisson structure, it is related to the geometry of double Bruhat cells.

For loop groups with rational, trigonometric, or elliptic $r$-matrices, dressing action is associated with auxiliary factorization problems in the loop group. Roughly speaking, symplectic leaves correspond to rational loops with prescribed singularities. Many important examples have been described in connection with integrable lattice systems, although a complete classification theorem is still not available. For $\mathfrak{g} = \mathfrak{sl}(2)$, the elliptic Manin triple described earlier leads to the Poisson structure on the group of "elliptic loops" with values in SL(2); its simplest symplectic leaves (corresponding to loops with simple poles) are associated with a remarkable Poisson algebra, the Sklyanin algebra (with four generators and two Casimir functions), which admits an interesting explicit quantization.

Dressing action is a nontrivial example of a Poisson group action. In general, such actions are not Hamiltonian in the usual sense; the appropriate generalization is provided by the notion of the nonabelian moment map. Let $G \times \mathcal{M} \to \mathcal{M}$ be an action of a Poisson group $G$ on a Poisson manifold $\mathcal{M}, \mathfrak{g} \to \mathrm{Vect}\,\mathcal{M}$, the associated homomorphism of Lie algebras. A mapping $\mu : \mathcal{M} \to G^*$ is called the nonabelian moment map associated with this action, if for any $X \in \mathfrak{g}$ and $\varphi \in F(\mathcal{M})$, we have

$$X \cdot \varphi = \langle \mu^{-1} \{\mu, \varphi\}_{\mathcal{M}}, X \rangle$$

In this case, $G \times \mathcal{M} \to \mathcal{M}$ is *a fortiori* a Poisson map. Both dressing actions $G^* \times G \to G$ and $G \times G^* \to G^*$ admit nonabelian moment maps, which are just the identity maps $\mu = \mathrm{id}_G$ and $\mu^* = \mathrm{id}_{G^*}$. For compact Poisson groups, the nonabelian moment map has good convexity properties, which generalize the convexity properties of the ordinary moment map for Hamiltonian group actions.

The general theory of homogeneous Poisson spaces has some peculiarities. Typically, the $G$-covariant Poisson structure on a given homogeneous space is not unique (when it exists); this is true already for principal homogeneous spaces (a simple example is provided by the symplectic double $D_+$). Let $G$ be a Poisson Lie group, $(\mathfrak{g}, \mathfrak{g}^*)$ its tangent Lie bialgebra, $\mathfrak{d}$ its double, $U$ its Lie subgroup, $\mathfrak{u} = \mathrm{Lie}\, U$. A subalgebra $\mathfrak{l} \subset \mathfrak{d}$ is called Lagrangian if it is isotropic with respect to the canonical inner product in $\mathfrak{d}$. The general classification result, according to Drinfeld, asserts that there is a bijection between $G$-covariant Poisson structures on $G/U$ and the set of all Lagrangian subalgebras $\mathfrak{l} \subset \mathfrak{d}$ such that $\mathfrak{l} \cap \mathfrak{g} = \mathfrak{u}$. Various nontrivial examples arise, notably in the study of integrable systems. For instance, the geometric proof of the factorization theorem for lattice zero-curvature equation, which is stated in the following section, uses a different Poisson structure on the double (the so-called "twisted symplectic double).”

## Applications to Integrable Systems

The definition of Poisson–Lie groups was motivated by key examples which arise in the theory of integrable systems. In applications, one often deals with nonlinear differential equations which may be written in the form of the so-called "lattice zero curvature equations"

$$\frac{\mathrm{d}L_m}{\mathrm{d}t} = L_m M_m - M_{m+1} L_m, \quad m \in \mathbb{Z} \qquad [19]$$

where $L_m, M_m$ are matrices, possibly depending on an additional parameter (or, more generally, abstract linear operators). Equations [19] give the compatibility conditions for the auxiliary linear system

$$\psi_{m+1} = L_m \psi_m, \quad \frac{\mathrm{d}\psi_m}{\mathrm{d}t} = -M_m \psi_m, \qquad m \in \mathbb{Z} \quad [20]$$

The use of finite-difference operators associated with a one-dimensional lattice, as in [20], is particularly well suited for the study of "multiparticle" lattice models. Let we assume that the "potential" $L_m$ in [20] is periodic, $L_{m+N} = L_m$; the period $N$ may be interpreted as the number of copies of an "elementary" system. It is natural to presume that "Lax matrices" $L_m$ in [19] are elements of a matrix Lie group $G$ (or of a loop group, if they depend on an extra parameter). The auxiliary linear problem [20] leads to a family of dynamical systems on $G^N$ which remain integrable for any $N$. Let $T : G^N \to G$ be the "monodromy map" which assigns to the set $L_1, \ldots, L_N$ of local Lax matrices their ordered product $T_L = L_N L_{N-1} \cdots L_1$. Let us assume that $G$ is equipped with the Sklyanin bracket associated with a factorizable $r$-matrix $r$. Then $T$ is a Poisson map. Let $I(G)$ be the algebra of central functions on $G$; for $\varphi \in I(G)$, set $H_\varphi = \varphi \circ T$. All functions $H_\varphi, \varphi \in I(G)$ are in involution with respect to the product Poisson bracket on $G^N$ and give rise to lattice zero-curvature equations of the same form as [19]; for a given $\varphi$, we may choose the $M$-matrix in either of the two forms:

$$M_m^{\pm} = r_{\pm}\left(\psi_m \nabla\varphi(T_L)\psi_m^{-1}\right), \quad \psi_m = \prod_{1 \le k \le m} L_k$$

Let $L_m(t), m = 1, \ldots, N$, be the integral curve of this equation which starts at $L_m^0$. The construction of this curve reduces to the factorization problem associated with the chosen $r$-matrix. Explicitly, we get

$$L_m(t) = g_{m+1}(t)_+^{-1} L_m^0 g_m(t)_+ = g_{m+1}(t)_-^{-1} L_m^0 g_m(t)_-$$

where $(g_m(t)_+, g_m(t)_-)$ is the curve in $G^*$ which solves the factorization problem

$$g_m(t)_+ g_m(t)_-^{-1} = {}^0\psi_m \exp(t\nabla\varphi(T(L^0)))\, {}^0\psi_m^{-1},$$
$${}^0\psi_m = \psi_m(L^0)$$

This result exhibits the double role of the $r$-matrix. On the one hand, it serves to define the Poisson structure on $G^N$ which is adapted to the study of lattice zero-curvature equations; in particular, the dynamical flow associated with these equations is automatically confined to symplectic leaves in $G^N$. (In applications, $G$ is usually a loop group equipped with a factorizable $r$-matrix; despite the fact that $\dim G = \infty$, it admits plenty finite-dimensional symplectic leaves.) In its second incarnation, the $r$-matrix serves to define the factorization problem which solves these zero-curvature equations. In the loop

group case, this is a matrix Riemann problem; its explicit solution is based on the study of the spectral curve associated with the "monodromy matrix" $T_L$ and uses the technique of algebraic geometry.

The monodromy map $T : G^N \to G$ may be regarded as a nonabelian moment map associated with an action of the dual Lie algebra $\mathfrak{g}^*$ on the phase space. This action actually extends to an action of the (local) Lie group $G^*$ which transforms solutions into solutions again. This is the prototype "dressing" action (originally defined by Zakharov and Shabat in their study of zero-curvature equations related to Riemann–Hilbert problems). Dressing provides an effective tool to produce new solutions of zero-curvature equations from the "trivial" ones; it was also the first nontrivial example of a Poisson group action.

# Clifford Algebras and Their Representations

**A Trautman**, Warsaw University, Warsaw, Poland

## Introduction

### Introductory and Historical Remarks

Clifford (1878) introduced his "geometric algebras" as a generalization of Grassmann algebras, complex numbers, and quaternions. Lipschitz (1886) was the first to define groups constructed from "Clifford numbers" and use them to represent rotations in a Euclidean space. Cartan discovered representations of the Lie algebras $\mathrm{so}_n(\mathbb{C})$ and $\mathrm{so}_n(\mathbb{R}), n > 2$, that do not lift to representations of the orthogonal groups. In physics, Clifford algebras and spinors appear for the first time in Pauli's nonrelativistic theory of the "magnetic electron." Dirac (1928), in his work on the relativistic wave equation of the electron, introduced matrices that provide a representation of the Clifford algebra of Minkowski space. Brauer and Weyl (1935) connected the Clifford and Dirac ideas with Cartan's spinorial representations of Lie algebras; they found, in any number of dimensions, the spinorial, projective representations of the orthogonal groups.

Clifford algebras and spinors are implicit in Euclid's solution of the Pythagorean equation $x^2 - y^2 + z^2 = 0$, which is equivalent to

$$\begin{pmatrix} y-x & z \\ z & y+x \end{pmatrix} = 2\begin{pmatrix} p \\ q \end{pmatrix}(p \quad q) \qquad [1]$$

and gives $x = q^2 - p^2$, $y = p^2 + q^2$, $z = 2pq$. If the numbers appearing in [1] are real, then this equation can be interpreted as providing a representation of a vector $(x, y, z) \in \mathbb{R}^3$, null with respect to a quadratic form of signature $(1, 2)$, as the "square" of a spinor $(p, q) \in \mathbb{R}^2$. The pure spinors of Cartan (1938) provide a generalization of this observation to higher dimensions.

Multiplying the square matrix in [1] on the left by a real, $2 \times 2$ unimodular matrix, on the right by its transpose, and taking the determinant, one arrives at the exact sequence of group homomorphisms:

$$1 \to \mathbb{Z}_2 \to \mathrm{SL}_2(\mathbb{R}) = \mathrm{Spin}^0_{1,2} \to \mathrm{SO}^0_{1,2} \to 1$$

Multiplying the same matrix by

$$\varepsilon = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \qquad [2]$$

on the left and computing the square of the product, one obtains

$$\begin{pmatrix} z & x+y \\ x-y & -z \end{pmatrix}^2 = (x^2 - y^2 + z^2)\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$$

This equation is an illustration of the idea of representing a quadratic form as the square of a linear form in a Clifford algebra. Replacing $y$ by $\mathrm{i}y$, one arrives at complex spinors, the Pauli matrices,

$$\sigma_x = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \qquad \sigma_y = \mathrm{i}\varepsilon, \qquad \sigma_z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$$

$\mathrm{Spin}_3 = \mathrm{SU}_2$, etc.

This article reviews Clifford algebras, the associated groups, and their representations, for quadratic spaces over complex or real numbers. These notions have been generalized by Chevalley (1954) to quadratic spaces over arbitrary number fields.

## Notation

If $S$ is a vector space over $K = \mathbb{R}$ or $\mathbb{C}$, then $S^*$ denotes its dual, that is, the vector space over $K$ of all $K$-linear maps from $S$ to $K$. The value of $\omega \in S^*$ on $s \in S$ is sometimes written as $\langle s, \omega \rangle$. The transpose of a linear map $f: S_1 \to S_2$ is the map $f^*: S_2^* \to S_1^*$ defined by $\langle s, f^*(\omega)\rangle = \langle f(s), \omega\rangle$ for every $s \in S_1$ and $\omega \in S_2^*$. If $S_1$ and $S_2$ are complex vector spaces, then a map $f: S_1 \to S_2$ is said to be semilinear if it is $\mathbb{R}$-linear and $f(\mathrm{i}s) = -\mathrm{i}f(s)$. The complex conjugate of a finite-dimensional complex vector space $S$ is the complex vector space $\bar{S}$ of all semilinear maps from $S^*$ to $\mathbb{C}$. There is a natural semilinear isomorphism (complex conjugation) $S \to \bar{S}$, $s \mapsto \bar{s}$ such that $\langle \omega, \bar{s}\rangle = \overline{\langle s, \omega\rangle}$ for every $\omega \in S^*$. The space $\bar{\bar{S}}$ can be identified with $S$ and then $\bar{\bar{s}} = s$. The spaces $(\bar{S})^*$ and $\overline{S^*}$ are identified. If $f: S_1 \to S_2$ is a complex-linear map, then there is the complex-conjugate map $\bar{f}: \bar{S}_1 \to \bar{S}_2$ given by $\bar{f}(\bar{s}) = \overline{f(s)}$ and the Hermitian conjugate map $f^\dagger \overset{\mathrm{def}}{=} \bar{f}^*: S_1 \to \bar{S_2}^*$. A linear map $A: S \to \bar{S}^*$ such that $A^\dagger = A$ is said to be Hermitian. $K(N)$ denotes, for $K = \mathbb{R}$, $\mathbb{C}$ or $\mathbb{H}$, the set of all $N$ by $N$ matrices with elements in $K$.

## Real, Complex, and Quaternionic Structures

A real structure on a complex vector space $S$ is a complex-linear map $C: S \to \bar{S}$ such that $\bar{C}C = \mathrm{id}_S$. A vector $s \in S$ is said to be real if $\bar{s} = C(s)$. The set of all real vectors is a real vector space; its real dimension is the same as the complex dimension of $S$.

A complex-linear map $C: S \to \bar{S}$ such that $\bar{C}C = -\mathrm{id}_S$ defines on $S$ a quaternionic structure; a necessary condition for such a structure to exist is that the complex dimension $m$ of $S$ be even, $m = 2n$, $n \in \mathbb{N}$. The space $S$ with a quaternionic structure can be made into a right vector space over the field $\mathbb{H}$ of quaternions. In the context of quaternions, it is convenient to represent the imaginary unit of $\mathbb{C}$ as $\sqrt{-1}$. Multiplication on the right by the quaternion unit i is realized as the multiplication (on the left) by $\sqrt{-1}$. If j and $\mathrm{k} = \mathrm{ij}$ are the other two quaternion units and $s \in S$, then one puts $s\mathrm{j} = \bar{C}(\bar{s})$ and $s\mathrm{k} = s\mathrm{ij}$.

A real vector space $S$ can be complexified by forming the tensor product $\mathbb{C} \otimes_{\mathbb{R}} S = S \oplus \mathrm{i}S$.

The realification of a complex vector space $S$ is the real vector space having $S$ as its set of vectors so that $\dim_{\mathbb{R}} S = 2\dim_{\mathbb{C}} S$. The complexification of a realification of $S$ is the "double" $S \oplus S$ of the original space.

## Inner-Product Spaces and Their Groups

**Definitions: quadratic and symplectic spaces** A bilinear map $B: S \times S \to K$ on a vector space $S$ over $K$ is said to make $S$ into an inner-product space. To save on notation, one also writes $B: S \to S^*$ so that $\langle s, B(t)\rangle = B(s, t)$ for all $s, t \in S$. The group of automorphisms of an inner-product space,

$$\mathrm{Aut}(S, B) = \{R \in \mathrm{GL}(S) | R^* \circ B \circ R = B\}$$

is a Lie subgroup of the general linear group $\mathrm{GL}(S)$. An inner-product space $(S, B)$ is said here to be

quadratic (resp., symplectic) if $B$ is symmetric (resp., antisymmetric and nonsingular). A quadratic space is characterized by its quadratic form $s \mapsto B(s,s)$. For $K=\mathbb{C}$, a Hermitian map $A: S \to \bar{S}^*$ defines a Hermitian scalar product $A(s,t) = \langle \bar{s}, A(t) \rangle$.

An orthogonal space is defined here as a quadratic space $(S,B)$ such that $B: S \to S^*$ is an isomorphism. The group of automorphisms of an orthogonal space is the orthogonal group $\mathrm{O(S,B)}$. The group of automorphisms of a symplectic space is the symplectic group $\mathrm{Sp}(S,B)$. The dimension of a symplectic space is even. If $S = K^{2n}$ is a symplectic space over $K=\mathbb{R}$ or $\mathbb{C}$, then its symplectic group is denoted by $\mathrm{Sp}_{2n}(K)$. Two quaternionic symplectic groups appear in the list of spin groups of low-dimensional spaces:

$$\mathrm{Sp}_2(\mathbb{H}) = \{a \in \mathbb{H}(2) \mid a^\dagger a = I\}$$

and

$$\mathrm{Sp}_{1,1}(\mathbb{H}) = \{a \in \mathbb{H}(2) \mid a^\dagger \sigma_z a = \sigma_z\}$$

Here $a^\dagger$ denotes the matrix obtained from $a$ by transposition and quaternionic conjugation.

**Contractions, frames, and orthogonality** From now on, unless otherwise specified, $(V,g)$ is a quadratic space of dimension $m$. Let $\wedge V = \oplus_{p=0}^{m} \wedge^p V$ be its exterior (Grassmann) algebra. For every $v \in V$ and $w \in \wedge V$ there is the contraction $g(v) \rfloor w$ characterized as follows. The map $V \times \wedge V \to \wedge V$, $(v,w) \mapsto g(v) \rfloor w$, is bilinear; if $x \in \wedge^p V$, then $g(v) \rfloor (x \wedge w) = (g(v) \rfloor x) \wedge w + (-1)^p x \wedge (g(v) \rfloor w)$ and $g(v) \rfloor v = g(v,v)$.

A frame $(e_\mu)$ in a quadratic space $(V,g)$ is said to be a quadratic frame if $\mu \neq \nu$ implies $g(e_\mu, e_\nu) = 0$.

For every subset $W$ of $V$ there is the orthogonal subspace $W^\perp$ containing all vectors that are orthogonal to every element of $W$.

If $(V,g)$ is a real orthogonal space, then there is an orthonormal frame $(e_\mu)$, $\mu = 1, \ldots, m$, in $V$ such that $k$ frame vectors have squares equal to $-1$, $l$ frame vectors have squares equal to 1 and $k + l = m$. The pair $(k,l)$ is the signature of $g$. The quadratic form $g$ is said to be neutral if the orthogonal space $(V,g)$ admits two maximal totally null subspaces $W$ and $W'$ such that $V = W \oplus W'$. Such a space $V$ is $2n$-dimensional, either complex or real with $g$ of signature $(n,n)$. A Lorentzian space has maximal totally null subspaces of dimension 1 and a Euclidean space, characterized by a definite quadratic form, has no null subspaces. The Minkowski space is a Lorentzian space of dimension 4.

If $(V,g)$ is a complex orthogonal space, then an orthonormal frame $(e_\mu)$, $\mu = 1, \ldots, m$, can be chosen in $V$ so that, defining $g_{\mu\nu} = g(e_\mu, e_\nu)$, one has $g_{\mu\mu} = (-1)^{\mu+1}$ and, if $\mu \neq \nu$, then $g_{\mu\nu} = 0$.

If $A: S \to \bar{S}^*$ is a Hermitian isomorphism, then there is a (pseudo)unitary frame $(e_\alpha)$ in $S$ such that the matrix $A_{\bar{\alpha}\beta} = A(e_\alpha, e_\beta)$ is diagonal, has $p$ 1's and $q$ $-1$'s on the diagonal, $p + q = \dim S$. If $p = q$, then $A$ is said to be neutral. $A$ is definite if either $p$ or $q = 0$.

## Algebras

**Definitions** An algebra over $K$ is a vector space $\mathcal{A}$ over $K$ with a bilinear map $\mathcal{A} \times \mathcal{A} \to \mathcal{A}$, $(a,b) \mapsto ab$, which is distributive with respect to addition. The algebra is associative if $(ab)c = a(bc)$ holds for all $a,b,c \in \mathcal{A}$. It is commutative if $ab = ba$ for all $a,b \in \mathcal{A}$. An element $1_\mathcal{A}$ is the unit of $\mathcal{A}$ if $1_\mathcal{A} a = a 1_\mathcal{A} = a$ holds for every $a \in \mathcal{A}$.

From now on, unless otherwise specified, the bare word algebra denotes a finite-dimensional, associative algebra over $K = \mathbb{R}$ or $\mathbb{C}$, with a unit element. If $S$ is an $N$-dimensional vector space over $K$, then the set $\mathrm{End}\, S$ of all endomorphisms of $S$ is an $N^2$-dimensional algebra over $K$, the product being defined by composition; if $f, g \in \mathrm{End}\, S$, then one writes $fg$ instead of $f \circ g$; the unit of $\mathrm{End}\, S$ is the identity map $I$. By definition, homomorphisms of algebras map units into units. The map $K \to \mathcal{A}$, $a \mapsto a 1_\mathcal{A}$ is injective and one identifies $K$ with its image in $\mathcal{A}$ by this map so that the unit can be represented by $1 \in K \subset \mathcal{A}$. A set $\mathcal{B} \subset \mathcal{A}$ is said to generate $\mathcal{A}$ if every element of $\mathcal{A}$ can be represented as a linear combination of products of elements of $\mathcal{B}$. For example, if $V$ is a vector space over $K$, then its tensor algebra

$$\mathcal{T}(V) = \oplus_{p=0}^{\infty} \otimes^p V$$

is an (infinite-dimensional) algebra over $K$ generated by $K \oplus V$. The algebra of all $N \times N$ matrices with entries in an algebra $\mathcal{A}$ is denoted by $\mathcal{A}(N)$. Its unit element is the unit matrix $I$. In particular, $\mathbb{R}(N)$, $\mathbb{C}(N)$, and $\mathbb{H}(N)$ are algebras over $\mathbb{R}$. The algebra $\mathbb{R}(2)$ is generated by the set $\{\sigma_x, \sigma_z\}$. As a vector space, the algebra $\mathbb{R}(2)$ is spanned by the set $\{I, \sigma_x, \varepsilon, \sigma_z\}$.

The direct sum $\mathcal{A} \oplus \mathcal{B}$ of the algebras $\mathcal{A}$ and $\mathcal{B}$ over $K$ is an algebra over $K$ such that its underlying vector space is $\mathcal{A} \times \mathcal{B}$ and the product is defined by $(a,b) \cdot (a',b') = (aa', bb')$ for every $a, a' \in \mathcal{A}$ and $b, b' \in \mathcal{B}$. Similarly, the product in the tensor product algebra $\mathcal{A} \otimes_K \mathcal{B}$ is defined by

$$(a \otimes b) \cdot (a' \otimes b') = aa' \otimes bb' \qquad [3]$$

For example, if $\mathcal{A}$ is an algebra over $\mathbb{R}$, then the tensor product algebra $\mathbb{R}(N) \otimes_{\mathbb{R}} \mathcal{A}$ is isomorphic to $\mathcal{A}(N)$ and

$$K(N) \otimes_K K(N') = K(NN') \quad [4]$$

for $K = \mathbb{R}$ or $\mathbb{C}$ and $N, N' \in \mathbb{N}$. There are isomorphisms of algebras over $\mathbb{R}$:

$$\begin{aligned} \mathbb{C} \otimes_{\mathbb{R}} \mathbb{C} &= \mathbb{C} \oplus \mathbb{C} \\ \mathbb{C} \otimes_{\mathbb{R}} \mathbb{H} &= \mathbb{C}(2) \\ \mathbb{H} \otimes_{\mathbb{R}} \mathbb{H} &= \mathbb{R}(4) \end{aligned} \quad [5]$$

An algebra over $\mathbb{R}$ can be complexified by complexifying its underlying vector space; it follows from [5] that $\mathbb{C}(2)$ is the complex algebra obtained by complexification of the real algebra $\mathbb{H}$.

The center of an algebra $\mathcal{A}$ is the set

$$\mathcal{Z}(\mathcal{A}) = \{a \in \mathcal{A} \mid ab = ba \ \forall \ b \in \mathcal{A}\}$$

The center is a commutative subalgebra containing $K$. An algebra over $K$ is said to be central if its center coincides with $K$. The algebras $\mathbb{R}(N)$ and $\mathbb{H}(N)$ are central over $\mathbb{R}$. The algebra $\mathbb{C}(N)$ is central over $\mathbb{C}$, but not over $\mathbb{R}$.

**Simplicity and representations** Let $\mathcal{B}_1$ and $\mathcal{B}_2$ be subsets of the algebra $\mathcal{A}$. Define $\mathcal{B}_1\mathcal{B}_2 = \{b_1 b_2 \mid b_1 \in \mathcal{B}_1, b_2 \in \mathcal{B}_2\}$. A vector subspace $\mathcal{B}$ of $\mathcal{A}$ is said to be a left (resp., right) ideal of $\mathcal{A}$ if $\mathcal{A}\mathcal{B} \subset \mathcal{B}$ (resp., $\mathcal{B}\mathcal{A} \subset \mathcal{B}$). A two-sided ideal – or simply an ideal – is a left and right ideal. An algebra $\mathcal{A} \neq \{0\}$ is said to be simple if its only two-sided ideals are $\{0\}$ and $\mathcal{A}$.

For example, the algebras $\mathbb{R}(N)$ and $\mathbb{H}(N)$ are simple over $\mathbb{R}$; the algebra $\mathbb{C}(N)$ is simple when considered as an algebra over both $\mathbb{R}$ and $\mathbb{C}$; every associative, finite-dimensional simple algebra over $\mathbb{R}$ or $\mathbb{C}$ is isomorphic to one of them.

A representation of an algebra $\mathcal{A}$ over $K$ in a vector space $S$ over $K$ is a homomorphism of algebras $\rho : \mathcal{A} \to \operatorname{End} S$. If $\rho$ is injective, then the representation is said to be faithful. For example, the regular representation $\rho$: $\mathcal{A} \to \operatorname{End} A$ of an algebra $\mathcal{A}$, defined by $\rho(a)b = ab$ for all $a, b \in \mathcal{A}$, is faithful. A vector subspace $T$ of the vector space $S$ carrying a representation $\rho$ of $\mathcal{A}$ is said to be invariant for $\rho$ if $\rho(a)T \subset T$ for every $a \in \mathcal{A}$; it is proper if distinct from both $\{0\}$ and $S$. For example, a left ideal of $\mathcal{A}$ is invariant for the regular representation. Given an invariant subspace $T$ of $\rho$ one can reduce $\rho$ to $T$ by forming the representation $\rho_T : \mathcal{A} \to \operatorname{End} T$, where $\rho_T(a)s = \rho(a)s$ for every $a \in \mathcal{A}$ and $s \in T$. A representation is irreducible if it has no proper invariant subspaces.

A linear map $F : S_1 \to S_2$ is said to intertwine the representations $\rho_1 : \mathcal{A} \to \operatorname{End} S_1$ and $\rho_2 : \mathcal{A} \to \operatorname{End} S_2$ if $F\rho_1(a) = \rho_2(a)F$ holds for every $a \in \mathcal{A}$. If $F$ is an isomorphism, then the representations $\rho_1$ and $\rho_2$ are said to be equivalent, $\rho_1 \sim \rho_2$. The following two propositions are classical:

**Proposition (A)**

(i) *An algebra over $K$ is simple if and only if it admits a faithful irreducible representation in a vector space over $K$. Such a representation is unique, up to equivalence.*

(ii) *The complexification of a central simple algebra over $\mathbb{R}$ is a central simple algebra over $\mathbb{C}$.*

For real algebras, one often considers complex representations, that is, representations in complex vector spaces. Two such representations $\rho_1 : \mathcal{A} \to \operatorname{End} S_1$ and $\rho_2 : \mathcal{A} \to \operatorname{End} S_2$ are said to be complex equivalent if there is a complex isomorphism $F : S_1 \to S_2$ intertwining the representations; they are real equivalent if there is an isomorphism among the realifications of $S_1$ and $S_2$, intertwining the representations. For example, $\mathbb{C}$, considered as an algebra over $\mathbb{R}$, has two complex-inequivalent representations in $\mathbb{C}$: the identity representation and its complex conjugate. The realifications of these representations, given by $\mathrm{i} \mapsto \varepsilon$ and $\mathrm{i} \mapsto -\varepsilon$, respectively, are real equivalent: they are intertwined by $\sigma_z$. The real algebra $\mathbb{H}$, being central simple, has only one, up to complex equivalence, representation in $\mathbb{C}^2$: every such representation is equivalent to the one given by

$$\mathrm{i} \mapsto \sigma_x/\sqrt{-1}, \qquad \mathrm{j} \mapsto \sigma_y/\sqrt{-1}, \qquad \mathrm{k} \mapsto \sigma_z/\sqrt{-1}$$

This representation extends to an injective homomorphism of algebras $i : \mathbb{H}(N) \to \mathbb{C}(2N)$ which is used to define the quaternionic determinant of a matrix $a \in \mathbb{H}(N)$ as $\det_{\mathbb{H}}(a) = \det i(a)$, so that $\det_{\mathbb{H}}(a) \geqslant 0$ and $\det_{\mathbb{H}}(ab) = \det_{\mathbb{H}}(a)\det_{\mathbb{H}}(b)$ for every $a, b \in \mathbb{H}(N)$. In particular, if $q \in \mathbb{H}$ and $\lambda, \mu \in \mathbb{R}$, then $\det_{\mathbb{H}}(q) = \bar{q}q$ and

$$\det_{\mathbb{H}} \begin{pmatrix} \lambda & q \\ -\bar{q} & \mu \end{pmatrix} = (\lambda\mu + \bar{q}q)^2 \quad [6]$$

There are quaternionic unimodular groups $\mathrm{SL}_N(\mathbb{H}) = \{a \in \mathbb{H}(N) \mid \det_{\mathbb{H}}(a) = 1\}$. For example, the group $\mathrm{SL}_1(\mathbb{H})$ is isomorphic to $\mathrm{SU}_2$ and $\mathrm{SL}_2(\mathbb{H})$ is a noncompact, 15-dimensional Lie group, one of the spin groups in six dimensions.

**Antiautomorphisms and inner products** An automorphism of an algebra $\mathcal{A}$ is a linear isomorphism $\alpha$: $\mathcal{A} \to \mathcal{A}$ such that $\alpha(ab) = \alpha(a)\alpha(b)$. An invertible element $c \in \mathcal{A}$ defines an inner automorphism $\mathrm{Ad}(c) \in \mathrm{GL}(\mathcal{A})$, $\mathrm{Ad}(c)a = cac^{-1}$. Complex conjugation in $\mathbb{C}$, considered as an algebra over $\mathbb{R}$, is an automorphism that is not inner. An antiautomorphism of an

algebra $\mathcal{A}$ is a linear isomorphism $\beta:\mathcal{A}\to\mathcal{A}$ such that $\beta(ab)=\beta(b)\beta(a)$ for all $a,b\in\mathcal{A}$. An (anti)automorphism $\beta$ is involutive if $\beta^2=\mathrm{id}$. For example, conjugation of quaternions defines an involutive antiautomorphism of $\mathbb{H}$.

Let $\rho:\mathcal{A}\to\mathrm{End}\,S$ be a representation of an algebra with an involutive antiautomorphism $\beta$. There is then the contragredient representation $\check{\rho}:\mathcal{A}\to\mathrm{End}\,S^*$ given by $\check{\rho}(a)=(\rho(\beta(a)))^*$. If, moreover, $\mathcal{A}$ is central simple and $\rho$ is faithful irreducible, then there is an isomorphism $B:S\to S^*$ intertwining $\rho$ and $\check{\rho}$ which is either symmetric, $B^*=B$, or antisymmetric, $B^*=-B$. It defines on $S$ the structure of an inner-product space. This structure extends to $\mathrm{End}\,S$: there is a symmetric isomorphism $B\otimes B^{-1}:\mathrm{End}\,S\to(\mathrm{End}\,S)^*=\mathrm{End}\,S^*$ given, for every $f\in\mathrm{End}\,S$, by $(B\otimes B^{-1})(f)=BfB^{-1}$.

Let $K^\times=K\backslash\{0\}$ be the multiplicative group of the field $K$. Given a simple algebra $\mathcal{A}$ with an involutive antiautomorphism $\beta$, one defines $N(a)=\beta(a)a$ and the group

$$\mathcal{G}(\beta)=\{a\in\mathcal{A}\,|\,N(a)\in K^\times\}$$

Let $\rho:\mathcal{A}\to\mathrm{End}\,S$ be the faithful irreducible representation as above, then, for $a\in\mathcal{A}$ and $s,t\in S$, one has

$$B(\rho(a)s,\rho(a)t)=N(a)B(s,t)$$

If $a\in\mathcal{G}(\beta)$ and $\lambda\in K^\times$, then $\lambda a\in\mathcal{G}(\beta)$ and the norm $N$ satisfies $N(\lambda a)=\lambda^2N(a)$. The inner product $B$ is invariant with respect to the action of the group

$$\mathcal{G}_1(\beta)=\{a\in\mathcal{G}(\beta)\,|\,N(a)=1\}$$

**Proposition (B)** *Let $\mathcal{A}$ be a central simple algebra over $K$ with an involutive antiautomorphism $\beta$ and a faithful irreducible representation $\rho$ so that*

$$\check{\rho}(a)=B\rho(a)B^{-1}$$

*The map $h:\mathcal{A}\times\mathcal{A}\to K$ defined by*

$$h(a,b)=\mathrm{tr}\,\rho(\beta(a)b)$$

is bilinear, symmetric, and nondegenerate. The map *$\rho$ is an isometry of the quadratic space $(\mathcal{A},h)$ on its image in the quadratic space* $(\mathrm{End}\,S, B\otimes B^{-1})$.

## Graded Algebras

**Definitions** An algebra $\mathcal{A}$ is said to be $\mathbb{Z}$-graded (resp., $\mathbb{Z}_2$-graded) if there is a decomposition of the underlying vector space $\mathcal{A}=\oplus_{p\in\mathbb{Z}}\mathcal{A}^p$ (resp., $\mathcal{A}=\mathcal{A}^0\oplus\mathcal{A}^1$) such that $\mathcal{A}^p\mathcal{A}^q\subset\mathcal{A}^{p+q}$. In a $\mathbb{Z}_2$-graded algebra, it is understood that $p+q$ is reduced mod 2. If $a\in\mathcal{A}^p$, then $a$ is said to be homogeneous of degree $p$. The exterior algebra $\wedge V$ of a vector space $V$ is $\mathbb{Z}$-graded. Every $\mathbb{Z}$-graded algebra becomes $\mathbb{Z}_2$-graded when one reduces the degree of every element mod 2. A graded isomorphism of graded algebras is an isomorphism that preserves the grading.

A $\mathbb{Z}_2$-grading of $\mathcal{A}$ is characterized by the involutive automorphism $\alpha$ such that, if $a\in\mathcal{A}^p$, then $\alpha(a)=(-1)^pa$. From now on, grading means $\mathbb{Z}_2$-grading unless otherwise specified. The elements of $\mathcal{A}^0$ (resp., $\mathcal{A}^1$) are said to be even (resp., odd). It is often convenient to denote the graded algebra as

$$\mathcal{A}^0\to\mathcal{A} \qquad [7]$$

Given such an algebra over $K$ and $N\in\mathbb{N}$, one constructs the graded algebra $\mathcal{A}^0(N)\to\mathcal{A}(N)$. Two graded algebras over $K$, $\mathcal{A}^0\to\mathcal{A}$ and $\mathcal{A}'^0\to\mathcal{A}'$ are said to be of the same type if there are integers $N$ and $N'$ such that the algebras $\mathcal{A}^0(N)\to\mathcal{A}(N)$ and $\mathcal{A}'^0(N')\to\mathcal{A}'(N')$ are graded isomorphic. The property of being of the same type is an equivalence relation in the set of all graded algebras over $K$.

Given an algebra $\mathcal{A}$, one constructs two "canonical" graded algebras as follows:

1. the double algebra

$$\mathcal{A}\to\mathcal{A}\oplus\mathcal{A}$$

graded by the "swap" automorphism, $\alpha(a_1,a_2)=(a_2,a_1)$ for $a_1,a_2\in\mathcal{A}$;

2. the algebra

$$\mathcal{A}\oplus\mathcal{A}\to\mathcal{A}(2)$$

is defined by declaring the diagonal (resp., antidiagonal) elements of $\mathcal{A}(2)$ to be even (resp., odd).

The real algebra $\mathbb{R}(2)$ has also another grading, given by the involutive automorphism $\alpha$ such that $\alpha(a)=\varepsilon a\varepsilon^{-1}$, where $a\in\mathbb{R}(2)$ and $\varepsilon$ is as in [2]. In this case, [7] reads

$$\mathbb{C}\to\mathbb{R}(2)$$

There are also graded algebras over $\mathbb{R}$:

$$\mathbb{R}\to\mathbb{C},\quad \mathbb{C}\to\mathbb{H},\quad \text{and}\quad \mathbb{H}\to\mathbb{C}(2)$$

The grading of the last algebra can be defined by declaring the Pauli matrices and i$I$ to be odd.

**Super Lie algebras** A super Lie algebra is a graded algebra $\mathcal{A}$ such that the product $(a,b)\mapsto[a,b]$ is super anticommutative, $[a,b]=-(-1)^{pq}[b,a]$, and satisfies the super Jacobi identity,

$$[a,[b,c]]=[[a,b],c]+(-1)^{pq}[b,[a,c]]$$

for every $a\in\mathcal{A}^p$, $b\in\mathcal{A}^q$ and $c\in\mathcal{A}$. To every graded associative algebra $\mathcal{A}$ there corresponds a super Lie algebra $\mathcal{GLA}$: its underlying vector space and grading are as in $\mathcal{A}$ and the product, for $a\in\mathcal{A}^p$

and $b \in \mathcal{A}^q$, is given as the supercommutator $[a, b] = ab - (-1)^{pq} ba$.

**Supercentrality and graded simplicity** A graded algebra $\mathcal{A}$ over $K$ is supercentral if $\mathcal{Z}(\mathcal{A}) \cap \mathcal{A}^0 = K$. The algebra $\mathbb{R} \to \mathbb{C}$ is supercentral, but the real ungraded algebra $\mathbb{C}$ is not central.

A subalgebra $\mathcal{B}$ of a graded algebra $\mathcal{A}$ is said to be a graded subalgebra if $\mathcal{B} = \mathcal{B} \cap \mathcal{A}^0 \oplus \mathcal{B} \cap \mathcal{A}^1$. A graded ideal of $\mathcal{A}$ is an ideal that is a graded subalgebra. A graded algebra $\mathcal{A} \neq \{0\}$ is said to be graded simple if it has no graded ideals other than $\{0\}$ and $\mathcal{A}$. The double algebra of a simple algebra is graded simple, but not simple.

**The graded tensor product** Let $\mathcal{A}$ and $\mathcal{B}$ be graded algebras; the tensor product of their underlying vector spaces admits a natural grading, $(\mathcal{A} \otimes \mathcal{B})^p = \oplus_q \mathcal{A}^q \otimes \mathcal{B}^{p-q}$. The product defined in [3] makes $\mathcal{A} \otimes \mathcal{B}$ into a graded algebra. There is another "super" product in the same graded vector space given by

$$(a \otimes b) \cdot (a' \otimes b') = (-1)^{pq} aa' \otimes bb'$$

for $a' \in \mathcal{A}^p$ and $b \in \mathcal{B}^q$. The resulting graded algebra is referred to as the graded tensor product and denoted by $\mathcal{A} \hat{\otimes} \mathcal{B}$. For example, if $V$ and $W$ are vector spaces, then the Grassmann algebra $\wedge(V \oplus W)$ is isomorphic to $\wedge V \hat{\otimes} \wedge W$.

## Clifford Algebras

### Definitions: The Universal Property and Grading

The Clifford algebra associated with a quadratic space $(V, g)$ is the quotient algebra

$$\mathcal{C}\ell(V, g) = \mathcal{T}(V)/\mathcal{J}(V, g) \qquad [8]$$

where $\mathcal{J}(V, g)$ is the ideal in the tensor algebra $\mathcal{T}(V)$ generated by all elements of the form $v \otimes v - g(v, v)1_{\mathcal{T}(V)}$, $v \in V$.

The Clifford algebra is associative with a unit element denoted by 1. One denotes by $\kappa$ the canonical map of $\mathcal{T}(V)$ onto $\mathcal{C}\ell(V, g)$ and by $ab$ the product of two elements $a, b \in \mathcal{C}\ell(V, g)$ so that $\kappa(P \otimes Q) = \kappa(P)\kappa(Q)$ for $P, Q \in \mathcal{T}(V)$. The map $\kappa$ is injective on $K \oplus V$, and one identifies this subspace of $\mathcal{T}(V)$ with its image under $\kappa$. With this identification, for all $u, v \in V$, one has

$$uv + vu = 2g(u, v)$$

Clifford algebras are characterized by their universal property described in the following proposition.

**Proposition (C)** *Let $\mathcal{A}$ be an algebra with a unit $1_{\mathcal{A}}$ and let $f : V \to \mathcal{A}$ be a* Clifford map, *that is, a linear map such that $f(v)^2 = g(v, v)1_{\mathcal{A}}$ for every $v \in V$. There then exists a homomorphism $\hat{f}: \mathcal{C}\ell(V, g) \to \mathcal{A}$ of algebras with units, an extension of $f$, so that $f(v) = \hat{f}(v)$ for every $v \in V$.*

As a corollary, one obtains

**Proposition (D)** *If $f$ is an isometry of $(V, g)$ into $(W, h)$, then there is a homomorphism of algebras $\mathcal{C}\ell(f) : \mathcal{C}\ell(V, g) \to \mathcal{C}\ell(W, h)$ extending $f$ so that there is the commutative diagram*

$$\begin{array}{ccc} \mathcal{C}\ell(V, g) & \xrightarrow{\mathcal{C}\ell(f)} & \mathcal{C}\ell(W, h) \\ \uparrow & & \uparrow \\ V & \underset{f}{\longrightarrow} & W \end{array}$$

For example, the isometry $v \mapsto -v$ extends to the involutive main automorphism $\alpha$ of $\mathcal{C}\ell(V, g)$, defining its $\mathbb{Z}_2$-grading:

$$\mathcal{C}\ell(V, g) = \mathcal{C}\ell^0(V, g) \oplus \mathcal{C}\ell^1(V, g)$$

The algebra $\mathcal{C}\ell(V, g)$ admits also an involutive canonical antiautomorphism $\beta$ characterized by $\beta(1) = 1$ and $\beta(v) = v$ for every $v \in V$.

### The Vector Space Structure of Clifford Algebras

Referring to proposition (D), let $\mathcal{A} = \mathrm{End}(\wedge V)$ and, for every $v \in V$ and $w \in \wedge V$, put $f(v)w = v \wedge w + g(v) \rfloor w$, then $f : V \to \mathrm{End}(\wedge V)$ is a Clifford map and the map

$$i : \mathcal{C}\ell(V, g) \to \wedge V \qquad [9]$$

given by $i(a) = \hat{f}(a)1_{\wedge V}$ is an isomorphism of vector spaces. This proves

**Proposition (E)** *As a* vector space, *the algebra $\mathcal{C}\ell(V, g)$ is isomorphic to the exterior algebra $\wedge V$.*

If $V$ is $m$-dimensional, then $\mathcal{C}\ell(V, g)$ is $2^m$-dimensional. The linear isomorphism [9] defines a $\mathbb{Z}$-grading of the vector space underlying the Clifford algebra: if $i(a_k) \in \wedge^k V$, then $a_k$ is said to be of Grassmann degree $k$. Every element $a \in \mathcal{C}\ell(V, g)$ decomposes into its Grassmann components, $a = \sum_{k \in \mathbb{Z}} a_k$. The Clifford product of two elements of Grassmann degrees $k$ and $l$ decomposes as follows: $a_k b_l = \sum_{p \in \mathbb{Z}} (a_k b_l)_p$, and $(a_k b_l)_p = 0$ if $p < |k - l|$ or $p \equiv k - l + 1 \bmod 2$ or $p > m - |m - k - l|$.

One often uses [9] to identify the vector spaces $\wedge V$ and $\mathcal{C}\ell(V, g)$; this having been done, one can write, for every $v \in V$ and $a \in \mathcal{C}\ell(V, g)$,

$$va = v \wedge a + g(v) \rfloor a \qquad [10]$$

so that $[v, a] = 2g(v) \rfloor a$, where $[\,,\,]$ is the supercommutator. It defines a super Lie algebra structure in the vector space $K \oplus V$. The quadratic form defined by $g$ need not be nondegenerate; for example, if it is the

0-form, then [10] shows that the Clifford and exterior multiplications coincide and $\mathcal{C}\ell(V,0)$ is isomorphic, as an algebra, to the Grassmann algebra.

### Complexification of Real Clifford Algebras

**Proposition (F)** *If $(V,g)$ is a real quadratic space, then the algebras $\mathbb{C}\otimes\mathcal{C}\ell(V,g)$ and $\mathcal{C}\ell(\mathbb{C}\otimes V,\mathbb{C}\otimes g)$ are isomorphic, as graded algebras over $\mathbb{C}$.*

From now on, through the end of the article, one assumes that $(V,g)$ is an orthogonal space over $K=\mathbb{R}$ or $\mathbb{C}$.

The Clifford algebra associated with the orthogonal space $\mathbb{C}^m$ is denoted by $\mathcal{C}\ell_m$. The Clifford algebra associated with the orthogonal space $(\mathbb{R}^{k+l},g)$, where $g$ is of signature $(k,l)$, is denoted by $\mathcal{C}\ell_{k,l}$, so that $\mathbb{C}\otimes\mathcal{C}\ell_{k,l}=\mathcal{C}\ell_{k+l}$.

### Relations between Clifford Algebras in Spaces of Adjacent Dimensions

Consider an orthogonal space $(V,g)$ over $K$ and the one-dimensional orthogonal space $(K,h_1)$, having a unit vector $w\in K$, $h_1(w,w)=\varepsilon$, where $\varepsilon=1$ or $-1$. The map $V\ni v\mapsto vw\in\mathcal{C}\ell^0(V\oplus K,g\oplus h_1)$ satisfies $(vw)^2=-\varepsilon g(v,v)$ and extends to the isomorphism of algebras $\mathcal{C}\ell(V,-\varepsilon g)\to\mathcal{C}\ell^0(V\oplus K,g\oplus h_1)$. This proves

**Proposition (G)** *There are isomorphisms of algebras: $\mathcal{C}\ell_m\to\mathcal{C}\ell^0_{m+1}$ and $\mathcal{C}\ell_{k,l}\to\mathcal{C}\ell^0_{k+1,l}$.*

Consider the orthogonal space $(K^2,h)$ with a neutral $h$ such that, for $\lambda,\mu\in K$, one has $\langle(\lambda,\mu),h(\lambda,\mu)\rangle=\lambda\mu$. The map

$$K^2\to K(2),\qquad(\lambda,\mu)\mapsto\begin{pmatrix}0&\lambda\\ \mu&0\end{pmatrix}$$

has the Clifford property and establishes the isomorphisms represented by the horizontal arrows in the diagram

$$\begin{array}{ccc}\mathcal{C}\ell(K^2,h)&\to&K(2)\\ \uparrow&&\uparrow\\ \mathcal{C}\ell^0(K^2,h)&\to&K\oplus K\end{array}\qquad[11]$$

**Proposition (H)** *If $(K^2,h)$ is neutral and $(V,g)$ is over $K$, then the algebra $\mathcal{C}\ell(V\oplus K^2,g\oplus h)$ is isomorphic to the algebra $\mathcal{C}\ell(V,g)\otimes K(2)$. Specifically, there are isomorphisms*

$$\begin{aligned}\mathcal{C}\ell_{k+1,l+1}&=\mathcal{C}\ell_{k,l}\otimes\mathbb{R}(2)\\ \mathcal{C}\ell_{m+2}&=\mathcal{C}\ell_m\otimes\mathbb{C}(2)\end{aligned}\qquad[12]$$

### The Chevalley Theorem and the Brauer–Wall Group

If $(V,g)$ and $(W,h)$ are quadratic spaces over $K$, then their sum is the quadratic space $(V\oplus W,g\oplus h)$ characterized by $g\oplus h:V\oplus W\to V^*\oplus W^*$ so that $(g\oplus h)(v,w)=(g(v),h(w))$. By noting that the map $V\oplus W\ni(v,w)\mapsto v\otimes1+1\otimes w\in\mathcal{C}\ell(V,g)\hat{\otimes}\mathcal{C}\ell(W,h)$ has the Clifford property, Chevalley proved

**Proposition (I)** *The algebra $\mathcal{C}\ell(V\oplus W,g\oplus h)$ is isomorphic to the algebra $\mathcal{C}\ell(V,g)\hat{\otimes}\mathcal{C}\ell(W,h)$.*

The type of the (graded) algebra $\mathcal{C}\ell(V\oplus W,g\oplus h)$ depends only on the types of $\mathcal{C}\ell(V,g)$ and $\mathcal{C}\ell(W,h)$. The Chevalley theorem (I) shows that the set of types of Clifford algebras over $K$ forms an abelian group for a multiplication induced by the graded tensor product. The unit of this Brauer–Wall group of $K$ is the type of the algebra $\mathcal{C}\ell(K^2,h)$ described in [11]; for a full account with proofs, see Wall (1963).

### The Volume Element and the Centers

Let $e=(e_\mu)$ be an orthonormal frame in $(V,g)$. The volume element associated with $e$ is

$$\eta=e_1e_2\cdots e_m$$

If $\eta'$ is the volume element associated with another orthonormal frame $e'$ in the same orthogonal space, then either $\eta'=\eta$ ($e$ and $e'$ are of the same orientation) or $\eta'=-\eta$ ($e$ and $e'$ are of opposite orientation). For $K=\mathbb{C}$, one has $\eta^2=1$; for $K=\mathbb{R}$ and $g$ of signature $(k,l)$ one has

$$\eta^2=(-1)^{(1/2)(k-l)(k-l+1)}\qquad[13]$$

It is convenient to define $\iota\in\{1,i\}$ so that $\eta^2=\iota^2$. For every $v\in V$ one has $v\eta=(-1)^{m+1}\eta v$. The structure of the centers of Clifford algebras is as follows:

**Proposition (J)** *If $m$ is even, then $\mathcal{Z}(\mathcal{C}\ell(V,g))=K$ and $\mathcal{Z}(\mathcal{C}\ell^0\ (V,g))=K\oplus K\eta$. If $m$ is odd, then $\mathcal{Z}(\mathcal{C}\ell(V,g))=K\oplus K\eta$ and $\mathcal{Z}(\mathcal{C}\ell^0(V,g))=K$.*

*The graded algebra $\mathcal{C}\ell(V,g)$ is supercentral for every $m$.*

### The Structure of Clifford Algebras

**The complex case** Using [4] one obtains from [11] and [12] the isomorphisms of algebras

$$\mathcal{C}\ell^0_{2n+1}=\mathcal{C}\ell_{2n}=\mathbb{C}(2^n)\qquad[14]$$

$$\mathcal{C}\ell_{2n+1}=\mathcal{C}\ell^0_{2n+2}=\mathbb{C}(2^n)\oplus\mathbb{C}(2^n)\qquad[15]$$

for $n=0,1,2,\ldots$. Therefore, there are only two types of complex Clifford algebras, represented by $\mathbb{C}\to\mathbb{C}\oplus\mathbb{C}$ and $\mathbb{C}\oplus\mathbb{C}\to\mathbb{C}(2)$: the Brauer–Wall group of $\mathbb{C}$ is $\mathbb{Z}_2$.

**The real case** In view of proposition (I) and $\mathcal{C}\ell_{1,1} = \mathbb{R}(2)$, the algebra $\mathcal{C}\ell_{k,l}$ is of the same type as $\mathcal{C}\ell_{k-l,0}$ if $k > l$ and of the same type as $\mathcal{C}\ell_{0,l-k}$ if $k < l$. Since $\mathcal{C}\ell_{k,l} \hat{\otimes} \mathcal{C}\ell_{l,k} = \mathcal{C}\ell_{k+l,k+l}$, the type of $\mathcal{C}\ell_{l,k}$ is the inverse of the type of $\mathcal{C}\ell_{k,l}$. The algebra $\mathcal{C}\ell^0_{4,0} \to \mathcal{C}\ell_{4,0}$ is isomorphic to $\mathbb{H} \oplus \mathbb{H} \to \mathbb{H}(2)$: if $x = (x_1, x_2, x_3, x_4) \in \mathbb{R}^4 \subset \mathcal{C}\ell_{4,0}$, and $q = \mathrm{i}x_1 + \mathrm{j}x_2 + \mathrm{k}x_3 + x_4 \in \mathbb{H}$, then an isomorphism is obtained from the Clifford map $f$,

$$f(x) = \begin{pmatrix} 0 & q \\ -\bar{q} & 0 \end{pmatrix} \qquad [16]$$

In view of [13], the volume element $\eta$ satisfies $\eta^2 = 1$. By replacing $-\bar{q}$ with $\bar{q}$ in [16], one shows that $\mathcal{C}\ell_{0,4}$ is also isomorphic to $\mathbb{H}(2)$. The map $\mathbb{R}^4 \times \mathbb{R}^{k+l} \to \mathbb{H}(2) \otimes \mathcal{C}\ell_{k,l}$ given by $(x, y) \mapsto f(x) \otimes 1 + \eta \otimes y$ has the Clifford property and establishes the isomorphism of algebras $\mathcal{C}\ell_{k+4,l} = \mathbb{H} \otimes \mathcal{C}\ell_{k,l}$. Since, similarly, $\mathcal{C}\ell_{k,l+4} = \mathbb{H} \otimes \mathcal{C}\ell_{k,l}$, one obtains the isomorphism

$$\mathcal{C}\ell_{k+4,l} = \mathcal{C}\ell_{k,l+4}$$

Therefore,

$$\mathcal{C}\ell_{k+8,l} = \mathcal{C}\ell_{k+4,l+4} = \mathcal{C}\ell_{k,l+8} = \mathcal{C}\ell_{k,l} \otimes \mathbb{R}(16)$$

and the algebras $\mathcal{C}\ell_{k,l}$, $\mathcal{C}\ell_{k+8,l}$, and $\mathcal{C}\ell_{k,l+8}$ are all of the same type. This double periodicity of period 8 is subsumed by saying that real Clifford algebras can be arranged on a "spinorial chessboard." The type of $\mathcal{C}\ell^0_{k,l} \to \mathcal{C}\ell_{k,l}$ depends only on $k - l \bmod 8$; the eight types have the following low-dimensional algebras as representatives: $\mathcal{C}\ell_{1,0}$, $\mathcal{C}\ell_{2,0}$, $\mathcal{C}\ell_{3,0}$, $\mathcal{C}\ell_{4,0} = \mathcal{C}\ell_{0,4}$, $\mathcal{C}\ell_{0,3}$, $\mathcal{C}\ell_{0,2}$, and $\mathcal{C}\ell_{0,1}$. The Brauer–Wall group of $\mathbb{R}$ is $\mathbb{Z}_8$, generated by the type of $\mathcal{C}\ell^0_{1,0} \to \mathcal{C}\ell_{1,0}$, that is, by $\mathbb{R} \to \mathbb{C}$. Bearing in mind the isomorphism $\mathcal{C}\ell_{k,l} = \mathcal{C}\ell^0_{k+1,l}$ and abbreviating $\mathbb{C} \to \mathbb{R}(2)$ to $\mathbb{C} \to \mathbb{R}$, etc., one can arrange the types of real Clifford algebras in the form of a "spinorial clock":

$$\begin{array}{ccccc} \mathbb{R} & \overset{7}{\rightarrow} & \mathbb{R} \oplus \mathbb{R} & \overset{0}{\rightarrow} & \mathbb{R} \\ 6\uparrow & & & & \downarrow 1 \\ \mathbb{C} & & & & \mathbb{C} \\ 5\uparrow & & & & \downarrow 2 \\ \mathbb{H} & \underset{4}{\leftarrow} & \mathbb{H} \oplus \mathbb{H} & \underset{3}{\leftarrow} & \mathbb{H} \end{array} \qquad [17]$$

**Proposition (K)** *Recipe for determining* $\mathcal{C}\ell^0_{k,l} \to \mathcal{C}\ell_{k,l}$:

(i) *find the integers* $\mu$ *and* $\nu$ *such that* $k - l = 8\mu + \nu$ *and* $0\ \nu\ 7$;
(ii) *from the spinorial clock, read off* $\mathcal{A}^0_\nu \to \nu\mathcal{A}_\nu$ *and compute the real dimensions*, $\dim \mathcal{A}^0_\nu = 2^{\tau^0}$ *and* $\dim \mathcal{A}_\nu = 2^\tau$; *and*
(iii) *form* $\mathcal{C}\ell^0_{k,l} = \mathcal{A}^0_\nu(2^{(1/2)(k+l-1-\tau^0)})$ *and* $\mathcal{C}\ell_{k,l} = \mathcal{A}_\nu(2^{(1/2)(k+l-\tau)})$.

The spinorial clock is symmetric with respect to the reflection in the vertical line through its center; this is a consequence of the isomorphism of algebras $\mathcal{C}\ell_{k,l+2} = \mathcal{C}\ell_{l,k} \otimes \mathbb{R}(2)$.

Note that the "abstract" algebra $\mathcal{C}\ell_{k,l}$ carries, in general, less information than the Clifford algebra defined in [8], which contains $V$ as a distinguished vector subspace with the quadratic form $v \mapsto v^2 = g(v, v)$. For example, the algebras $\mathcal{C}\ell_{8,0}$, $\mathcal{C}\ell_{4,4}$, and $\mathcal{C}\ell_{0,8}$ are all graded isomorphic.

### Theorem on Simplicity

From general theory (Chevalley 1954) or by inspection of [14], [15], and [17], one has

**Proposition (L)** *Let* $m$ *be the dimension of the orthogonal space* $(V, g)$ *over* $K$.

(i) *If* $m$ *is even (resp., odd), then the algebra* $\mathcal{C}\ell(V, g)$ *(resp.,* $\mathcal{C}\ell^0(V, g)$*) over* $K$ *is central simple.*
(ii) *If* $K = \mathbb{C}$ *and* $m$ *is odd (resp., even), then the algebra* $\mathcal{C}\ell(V, g)$ *(resp.,* $\mathcal{C}\ell^0(V, g)$*) is the direct sum of two isomorphic complex central simple algebras.*

## Representations

### The Pauli, Cartan, Dirac, and Weyl Representations

**Odd dimensions** Let $(V, g)$ be of dimension $m = 2n + 1$ over $K$. From propositions (A) and (L) it follows that the central simple algebra $\mathcal{C}\ell^0(V, g)$ has a unique, up to equivalence, faithful, and irreducible representation in the complex $2^n$-dimensional vector space $S$ of Pauli spinors. By putting $\sigma(\eta) = \iota I$ it is extended to a Pauli representation $\sigma : \mathcal{C}\ell(V, g) \to \operatorname{End} S$. Given an orthonormal frame $(e_\mu)$ in $V$, Pauli endomorphisms (matrices if $S$ is identified with $\mathbb{C}^{2^n}$) are defined as $\sigma_\mu = \sigma(e_\mu) \in \operatorname{End} S$. The representations $\sigma$ and $\sigma \circ \alpha$ are complex inequivalent. For $K = \mathbb{C}$ none of them is faithful; their direct sum is the faithful Cartan representation of $\mathcal{C}\ell(V, g)$ in $S \oplus S$. For $K = \mathbb{R}$ and $(1/2)(k - l - 1)$ even, the representations $\sigma$ and $\sigma \circ \alpha$ are real equivalent and faithful. On computing $\beta(\eta)$ one finds that the contragredient representation $\check{\sigma}$ is equivalent to $\sigma$ for $n$ even and to $\sigma \circ \alpha$ for $n$ odd.

**Even dimensions** Similarly, for $(V, g)$ of dimension $m = 2n$ over $K$, the central simple algebra $\mathcal{C}\ell(V, g)$ has a unique, up to equivalence, faithful, and

irreducible representation $\gamma : \mathcal{C}\ell(V,g) \to \operatorname{End} S$ in the $2^n$-dimensional complex vector space $S$ of Dirac spinors. The Dirac endomorphisms (matrices) are $\gamma_\mu = \gamma(e_\mu)$. Put $\Gamma = \iota\gamma(\eta)$ so that $\Gamma^2 = I$: the matrix $\Gamma$ generalizes the familiar $\gamma_5$. The Dirac representation $\gamma$ restricted to $\mathcal{C}\ell^0(V,g)$ decomposes into the sum $\gamma_+ \oplus \gamma_-$ of two irreducible representations in the vector spaces

$$S_\pm = \{s \in S \,|\, \Gamma s = \pm s\}$$

of Weyl (chiral) spinors. The elements of $S_+$ are said to be of opposite chirality with respect to those of $S_-$. The transpose $\Gamma^*$ defines a similar split of $S^*$. The representations $\gamma_+$ and $\gamma_-$ are never complex-equivalent, but they are real equivalent and faithful for $K = \mathbb{R}$ and $(1/2)(k-l)$ odd.

The representations $\gamma \circ \alpha$ and $\check{\gamma}$ are both equivalent to $\gamma$. It is convenient to describe simultaneously the properties of the transpositions of the Pauli and Dirac matrices; let $\rho_\mu$ be either the Pauli matrices for $V$ of dimension $2n+1$ or the Dirac matrices for $V$ of dimension $2n$. There is a complex isomorphism $B : S \to S^*$ such that

$$\rho^*_\mu = (-1)^n B \rho_\mu B^{-1} \qquad [18]$$

In the case of the Dirac matrices, the factor $(-1)^n$ in [18] implies that this equation also holds for $\Gamma$ in place of $\rho_\mu$. The isomorphism $B$ preserves (resp., changes) the chirality of Weyl spinors for $n$ even (resp., odd). Every matrix of the form $B\gamma_{\mu_1} \ldots \gamma_{\mu_p}$, where

$$1 \leqslant \mu_1 < \cdots < \mu_p 2n \qquad [19]$$

is either symmetric or antisymmetric, depending on $p$ and the symmetry of $B$. A simple argument, based on counting the number of such products of one symmetry, leads to the equation

$$B^* = (-1)^{(1/2)n(n+1)} B$$

valid in dimensions $2n$ and $2n+1$.

**Inner products on spinor spaces** Let $S$ be the complex vector space of Dirac or Pauli spinors associated with $(V,g)$ over $K$. The isomorphism $B$: $S \to S$ defines on $S$ an inner product $B(s,t) = \langle s, B(t)\rangle$, $s,t \in S$, which is orthogonal for $m \equiv 0,1,6,$ or $7 \bmod 8$ and symplectic for $m \equiv 2,3,4,$ or $5 \bmod 8$. For $m \equiv 0 \bmod 4$, this product restricts to an inner product on the space of Weyl spinors that is orthogonal for $m \equiv 0 \bmod 8$ and symplectic for $m \equiv 4 \bmod 8$. For $m \equiv 2 \bmod 4$, the map $B$ defines the isomorphisms $B_\pm : S_\pm \to S^*_\mp$.

**Example** One of the most used representations $\gamma$: $\mathcal{C}\ell_{3,1} \to \mathbb{C}(4)$ is given by the Dirac matrices

$$\gamma_1 = \begin{pmatrix} 0 & \sigma_x \\ -\sigma_x & 0 \end{pmatrix}, \qquad \gamma_2 = \begin{pmatrix} 0 & \sigma_y \\ -\sigma_y & 0 \end{pmatrix}$$

$$\gamma_3 = \begin{pmatrix} 0 & \sigma_z \\ -\sigma_z & 0 \end{pmatrix}, \qquad \gamma_4 = \begin{pmatrix} 0 & I \\ I & 0 \end{pmatrix} \qquad [20]$$

### Change Conjugation and Majorana Spinors

Throughout this section and next, one assumes $K = \mathbb{R}$ so that, given a representation $\rho : \mathcal{C}\ell(V,g) \to \operatorname{End} S$,one can form the complex- ("charge") conjugate representation $\bar{\rho} : \mathcal{C}\ell(V,g) \to \operatorname{End} \bar{S}$ defined by $\bar{\rho}(a) = \overline{\rho(a)}$ and the Hermitian conjugate representation $\rho^\dagger : \mathcal{C}\ell(V,g) \to \operatorname{End} \bar{S}^*$, where $\rho^\dagger(a) = \overline{\check{\rho}(a)}$.

**Even dimensions** The representations $\bar{\gamma}$ and $\gamma$ are equivalent: there is an isomorphism $C : S \to \bar{S}$ such that

$$\overline{\gamma}_\mu = C\gamma_\mu C^{-1} \qquad [21]$$

The automorphism $\bar{C}C$ is in the commutant of $\gamma$; it is, therefore, proportional to $I$ and, by a change of scale, one can achieve $\bar{C}C = I$ for $k - l \equiv 0$ or $6 \bmod 8$ and $\bar{C}C = -I$ for $k - l \equiv 2$ or $4 \bmod 8$.

The spinor $s_c = C^{-1}\bar{s} \in S$ is the charge conjugate of $s \in S$. If $\psi : V \to S$ is a solution of the Dirac equation

$$(\gamma^\mu(\partial_\mu - \mathrm{i}qA_\mu) - \kappa)\psi = 0$$

for a particle of electric charge $q$, then $\psi_c$ is a solution of the same equation with the opposite charge. Since

$$\overline{\Gamma} = \iota^2 C\Gamma C^{-1}$$

charge conjugation preserves (resp., changes) the chirality of Weyl spinors for $(1/2)(k-l)$ even (resp., odd).

If $\bar{C}C = I$, then

$$\operatorname{Re} S = \{s \in S \,|\, s_c = s\}$$

is a real vector space of dimension $2^n$, the space of Dirac–Majorana spinors. The representation $\gamma$ is real: restricted to $\operatorname{Re} S$ and expressed with respect to a frame in this space, it is given by real $2^n \times 2^n$ matrices. For $k - l \equiv 0 \bmod 8$ the representations $\gamma_+$ and $\gamma_-$ are both real: in this case there are Weyl–Majorana spinors.

**Odd dimensions** On computing $\overline{\sigma(\eta)}$ one finds that the conjugate representation $\bar{\sigma}$ is equivalent to $\sigma$

(resp., $\sigma \circ \alpha$) if $\eta^2 = 1$ (resp., $\eta^2 = -1$). There is an isomorphism $C : S \to \bar{S}$ such that

$$\overline{\sigma}_\mu = (-1)^{(1/2)(k-l+1)} C \sigma_\mu C^{-1} \qquad [22]$$

and $\bar{C}C = I$ (resp., $\bar{C}C = -I$) for $k - l \equiv 1$ or $7 \bmod 8$ (resp., $k - l \equiv 3$ or $5 \bmod 8$). For $k - l \equiv 1 \bmod 8$, the restriction of the Pauli representation to $\mathcal{C}\ell^0_{k,l}$ is real and the Pauli matrices are pure imaginary; for $k - l \equiv 7 \bmod 8$, the Pauli representations of $\mathcal{C}\ell_{k,l}$ are both real and so are the Pauli matrices. In both these cases there are Pauli–Majorana spinors.

### Hermitian Scalar Products and Multivectors

For $m = k + l$ odd and $C$ as in [22], the map $A = \bar{B}C : S \to \bar{S}^*$ intertwines the representations $\sigma^\dagger$ and $\sigma$ (resp., $\sigma \circ \alpha$) for $k$ even (resp., odd),

$$\sigma^\dagger_\mu = (-1)^k A \sigma_\mu A^{-1}$$

By rescaling of $B$, the map $A$ can be made Hermitian. The corresponding Hermitian form $s \mapsto A(s, s)$ is definite if and only if $k$ or $l = 0$; otherwise, it is neutral.

For $m = k + l$ even, the representations $\gamma^\dagger$ and $\gamma$ are equivalent and one can define a Hermitian isomorphism $A : S \to \bar{S}^*$ so that

$$\gamma^\dagger_\mu = A \gamma_\mu A^{-1} \qquad [23]$$

The isomorphism $A' = A\Gamma$ intertwines the representations $\gamma^\dagger$ and $\gamma \circ \alpha$; it can also be made Hermitian by rescaling. The Hermitian form $A(s, s)$ is definite for $k = 0$ and $A'(s, s)$ is definite for $l = 0$; otherwise, these forms are neutral. For example, in the familiar representation [20], one has $A = \gamma_4$, a neutral form.

For $p = 0, 1, \ldots, m = 2n$, two spinors $s$ and $t \in S$ define the $p$-vector with components

$$A_{\mu_1 \ldots \mu_p}(s, t) = \langle \bar{s}, A \gamma_{\mu_1} \ldots \gamma_{\mu_p} t \rangle \qquad [24]$$

where the indices are as in [19]. The Hermiticity of $A$ and [23] imply

$$\overline{A_{\mu_1 \ldots \mu_p}(s, t)} = (-1)^{(1/2)p(p-1)} A_{\mu_1 \ldots \mu_p}(t, s)$$

In view of $\Gamma^\dagger = (-1)^k A \Gamma A^{-1}$, the map $A$ defines, for $k$ even, a nondegenerate Hermitian scalar product on the spaces $S_\pm$ whereas $A(s, t) = 0$ if $s$ and $t$ are Weyl spinors of opposite chiralities. For $k$ odd, $A$ changes the chirality.

## The Radon–Hurwitz Numbers

**Proposition** (M) *For every integer $m > 0$, the algebra $\mathcal{C}\ell_{m,0}$ has an irreducible real representation $\rho$ of dimension $2^{\chi(m)}$, where $\chi(m)$ is the mth Radon–Hurwitz number given by*

| $m =$ | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 |
|---|---|---|---|---|---|---|---|---|
| $\chi(m) =$ | 1 | 2 | 2 | 3 | 3 | 3 | 3 | 4 |

*and $\chi(m + 8) = \chi(m) + 4$. The matrices $\rho_\mu \in \mathbb{R}(2^{\chi(m)})$, $\mu = 1, \ldots, m$, defining these representations satisfy*

$$\rho_\mu \rho_\nu + \rho_\nu \rho_\mu = -2\delta_{\mu\nu} I$$

*and can be chosen so as to be antisymmetric. In all dimensions other than $m \equiv 3 \bmod 4$ the representations are faithful.*

*For $m \equiv 2$ and $4 \bmod 8$ (resp., $m \equiv 1, 3,$ and $5 \bmod 8$) the representations $\rho$ are the realifications of the corresponding Dirac (resp., Pauli) representations. In dimensions $m \equiv 0$ and $6 \bmod 8$ (resp., $m \equiv 7 \bmod 8$) the Dirac (resp., Pauli) representations themselves are real.*

## Inductive Construction of Representations

An inductive construction of the Pauli representations

$$\sigma : \mathcal{C}\ell_{n-1,n} \to \mathbb{R}(2^{n-1}), \quad n = 1, 2, \ldots$$

and of the Dirac representations

$$\gamma : \mathcal{C}\ell_{n,n} \to \mathbb{R}(2^n), \quad n = 1, 2, \ldots$$

is as follows.

1. In dimension 1, put $\sigma_1 = 1$.
2. Given $\sigma_\mu \in \mathbb{R}(2^{n-1})$, $\mu = 1, \ldots, 2n - 1$, define

$$\gamma_\mu = \begin{pmatrix} 0 & \sigma_\mu \\ \sigma_\mu & 0 \end{pmatrix} \quad \text{for } \mu = 1, \ldots, 2n - 1$$

and

$$\gamma_{2n} = \begin{pmatrix} 0 & -I \\ I & 0 \end{pmatrix}$$

3. Given $\gamma_\mu \in \mathbb{R}(2^n)$, $\mu = 1, \ldots, 2n$, define $\sigma_\mu = \gamma_\mu$ for $\mu = 1, \ldots, 2n$, and $\sigma_{2n+1} = \gamma_1 \cdots \gamma_{2n}$.

All entries of these matrices are either 0, 1, or $-1$; therefore, they can be used to construct representations of Clifford algebras of orthogonal spaces over any commutative field of characteristic $\neq 2$.

By induction, one has $\sigma^*_\mu = (-1)^{\mu+1} \sigma_\mu$. Therefore, the isomorphisms appearing in [18] are $B = \gamma_2 \gamma_4 \cdots \gamma_{2n}$ for both $m = 2n$ and $2n + 1$.

By multiplying some of the matrices $\sigma_\mu$ or $\gamma_\mu$ by the imaginary unit, one obtains complex representations of the Clifford algebras associated with the quadratic

forms of other signatures. For example, in dimension 3, $(\sigma_1, i\sigma_2, \sigma_3)$ are the Pauli matrices. In dimension 4, multiplying $\gamma_2$ by i one obtains the Dirac matrices for $g$ of signature $(1,3)$, in the "chiral representation":

$$\gamma_1 = \begin{pmatrix} 0 & \sigma_x \\ \sigma_x & 0 \end{pmatrix}, \qquad \gamma_2 = \begin{pmatrix} 0 & \sigma_y \\ \sigma_y & 0 \end{pmatrix}$$
$$\gamma_3 = \begin{pmatrix} 0 & \sigma_z \\ \sigma_z & 0 \end{pmatrix}, \qquad \gamma_4 = \begin{pmatrix} 0 & -I \\ I & 0 \end{pmatrix} \qquad [25]$$

To obtain the real Majorana representation one uses the following fact:

**Proposition (N)** *If the matrix* $C \in \mathbb{R}(2^n)$ *is such that* $C^2 = I$ *and* [21] *holds, then the matrices* $(I + iC)\gamma_\mu(I + iC)^{-1}$, $\mu = 1, \ldots, 2n$, {\it are real}.

For the matrices [25], one can take $C = \gamma_1\gamma_3\gamma_4$ to obtain

$$\gamma'_1 = \begin{pmatrix} 0 & \sigma_x \\ \sigma_x & 0 \end{pmatrix}, \qquad \gamma'_2 = \begin{pmatrix} I & 0 \\ 0 & -I \end{pmatrix}$$
$$\gamma'_3 = \begin{pmatrix} 0 & \sigma_z \\ \sigma_z & 0 \end{pmatrix}, \qquad \gamma'_4 = \begin{pmatrix} 0 & -I \\ I & 0 \end{pmatrix}$$

The real representations described in proposition (M) can be obtained by the following direct inductive construction. Consider the following seven real antisymmetric and anticommuting $8 \times 8$ matrices:

$$\begin{aligned} &\rho_1 = \sigma_z \otimes I \otimes \varepsilon, && \rho_2 = \sigma_z \otimes \varepsilon \otimes \sigma_x \\ &\rho_3 = \sigma_z \otimes \varepsilon \otimes \sigma_z, && \rho_4 = \sigma_x \otimes \varepsilon \otimes I \\ &\rho_5 = \sigma_x \otimes \sigma_x \otimes \varepsilon, && \rho_6 = \sigma_x \otimes \sigma_z \otimes \varepsilon \\ &\rho_7 = \varepsilon \otimes I \otimes I \end{aligned} \qquad [26]$$

For $m = 4, 5, 6,$ and $7$ the matrices $\rho_1, \ldots, \rho_m$ generate the representations of $C\ell_{m,0}$ in $\mathbb{R}^8$. The eight matrices $\theta_\mu = \sigma_x \otimes \rho_\mu, \mu = 1, \ldots, 7,$ and $\theta_8 = \varepsilon \otimes I \otimes I \otimes I$ give the required representation of $C\ell_{8,0}$ in $\mathbb{R}^{16}$. By dropping the first factor in $\rho_1, \rho_2, \rho_3$, one obtains the matrices generating a representation of $C\ell_{3,0}$ in $\mathbb{R}^4$, etc. The symmetric matrix $\Theta = \theta_1 \cdots \theta_8 = \sigma_z \otimes I \otimes I \otimes I$ anticommutes with all the $\theta$s and $\Theta^2 = I$. If the matrices $\rho_\mu \in \mathbb{R}(2^{\chi(m)})$ correspond to a representation of $C\ell_{m,0}$, then the $m + 8$ matrices $\Theta \otimes \rho_1, \ldots, \Theta \otimes \rho_m, \theta_1 \otimes I, \ldots, \theta_8 \otimes I$ generate the required representation of $C\ell_{m+8,0}$.

## Vector Fields on Spheres and Division Algebras

It is known that even-dimensional spheres have no nowhere-vanishing tangent vector fields. All such fields on odd-dimensional spheres can be constructed with the help of the representation $\rho$ described in proposition (M). Given a positive even integer $N$, let $m$ be the largest integer such that $N = 2^{\chi(m)}p$, where $p$ is an odd integer. Consider the unit sphere $\mathbb{S}_{N-1} = \{x \in \mathbb{R}^N \mid ||x|| = 1\}$ of dimension $N - 1$. For $v \in \mathbb{R}^m$, put $\rho'(v) = \rho(v) \otimes I$, where $I \in \mathbb{R}(p)$ is the unit matrix. Since $\rho(v)$ is antisymmetric, so is the matrix $\rho'(v) \in \mathbb{R}(N)$. Therefore, for every $x \in \mathbb{S}_{N-1}$, the vector $\rho'(v)x$ is orthogonal to $x$. The map $x \mapsto \rho'(v)x$ defines a vector field on $\mathbb{S}_{N-1}$ that vanishes nowhere unless $v = 0$: the $(N-1)$-sphere admits a set of $m$ tangent vector fields which are linearly independent at every point. Using methods of algebraic topology, it has been shown that this method gives the maximum number of linearly independent tangent vector fields on spheres.

If $m = 1, 3,$ or $7$, then $m + 1 = 2^{\chi(m)}$ and, for these values of $m$, the sphere $\mathbb{S}_m$ is parallelizable. Moreover, one can then introduce in $\mathbb{R}^{m+1}$ the structure of an algebra $A_m$ as follows. Put $\rho_0 = I$. If $e_0 \in \mathbb{R}^{m+1}$ is a unit vector and $e_\mu = \rho_\mu(e_0)$, then $(e_0, e_1, \ldots, e_m)$ is an orthonormal frame in $\mathbb{R}^{m+1}$. The product of $x = \sum_{\mu=0}^m x_\mu e_\mu$ and $y = \sum_{\mu=0}^m y_\mu e_\mu$ is defined to be

$$x \cdot y = \sum_{\mu,v=0}^{m} x_\mu y_v \rho_\mu(e_v)$$

so that $e_0$ is the unit element for this product. Defining $\mathrm{Re}\,x = x_0 e_0$, $\mathrm{Im}\,x = x - \mathrm{Re}\,x$, $\bar{x} = \mathrm{Re}\,x - \mathrm{Im}\,x$, one has $\bar{x} \cdot x = e_0||x||^2$ and $\bar{x} \cdot (x \cdot y) = (\bar{x} \cdot x) \cdot y$, so that $x \cdot y = 0$ implies $x = 0$ or $y = 0$: $A_m$ is a normed algebra without zero divisors. The algebras $A_1$ and $A_3$ are isomorphic to $\mathbb{C}$ and $\mathbb{H}$, respectively, and $A_7$ is, by definition, the algebra $\mathbb{O}$ of octonions discovered by Graves and Cayley. The algebra $\mathbb{O}$ is nonassociative; its multiplication table is obtained with the help of [26].

## Spinor Groups

Let $(V, g)$ be a quadratic space over $K$. If $u \in V$ is not null, then it is invertible as an element of $C\ell(V, g)$ and the map $v \mapsto -uvu^{-1}$ is a reflection in the hyperplane orthogonal to $u$. The orthogonal group $\mathrm{O}(V, g) = \mathrm{O}(V, -g) = \{R \in \mathrm{GL}(V) \mid R^* \circ g \circ R = g\}$ is generated by the set of all such reflections. A spinor group $G$ is a subset of $C\ell(V, g)$ that is a group with respect to multiplication induced by the product in the algebra, with a homomorphism $\rho: G \to \mathrm{GL}(V)$ whose image contains the connected component $\mathrm{SO}^0(V, g)$ of the group of rotations of $(V, g)$. In the case of real quadratic spaces, one considers also spinor groups that are subsets of $\mathbb{C} \otimes C\ell(V, g)$ with similar properties. By restriction, every

representation of $C\ell(V,g)$ or $\mathbb{C}\otimes C\ell(V,g)$ gives spinor representations of the spinor groups it contains.

### Pin Groups

It is convenient to define a unit vector $v\in V\subset C\ell(V,g)$ to be such that $v^2=1$ for $V$ complex and $v^2=1$ or $-1$ for $V$ real. The group $\mathrm{Pin}(V,g)$ is defined as the subgroup of $\mathrm{Cpin}(V,g)$ consisting of products of all finite sequences of unit vectors. Defining now the twisted adjoint representation $\widetilde{\mathrm{Ad}}$ by $\widetilde{\mathrm{Ad}}(a)v=\alpha(a)va^{-1}$, one ontains the exact sequence

$$1\to\mathbb{Z}_2\to\mathrm{Pin}(V,g)\overset{\widetilde{\mathrm{Ad}}}{\to}\mathrm{O}(V,g)\to 1 \qquad [27]$$

If $\dim V$ is even, then the adjoint representation $\mathrm{Ad}(a)v=ava^{-1}$ also yields an exact sequence like [27]; if it is odd, then the image of Ad is $\mathrm{SO}(V,g)$ and the kernel is the four-element group $\{1,\,-1,\eta,\,-\eta\}$.

Given an orthonormal frame $(e_\mu)$ in $(V,g)$ and $a\in\mathrm{Pin}(V,g)$, one defines the orthogonal matrix $R(a)=(R_\mu^\nu(a))$ by

$$\widetilde{\mathrm{Ad}}(a)e_\mu=e_\nu R_\mu^\nu(a) \qquad [28]$$

If $(V,g)$ is complex, then the algebras $C\ell(V,g)$ and $C\ell(V,\,-g)$ are isomorphic; this induces an isomorphism of the groups $\mathrm{Pin}(V,g)$ and $\mathrm{Pin}(V,\,-g)$. If $V=\mathbb{C}^m$, then this group is denoted by $\mathrm{Pin}_m(\mathbb{C})$. If $V=\mathbb{R}^{k+l}$ and $g$ of signature $(k,l)$, then one writes $\mathrm{Pin}(V,g)=\mathrm{Pin}_{k,l}$. A similar notation is used for the groups spin, see below.

### Spin Groups

The spin group $\mathrm{Spin}(V,g)=\mathrm{Pin}(V,g)\cap C\ell^0(V,g)$ is generated by products of all sequences of an even number of unit vectors. Since the algebras $C\ell^0(V,g)$ and $C\ell^0(V,\,-g)$ are isomorphic, so are the groups $\mathrm{Spin}(V,g)$ and $\mathrm{Spin}(V,\,-g)$. Since $\alpha(a)=a$ for $a\in\mathrm{Spin}(V,g)$, the twisted adjoint representation reduces to the adjoint representation and yields the exact sequence

$$1\to\mathbb{Z}_2\to\mathrm{Spin}(V,g)\xrightarrow{\mathrm{Ad}}\mathrm{SO(V,g)}\to 1 \qquad [29]$$

For $V=\mathbb{C}^m$, the spin group is denoted by $\mathrm{Spin}_m(\mathbb{C})$. Since $\mathrm{Spin}_m(\mathbb{C})\subset G_1(\beta)$, the bilinear form $B$ is invariant with respect to the action of this group.

### Spin$^0$ Groups

The connected component $\mathrm{Spin}^0(V,g)$ of the group $\mathrm{Spin}(V,g)$ coincides with $\mathrm{Spin}(V,g)$ if either the quadratic space $(V,g)$ is complex or real and $kl=0$. In signature $(k,l)$, the connect group $\mathrm{Spin}^0_{k,l}$ is generated in $C\ell^0_{k,l}$ by all products of the form $u_1\ldots u_{2_p}v_1\ldots v_{2_q}$ such that $u_i^2=-1$ and $v_j^2=1$. The connected groups $\mathrm{Spin}_{m,0}$ and $\mathrm{Spin}_{0,m}$ are isomorphic and denoted by $\mathrm{Spin}_m$. Since $\mathrm{Spin}^0_{k,l}\subset G_1(\beta)$, the Hermitian form $A$ and the bilinear form $B$ are invariant with respect to the action of this group. Moreover, for $k+l$ even, from [24] and [28] there follows the transformation law of multivectors formed from pairs of spinors,

$$A_{\mu_1\cdots\mu_p}(\gamma(a)s,\gamma(a)t) = A_{\nu_1\ldots\nu_p}(s,t)R^{\nu_1}_{\mu_1}(a^{-1})\ldots R^{\nu_p}_{\mu_p}(a^{-1})$$

Consider $\mathrm{Spin}^0(V,g)$ and assume that either $V$ is complex of dimension $\geqslant 2$ or real with $k$ or $l\geqslant 2$. Then there are two unit orthogonal vectors $e_1,e_2\in V$ such that $(e_1,e_2)^2=-1$. The vector $u(t)=e_1\cos t+\,e_2\sin t$ is obtained from $e_1$ by rotation in the plane span $\{e_1,e_2\}$ by the angle $t\in\mathbb{R}$. The curve $t\mapsto e_1u(t)$, $0\le t\le\pi$, connects the elements $1$ and $-1$ of $\mathrm{Spin}^0(V,g)$. Its image in $\mathrm{SO}^0(V,g)$, that is, the curve $t\mapsto\mathrm{Ad}(e_1u(t))$, $0\le t\le\pi$, is closed: $\mathrm{Ad}(1)=\mathrm{Ad}(-1)$. This fact is often expressed by saying that "a spinor undergoing a rotation by $2\pi$ changes sign." There is no homomorphism – not even a continuous map – $f:\mathrm{SO}^0(V,g)\to\mathrm{Spin}^0(V,g)$ such that $\mathrm{Ad}\circ f=\mathrm{id}$.

### Spin$^c$ Groups

For the purposes of physics, to describe charged fermions, and in the theory of the Seiberg–Witten invariants, one needs the Spin$^c$ groups that are spinorial extensions of the real orthogonal groups by the group $\mathrm{U}_1$ of "phase factors." Assume $V$ to be real and $g$ of signature $(k,l)$ so that the sequence [29] can be written as

$$1\to\mathbb{Z}_2\to\mathrm{Spin}_{k,l}\to\mathrm{SO}_{k,l}\to 1$$

Define the action of $\mathbb{Z}_2=\{1,\,-1\}$ in $\mathrm{Spin}_{k,l}\times\mathrm{U}_1$ so that $(-1)(a,z)=(-a,-z)$. The quotient $(\mathrm{Spin}_{k,l}\times\mathrm{U}_1)/\mathbb{Z}_2=\mathrm{Spin}^c_{k,l}$ yields the extensions

$$1\to\mathrm{U}_1\to\mathrm{Spin}^c_{k,l}\to\mathrm{SO}_{k,l}\to 1$$

and

$$1\to\mathrm{Spin}_{k,l}\to\mathrm{Spin}^c_{k,l}\to\mathrm{U}_1\to 1$$

For example, $\mathrm{Spin}_3=\mathrm{SU}_2$ and $\mathrm{Spin}^c_3=\mathrm{U}_2$.

### Spin Groups in Dimensions $\leqslant$6

The connected components of spin groups associated with orthogonal spaces of dimension $\leqslant 6$ are isomorphic to classical groups. They can be explicitly described starting from the following observations.

Consider the four-dimensional vector space (of twistors) $T$ over $K$, with a volume element $\mathrm{vol} \in \wedge^4 T$. The six-dimensional vector space $V = \wedge^2 T$ has a scalar product $g$ defined by $g(u,v)\mathrm{vol} = 2u \wedge v$ for $u, v \in V$. The quadratic form $g(u,u)$ is the Pfaffian, $\mathrm{Pf}(u)$. If $u \in V$ is represented by the corresponding isomorphism $T^* \to T$ and $a \in \mathrm{End}\, T$, then $\mathrm{Pf}(aua^*) = \det a \mathrm{Pf}(u)$. The last formula shows $\mathrm{Spin}^0(V,g) = \mathrm{SL}(T)$, so that $\mathrm{Spin}_6(\mathbb{C}) = \mathrm{SL}_4(\mathbb{C})$. For $K = \mathbb{R}$, the Pfaffian is of signature $(3,3)$, so that $\mathrm{Spin}^0_{3,3} = \mathrm{SL}_4(\mathbb{R})$. A non-null vector $v \in V$ defines a symplectic form on $T^*$. The five-dimensional vector space $v^\perp \subset V$ is invariant with respect to the symplectic group $\mathrm{Sp}(T^*, u) = \mathrm{Spin}^0(v^\perp, \mathrm{Pf}|v^\perp)$. This shows that $\mathrm{Spin}_5(\mathbb{C}) = \mathrm{Sp}_4(\mathbb{C})$ and $\mathrm{Spin}^0_{2,3} = \mathrm{Sp}_4(\mathbb{R})$. Spin groups for other signatures in real dimensions 6 and 5 are obtained by considering appropriate real subspaces of $\mathbb{C}^6$ and $\mathbb{C}^5$, respectively. For example, [6] is used to show that $\mathrm{Spin}^0_{1,5} = \mathrm{SL}_2(\mathbb{H})$.

Spin groups in dimensions 4 and lower are similarly obtained from the observation that det is a quadratic form on the four-dimensional space $K(2)$ and $C\ell^0(K(2), \det) = K(2) \oplus K(2)$.

Several spin groups are listed below.

*The complex spin groups*

$$\mathrm{Spin}_2(\mathbb{C}) = \mathbb{C}^\times, \qquad \mathrm{Spin}_3(\mathbb{C}) = \mathrm{SL}_2(\mathbb{C})$$
$$\mathrm{Spin}_4(\mathbb{C}) = \mathrm{SL}_2(\mathbb{C}) \times \mathrm{SL}_2(\mathbb{C})$$
$$\mathrm{Spin}_5(\mathbb{C}) = \mathrm{Sp}_4(\mathbb{C})$$
$$\mathrm{Spin}_6(\mathbb{C}) = \mathrm{SL}_4(\mathbb{C})$$

*The real, compact spin groups*

$$\mathrm{Spin}_2 = \mathrm{U}_1, \qquad \mathrm{Spin}_3 = \mathrm{SU}_2$$
$$\mathrm{Spin}_4 = \mathrm{SU}_2 \times \mathrm{SU}_2, \qquad \mathrm{Spin}_5 = \mathrm{Sp}_2(\mathbb{H})$$
$$\mathrm{Spin}_6 = \mathrm{SU}_4$$

*The groups* $\mathrm{Spin}^0_{k,l}$ *for* $1 \leqslant k \leqslant l$ *and* $k + l \leq 6$

$$\mathrm{Spin}^0_{1,1} = \mathbb{R}^\times, \qquad \mathrm{Spin}^0_{1,2} = \mathrm{SL}_2(\mathbb{R})$$
$$\mathrm{Spin}^0_{1,3} = \mathrm{SL}_2(\mathbb{C})$$
$$\mathrm{Spin}^0_{2,2} = \mathrm{SL}_2(\mathbb{R}) \times \mathrm{SL}_2(\mathbb{R})$$
$$\mathrm{Spin}^0_{1,4} = \mathrm{Sp}_{1,1}(\mathbb{H})$$
$$\mathrm{Spin}^0_{2,3} = \mathrm{Sp}_4(\mathbb{R}), \qquad \mathrm{Spin}^0_{1,5} = \mathrm{SL}_2(\mathbb{H})$$
$$\mathrm{Spin}^0_{2,4} = \mathrm{SU}_{2,2}$$
$$\mathrm{Spin}^0_{3,3} = \mathrm{SL}_4(\mathbb{R})$$

# Cluster Expansion

**R Kotecký**, Charles University, Prague,
Czech Republic, and the University of Warwick, UK

## Introduction

The method of cluster expansions in statistical physics provides a systematic way of computing power series for thermodynamic potentials (logarithms of partition funtions) as well as correlations. It originated from the works of Mayer and others devoted to expansions for dilute gas.

## Mayer Expansion

Consider a system of interacting particles with Hamiltonian

$$H_N(\boldsymbol{p}_1,\ldots,\boldsymbol{p}_N,\boldsymbol{r}_1,\ldots,\boldsymbol{r}_N) = \sum_{i=1}^{N}\frac{\boldsymbol{p}_i^2}{2m} + \sum_{i,j=1}^{N}\Phi(\boldsymbol{r}_i-\boldsymbol{r}_j) \qquad [1]$$

where $\Phi$ is a *stable* and *regular* pair potential. Namely, we assume that there exists $B \geq 0$ such that

$$\sum_{i,j=1}^{N}\Phi(\boldsymbol{r}_i-\boldsymbol{r}_j) \geq -BN \qquad [2]$$

for all $N = 2, 3, \ldots$ and all $(\boldsymbol{r}_1,\ldots,\boldsymbol{r}_N) \in \mathbb{R}^{3N}$, and that

$$C(\beta) = \int \left|e^{-\beta\Phi(\boldsymbol{r})} - 1\right| d^3\boldsymbol{r} < \infty \qquad [3]$$

for some $\beta > 0$ (and hence all $\beta > 0$). Basic thermodynamic quantities are given in terms of the *grand-canonical partition function*

$$Z(\beta,\lambda,V) = \sum_{N=0}^{\infty}\frac{z^N}{N!}\int_{\mathbb{R}^{3N}\times V^N} e^{-\beta H_N}\frac{\prod d^3\boldsymbol{p}_i\prod d^3\boldsymbol{r}_i}{h^{3N}} = \sum_{N=0}^{\infty}\frac{\lambda^N}{N!}\int_{V^N} e^{-\beta\sum_{i,j}\Phi(\boldsymbol{r}_i-\boldsymbol{r}_j)}\prod d^3\boldsymbol{r}_i \qquad [4]$$

In the second expression we absorbed the factor resulting from the integration over impulses into (configurational) activity $\lambda = (2\pi m/\beta h^2)^{3/2} z$. In particular, the *pressure* $p$ and the *density* $\rho$ are defined by the thermodynamic limits (with $V \to \infty$ in the sense of Van Hove)

$$p(\beta,\lambda) = \frac{1}{\beta}\lim_{V\to\infty}\frac{1}{|V|}\log Z(\beta,\lambda,V) \qquad [5]$$

and

$$\rho(\beta,\lambda) = \lim_{V\to\infty}\frac{1}{|V|}\lambda\frac{\partial}{\partial\lambda}\log Z(\beta,\lambda,V) \qquad [6]$$

*Mayer series* are the expansions of $p$ and $\rho$ in powers of $\lambda$:

$$\beta p(\beta,\lambda) = \sum_{n=1}^{\infty} b_n\lambda^n \qquad [7]$$

and

$$\rho(\beta,\lambda) = \sum_{n=1}^{\infty} n b_n\lambda^n \qquad [8]$$

Mayer's idea for a systematic computation of coefficients $b_n$ was based on a reformulation of partition function $Z(\beta,\lambda,V)$ in terms of *cluster integrals*. Introducing the function

$$f(\boldsymbol{r}) = e^{-\beta\Phi(\boldsymbol{r})} - 1 \qquad [9]$$

and using $\mathcal{G}[N]$ to denote the set of all graphs on $N$ vertices $\{1,\ldots,N\}$, we get

$$Z(\beta,\lambda,V) = \sum_{N=0}^{\infty}\frac{\lambda^N}{N!}\int_{V^N}\prod_{i,j=1}^{N}\left(1+f(\boldsymbol{r}_i-\boldsymbol{r}_j)\right)\prod d^3\boldsymbol{r}_i = \sum_{N=0}^{\infty}\frac{\lambda^N}{N}\sum_{g\in\mathcal{G}[N]} w(g) \qquad [10]$$

where

$$w(g) = \int_{V^N}\prod_{\{i,j\}\in g} f(\boldsymbol{r}_i-\boldsymbol{r}_j)\prod d^3\boldsymbol{r}_i \qquad [11]$$

Observing that the weight $w$ is multiplicative in connected components (clusters) $g_1,\ldots,g_k$ of the graph $g$,

$$w(g) = \prod_{\ell=1}^{k} w(g_\ell) \qquad [12]$$

we can rewrite

$$Z(\beta,\lambda,V) = \sum_{N=0}^{\infty}\frac{\lambda^N}{N!}\sum_{\{g_l\}}\prod_{g\in\mathcal{G}} w(g) \qquad [13]$$

with the sum running over all disjoint collections $\{g_l\}$ of connected graphs with vertices in $\{1,\ldots,N\}$. A straightforward exponential expansion can be used to show that, at least in the sense of formal power series,

$$\log Z(\beta,\lambda,V) = \sum_{n=1}^{\infty}\frac{\lambda^n}{n!}\sum_{g\in\mathcal{C}[n]} w(g) \qquad [14]$$

where $\mathcal{C}[n]$ is the set of all connected graphs on $n$ vertices. Using $b_n^{(V)}$ to denote the coefficients

$$b_n^{(V)} = \frac{1}{|V|}\frac{1}{n!}\sum_{g\in\mathcal{C}[n]} w(g) \qquad [15]$$

and observing that the limits $\lim_{V\to\infty}(1/|V|)w(g)$ of cluster integrals exist, we get $b_n = \lim_{V\to\infty} b_n^{(V)}$. The convergence of Mayer series can be controlled directly by combinatorial estimates on the coefficients $b_n^{(V)}$. As a result, the diameter of convergence of the series [7] and [8] can be proved to be at least $(C(\beta)e^{2\beta B+1})^{-1}$. A less direct proof is based on an employment of linear integral Kirkwood–Salsburg equations in a suitable Banach space of correlation functions.

Similar combinatorial methods are available also for evaluation of coefficients of the *virial expansion* of pressure in powers of gas density,

$$\beta p(\beta,\rho) = \sum_{n=1}^{\infty}\beta_n\rho^n \qquad [16]$$

obtained by inverting [8] (notice that $b_1 = 1$) and inserting it into [7]. One is getting $\beta_n = \lim_{V\to\infty}\beta_n^{(V)}$ with

$$\beta_n^{(V)} = \frac{1}{|V|}\frac{1}{n!}\sum_{g\in\mathcal{B}[n]} w(g) \qquad [17]$$

where $\mathcal{B}[n] \subset \mathcal{C}[n]$ is the set of all 2-connected graphs on $\{1,\ldots,n\}$; namely, those graphs that cannot be split into disjoint subgraphs by erasing one vertex (and all adjacent edges). The diameter of convergence of the virial expansion turns out to be no less than $(C(\beta)e(e^{2\beta B}+1))^{-1}$.

## Abstract Polymer Models

An application of the ideas of Mayer expansions to lattice models is based on a reformulation of the partition function in terms of a *polymer model*, a formulation akin to [13] above. Namely, the partition function is rewritten as a sum over collections of pairwise compatible geometric objects – polymers. Most often, the compatibility means simply their disjointness.

While the reformulation of "physical partition function" in terms of a polymer model (including the definition of compatibility) depends on particularities of a given lattice model and on the considered region of parameters – high-temperature, low-temperature, large external fields, etc. – the essence and results of cluster expansion may be conveniently formulated in terms of an *abstract polymer model*.

Let $G = (V, E)$ be any (possibly infinite) countable graph and suppose that a map $w: V \to \mathbb{C}$ is given. Vertices $v \in V$ are called *abstract polymers*, with two abstract polymers connected by an edge in the graph $G$ called *incompatible*. We shall refer to $w(v)$ as to the *weight* of the abstract polymer $v$. For any finite $W \subset V$, we consider the induced subgraph $G[W]$ of $G$ spanned by $W$ and define

$$Z_W(w) = \sum_{I\subset W}\prod_{v\in I} w(v) \qquad [18]$$

Here the sum runs over all collections $I$ of compatible abstract polymers – or, in other words, the sum is over all *independent sets* $I$ of vertices in $W$ (no two vertices in $I$ are connected by an edge).

The partition function $Z_W(w)$ is an entire function in $w = \{w(v)\}_{v\in W} \in \mathbb{C}^{|W|}$ and $Z_W(0) = 1$. Hence, it is nonvanishing in some neighborhood of the origin $w = 0$ and its logarithm is, on this neighbourhood, an analytic function yielding a convergent Taylor series

$$\log Z_W(w) = \sum_{X\in\mathcal{X}(W)} a_W(X)w^X \qquad [19]$$

Here, $\mathcal{X}(W)$ is the set of all multi-indices $X: W \to \{0\,1,\ldots\}$ and $w^X = \prod_v w(v)^{X(v)}$. Inspecting the formula for $a_W(X)$ in terms of corresponding derivatives of $\log Z_W(w)$, it is easy to show that the Taylor coefficients $a_W(X)$ actually do not depend on $W: a_W(X) = a_{\text{supp}}\, X(X)$, where $\text{supp}\, X = \{v \in V: X\,(v) \neq 0\}$. As a result, one is getting the existence of coefficients $a(X)$ such that

$$\log Z_W(w) = \sum_{X\in\mathcal{X}(W)} a(X)w^X \qquad [20]$$

for every finite $W \subset V$.

The coefficients $a(X)$ can be obtained explicitly. One can pass from [18] to [20] in a similar way as passing from [10] to [13]. The starting point is to replace the restriction to compatible collections of abstract polymers in the sum [18] by the factor $\prod_{v,v'\in W}(1+F(v,v'))$ with

$$F(v,v') = \begin{cases} 0 \text{ if } v \text{ and } v' \text{ are compatible} \\ -1 \text{ otherwise } (v \text{ and } v' \\ \quad \text{connected by an edge from } G) \end{cases} \qquad [21]$$

and to expand the product afterwards. The resulting formula is

$$a(X) = (X!)^{-1}\sum_{H\subset G(X)} (-1)^{|E(H)|} \qquad [22]$$

Here, $G(X)$ is the graph with $|X| = \sum|X(v)|$ vertices induced from $G[\text{supp}\, X]$ by replacing each of its vertices $v$ by the complete graph on $|X(v)|$ vertices and $X!$ is the multifactorial $X! = \prod_{v\in\text{supp}\, X} X(v)!$. The sum is over all connected subgraphs $H \subset G(X)$ spanned by the set of vertices of $G(X)$ and $|E(H)|$ is the number of edges of the graph $H$.

A useful property of the coefficients $a(X)$ is their *alternating sign*,

$$(-1)^{|X|+1}a(X) \geq 0 \quad [23]$$

More important than an explicit form of the coefficients $a(X)$ are the convergence criteria for the series [20]. One way to proceed is to find direct combinatorial bounds on the coefficients as expressed by [22]. While doing so, one has to take into account the cancelations arising in view of the presence of terms of opposite signs in [22]. Indeed, disregarding them would lead to a failure since, as it is easy to verify, the number of connected graphs on $|X|$ vertices is bounded from below by $2^{(|X|-1)(|X|-2)/2}$. An alternative approach is to prove the convergence of [20] on polydisks $\mathcal{D}_{W,\boldsymbol{R}} = \{w : |w(v)| \leq R(v) \text{ for } v \in W\}$ by induction in $|W|$, once a proper condition on the set of radii $\boldsymbol{R} = \{R(v); v \in V\}$ is formulated. The most natural for the inductive proof (leading in the same time to the strongest claim) turns out to be the Dobrushin condition:

*There exists a function* $r : V \to [0, 1)$ *such that*, *for each* $v \in V$

$$R(v) \leq r(v) \prod_{v' \in \mathcal{N}(v)} (1 - r(v')) \quad [24]$$

Here $\mathcal{N}(v)$ is the set of vertices $v' \in V$ adjacent in graph $G$ to the vertex $v$.

Using $\mathcal{X}$ to denote the set of all multi-indices $X : V \to \{0, 1, \ldots\}$ with finite $|X| = \sum |X(v)|$ and saying that $X \in \mathcal{X}$ is a cluster if the graph $G$(supp $X$) is connected, we can summarize the cluster expansion claim for an abstract polymer model in the following way:

**Theorem** (Cluster expansion). *There exists a function* $a : \mathcal{X} \to \mathbb{R}$ *that is nonvanishing only on* clusters, *so that for any sequence of diameters* $\boldsymbol{R}$ *satisfying the condition* [24] *with a sequence* $\{r(v)\}$, *the following holds true*:

(i) *For every finite* $W \subset V$, *and any contour weight* $w \in \mathcal{D}_{W,\boldsymbol{R}}$, *one has* $Z_W(w) \neq 0$ *and*

$$\log Z_W(w) = \sum_{X \in \mathcal{X}(W)} a(X) w^X$$

(ii) $\sum_{X \in \mathcal{X} : \operatorname{supp} X \ni v} |a(X)||w|^X \leq -\log(1 - r(v))$.

Notice that, we have got not only an absolute convergence of the Taylor series of $\log Z_W$ in the closed polydisk $\mathcal{D}_{W,\boldsymbol{R}}$, but also the bound (ii) (uniform in $W$) on the sum over all terms containing a fixed vertex $v$. Such a bound turns out to be very useful in applications of cluster expansions. It yields, eventually, bounds on various error terms, avoiding a need of an explicit evaluation of the number of clusters of "given size."

The restriction to compatible collections of polymers can be actually relaxed. Namely, replacing [25] by

$$Z_W(w) = \sum_{W' \subset W} \prod_{v \in W'} w(v) \prod_{v, v' \in W'} U(v, v') \quad [25]$$

with $U(v, v') \in [0, 1]$ (soft repulsive interaction), and the condition [24] by

$$R(v) \leq r(v) \prod_{v' \neq v} \frac{1 - r(v')}{1 - U(v, v') r(v')} \quad [26]$$

one can prove that the partition function $Z_W(w)$ does not vanish on the polydisk $\mathcal{D}_{W,\boldsymbol{R}}$ implying thus that the power series of $\log Z_W(w)$ converges absolutely on $\mathcal{D}_{W,\boldsymbol{R}}$.

Polymers that arise in typical applications are geometric objects endowed with a "support" in the considered lattice, say $\mathbb{Z}^d, d \geq 1$, and their weights satisfy the condition of translation invariance. Cluster expansions then yield an explicit power series for the *pressure* (resp. free energy) in the thermodynamic limit as well as its finite-volume approximation.

To formulate it for an abstract polymer model, we assume that for each $x \in \mathbb{Z}^d$, an isomorphism $\tau_x : G \to G$ is given and that with each abstract polymer $v \in V$ a finite set $\Lambda(v) \subset \mathbb{Z}^d$ is associated so that $\Lambda(\tau_x(v)) = \Lambda(v) + x$ for every $v \in V$ and every $x \in \mathbb{Z}^d$. For any finite $W \subset V$ and any multi-index $X$, let $\Lambda(W) = \cup_{v \in W} \Lambda(v)$ and $\Lambda(X) = \Lambda(\operatorname{supp}(X))$. On the other hand, for any finite $\Lambda \subset \mathbb{Z}^d$, let $W(\Lambda) = \{v \in V : \Lambda(v) \subset \Lambda\}$. Assuming also that the weight $w : V \to \mathbb{C}$ is translation invariant – that is, $w(v) = w(\tau_x(v))$ for every $v \in V$ and every $x \in \mathbb{Z}^d$ – we get an explicit expression for the "pressure" of abstract polymer model in the thermodynamic limit

$$p = \lim_{\Lambda \to \infty} \frac{1}{|\Lambda|} \log Z_{W(\Lambda)}(w) = \sum_{X : \Lambda(X) \ni 0} \frac{a(X) w^X}{|\Lambda(X)|} \quad [27]$$

In addition, the finite-volume approximation can be explicitly evaluated, yielding

$$\log Z_{W(\Lambda)}(w) = p|\Lambda| + \sum_{X : \Lambda(X) \cap \Lambda^c \neq \emptyset} a(X) w^X \frac{|\Lambda(X) \cap \Lambda|}{|\Lambda(X)|} \quad [28]$$

Using the claim (ii), the second term can be bounded by const. $|\partial \Lambda|$.

## Cluster Expansions for Lattice Models

There is a variety of applications of cluster expansions to lattice models. As noticed above, the first step is always to rewrite the model in terms of a polymer representation.

### High-Temperature Expansions

Let us illustrate this point in the simplest case of the Ising model. Its partition function in volume $\Lambda \subset \mathbb{Z}^d$, with free boundary conditions and vanishing external field, is

$$Z_\Lambda(\beta) = \sum_{\sigma_\Lambda} \exp\left\{ \sum_{\substack{x,y\in\Lambda \\ |x-y|=1}} \sigma_x\sigma_y \right\} \qquad [29]$$

Using the identity

$$e^{\beta\sigma_x\sigma_y} = \cosh\,\beta + \sigma_x\sigma_y \sinh\,\beta \qquad [30]$$

it can be rewritten in the form

$$Z_\Lambda(\beta) = 2^{|\Lambda|}(\cosh\,\beta)^{|B(\Lambda)|} \sum_B (\tanh\,\beta)^{|B|} \qquad [31]$$

Here, the sum runs over all subsets $B$ of the set $B(\Lambda)$ of all bonds in $\Lambda$ (pairs of nearest-neighbor sites from $\Lambda$) such that each site is contained in an even number of bonds from $B$. Using $\Lambda(B)$ to denote the set of sites contained in bonds from $B$, we say that $B_1, B_2 \subset B(\Lambda)$ are disjoint if $\Lambda(B_1) \cap \Lambda(B_2) = \emptyset$. Splitting now $B$ into a collection $\mathcal{B} = \{B_1, \ldots, B_k\}$ of its connected components called (high-temperature) *polymers* and using $\mathcal{B}(\Lambda)$ to denote the set of all polymers in $\Lambda$, we are getting

$$Z_\Lambda(\beta) = 2^{|\Lambda|}(\cosh\,\beta)^{|B(\Lambda)|} \sum_{\mathcal{B}\subset\mathcal{B}(\Lambda)} \prod_{B\in\mathcal{B}} (\tanh\,\beta)^{|B|} \qquad [32]$$

with the sum running over all collections $\mathcal{B}$ of mutually disjoint polymers. This expression is exactly of the form [18], once we define compatibility of polymers by their disjointness. Introducing the weights

$$w(B) = (\tanh\,\beta)^{|B|} \qquad [33]$$

and taking the set $\mathcal{B}(\Lambda)$ of all polymers in $\Lambda$ for $W$, we get the *polymer representation* $Z_\Lambda(\beta) = 2^{|\Lambda|}(\cosh\,\beta)^{|B(\Lambda)|} Z_{\mathcal{B}(\Lambda)}(w)$.

To apply the cluster expansion theorem, we have to find a function $r$ such that the right-hand side of [24] is positive and yields thus the radius of a polydisk of convergence. Taking $r(B) = \epsilon^{|B|}$ with a suitable $\epsilon$, we get

$$\prod_{B'\in N(B)} (1 - r(B')) \geq e^{-2|B|} \qquad [34]$$

allowing to choose $R(B) = r(B)e^{-2|B|} = (\epsilon e^{-2})^{|B|}$. Indeed, to verify [34] we just notice that the number of polymers of size $n$ containing a fixed site is bounded by $\kappa^n$ with a suitable constant $\kappa$. Thus,

$$\sum_{B':\,\Lambda(B')\ni x} \epsilon^{|B'|} \leq \sum_{n=1}^{\infty} \kappa^n \epsilon^n \leq 1 \qquad [35]$$

once $\epsilon$ is sufficiently small, and thus

$$\sum_{B'\in N(B)} \epsilon^{|B|} \leq |\Lambda(B)| \leq |B| \qquad [36]$$

yielding [34] ($1 - t > e^{-2t}$ for $t < 1/2$). To have $w \in \mathcal{D}_{W,\boldsymbol{R}}$ (for any $W$) is, for $R(B) = (\epsilon e^{-2})^{|B|}$, sufficient to take $\beta \leq \beta_0$ with $\tanh\beta_0 = \epsilon e^{-2}$.

As a consequence, for $\beta \leq \beta_0$ we can use the cluster expansion theorem to obtain a convergent power series in powers of $\tanh\,\beta$. In particular, using $\Lambda(X) = \cup_{B\in\text{supp}X}\,\Lambda(B)$, we get the pressure by the explicit formula

$$\beta p(\beta) = \log\,2 + d\,\log(\cosh\,\beta) + \sum_{X:\Lambda(X)\ni x} \frac{a(X)}{|\Lambda(X)|} w^X \qquad [37]$$

for any fixed $x \in \mathbb{Z}^d$ (by translation invariance of the contributing terms, the choice of $x$ is irrelevant). The function $\beta p(\beta)$ is analytic on the region $\beta \leq \beta_0$ since it is obtained as a uniformly absolutely convergent series of analytic terms $(\tanh\,\beta)^{|X|}$.

This type of *high-temperature cluster expansion* can be extended to a large class of models with Boltzmann factor in the form $\exp\{-\beta\sum_A U_A(\phi)\}$, where $\phi = (\phi_x; x \in \mathbb{Z}^d)$ is the configuration with *a priori* on-site probability distribution $\nu(\mathrm{d}\phi_x)$ and $U_A$, for any finite $A \subset \mathbb{Z}^d$, are the multi-site interactions (depending only on $(\phi_x; x \in A)$). Using the Mayer trick we can rewrite

$$\exp\left\{-\beta \sum_{A\subset\Lambda} U_A(\phi)\right\} = \prod_A (1 + f_A(\phi)) \qquad [38]$$

with $f_A(\phi) = \exp\{-\beta U_A(\phi)\} - 1$. Expanding the product we will get a polymer representation with polymers $\mathcal{A}$ consisting of connected collections $\mathcal{A} = (A_1, \ldots, A_k)$ with weights

$$w(\mathcal{A}) = \int \prod_{A\in\mathcal{A}} f_A(\phi) \prod_{x\in\cup_{A\in\mathcal{A}}A} \nu(\mathrm{d}\phi_x) \qquad [39]$$

under appropriate bounds on the interactions $U_A$ and for $\beta$ small enough, using $\Lambda(\mathcal{A})$ to denote the set $\cup_{A\in\mathcal{A}}A$, we get,

$$\sum_{\mathcal{A}:\Lambda(\mathcal{A})\ni x} |w(\mathcal{A})| \leq 1 \qquad [40]$$

This assumption allows, as before in the case of the high-temperature Ising model, to apply the cluster expansion theorem yielding an explicit series expansion for the pressure.

### Correlations

Cluster expansions can be applied for evaluation of decay of correlations. Let us consider, for the class of models discussed above, the expectation

$$\langle\Psi\rangle_\Lambda = \frac{1}{Z_\Lambda} \int \Psi(\phi)\, e^{-\beta H_\Lambda(\phi)} \prod_{x\in\Lambda} \nu(\mathrm{d}\phi_x) \qquad [41]$$

with $H_\Lambda(\phi) = \sum_{A\subset\Lambda} U_A(\phi)$ and a function $\Psi$ depending only on variables $\phi_x$ on sites $x$ from a finite set $S \subset \Lambda \subset \mathbb{Z}^d$.

A convenient way of evaluating the expectation starts with introduction of the modified partition function

$$Z_{\Lambda,\Psi}(\alpha) = Z_\Lambda + \alpha Z_{\Lambda,\Psi} = Z_\Lambda(1 + \alpha\langle\Psi\rangle_\Lambda) \quad [42]$$

Clearly,

$$\langle\Psi\rangle_\Lambda = \left.\frac{\mathrm{d}\log Z_{\Lambda,\Psi}(\alpha)}{\mathrm{d}\alpha}\right|_{\alpha=0} \quad [43]$$

Thus, one may get an expression for the expectation $\langle\Psi\rangle_\Lambda$, by forming a polymer representation of $Z_{\Lambda,\Psi}(\alpha)$ and isolating terms linear in $\alpha$ in the corresponding cluster expansion. For the first step, in the just cited high-temperature case with general multi-site interactions, we first enlarge the original set $\mathcal{A}(\Lambda)$ of all polymers in $\Lambda$ (consisting of connected collections $\mathcal{A} = (A_1, \ldots, A_k)$) to $\mathcal{W}_S(\Lambda) = \mathcal{A}(\Lambda) \cup \mathcal{A}_S(\Lambda)$, where $\mathcal{A}_S(\Lambda)$ is the set of all collections $(\mathcal{A}_1, \ldots, \mathcal{A}_k)$ of polymers such that each of them intersects the set $S$ (polymers $(\mathcal{A}_1, \ldots, \mathcal{A}_k)$ are "glued" by $S$ into a single entity). Compatibility is defined as before by disjointness; in addition, any two collections from $\mathcal{A}_S(\Lambda)$ are declared to be incompatible as well as any polymer $\mathcal{A}$ from $\mathcal{A}(\Lambda)$ intersecting $S$ is considered to be incompatible with any collection from $\mathcal{A}_S(\Lambda)$. Defining now $w_\alpha(\mathcal{A}) = w(\mathcal{A})$ for $\mathcal{A} \in \mathcal{A}(\Lambda)$ and

$$w_\alpha(\mathcal{A}) = \alpha \int \Psi(\phi)\mathrm{e}^{-\beta H_\Lambda(\phi)} \prod_{x\in\cup_{A\in\mathcal{A}_1\cup\cdots\cup\mathcal{A}_k} A\cup S} \nu(\mathrm{d}\phi_x) \quad [44]$$

for $\mathcal{A} = (\mathcal{A}_1, \ldots, \mathcal{A}_k) \in \mathcal{A}_S(\Lambda)$, we get $Z_{\Lambda,\Psi}(\alpha)$ exactly in the form [18],

$$Z_{\Lambda,\Psi}(\alpha) = \sum_{\mathcal{I}\subset\mathcal{W}_S(\Lambda)} \prod_{\mathcal{A}\in\mathcal{I}} w_\alpha(\mathcal{A}) \quad [45]$$

As a result, we have

$$\log \mathcal{Z}_{\Lambda,\Psi}(\alpha) = \sum_{X\in\mathcal{X}(\mathcal{W}_S(\Lambda))} a(X) w_\alpha^X \quad [46]$$

allowing easily to isolate terms linear in $\alpha$: namely, the terms with multi-indices $X$ with $\operatorname{supp} X \cap \mathcal{A}_S(\Lambda)$ consisting of a single collection, say $\mathcal{A}_0$, that occurs with multiplicity one, $X(\mathcal{A}_0) = 1$. Explicitly, using

$$\mathcal{X}_{S,\mathcal{A}_0}(\Lambda) = \{X \in \mathcal{X}(\mathcal{W}_S(\Lambda)) : \operatorname{supp} X \cap \mathcal{A}_S(\Lambda) = \{\mathcal{A}_0\}, X(\mathcal{A}_0) = 1\} \quad [47]$$

we get

$$\langle\Psi\rangle_\Lambda = \sum_{\mathcal{A}_0\in\mathcal{A}_S(\Lambda)} \sum_{X\in\mathcal{X}_{S,\mathcal{A}_0}(\Lambda)} a(X) w^X \quad [48]$$

It is easy to show that, for sufficiently small $\beta$, the series on the right-hand side is absolutely convergent even if we extend $\mathcal{A}_S(\Lambda)$ to $\mathcal{A}_S = \cup_\Lambda \mathcal{A}_S(\Lambda)$ and $\mathcal{X}_{S,\mathcal{A}_0}(\Lambda)$ to $\mathcal{X}_{S,\mathcal{A}_0} = \cup_\Lambda \mathcal{X}_{S,\mathcal{A}_0}(\Lambda)$. As a result, we have an explicit expression for the limiting expectation $\langle\Psi\rangle$ in terms of an absolutely convergent power series. This can be immediately applied to show that $|\langle\Psi\rangle - \langle\Psi\rangle_\Lambda|$ decay exponentially in distance between $S$ and the complement of $\Lambda$. Indeed, it suffices to find a suitable bound on $\sum_X |\mathrm{a}(X)||w|^X$ with the sum running over all clusters $X$ reaching from the set $S$ to $\Lambda^c$. To this end one does not need to evaluate explicitly the number of clusters of given "diameter" $\operatorname{diam}(X) = \sum_{\mathcal{A}} X(\mathcal{A}) \operatorname{diam}(\Lambda(\mathcal{A})) = m$ with $m \geq \operatorname{dist}(S, \Lambda^c)$. The needed estimate is actually already contained in the condition (ii) from the cluster expansion theorem. It just suffices to choose a suitable $k$ and assume that $\beta$ is small enough to assure validity of (40) in a stronger form, $\sum_{\mathcal{A}:\Lambda(\mathcal{A})\ni x} |w(\mathcal{A})|K^{|\Lambda(\mathcal{A})|} \leq 1$, yielding eventually

$$\sum_{X:\operatorname{diam}(X)\geq\operatorname{dist}(S,\Lambda^c)} |a(X)||w|^X \leq K^{-\operatorname{dist}(S,\Lambda^c)} |S| \sum_{X:\cup_{\mathcal{A}\in\operatorname{supp}X}\Lambda(\mathcal{A})\ni x} |a(X)||w|^X K^{\sum X(\mathcal{A})|\Lambda(\mathcal{A})|} \leq |S| K^{-\operatorname{dist}(S,\Lambda^c)} \quad [49]$$

Exponential decay of correlations $\langle\Psi_1;\Psi_2\rangle_\Lambda = \langle\Psi_1\Psi_2\rangle_\Lambda - \langle\Psi_1\rangle_\Lambda\langle\Psi_2\rangle_\Lambda$ (and the limiting $\langle\Psi_1;\Psi_2\rangle$) in distance between supports of $\Psi_1$ and $\Psi_2$ can be established in a similar way by isolating terms proportional to $\alpha_1\alpha_2$ in the cluster expansion of $\log Z_{\Lambda,\Psi_1,\Psi_2}(\alpha_1, \alpha_2)$ with

$$Z_{\Lambda,\Psi_1,\Psi_2}(\alpha_1,\alpha_2) = Z_\Lambda(1 + \alpha_1\langle\Psi_1\rangle_\Lambda + \alpha_2\langle\Psi_2\rangle_\Lambda + \alpha_1\alpha_2\langle\Psi_1\Psi_2\rangle_\Lambda) \quad [50]$$

The resulting claim can be readily generalized to one about the decay of the correlation $\langle\Psi_1;\ldots;\Psi_k\rangle$ in terms of the shortest tree connecting supports $S_1, \ldots, S_k$ of the functions $\Psi_1, \ldots, \Psi_k$.

### Low-Temperature Expansions

Finally, in some models with symmetries, we can apply cluster expansion also at low temperatures. Let us illustrate it again in the case of Ising model. This time, we take the partition function $Z_\Lambda^+(\beta)$ with plus boundary conditions. First, let us define for each nearest-neighbor bond $\langle x, y\rangle$ its dual as the $(d-1)$-dimensional closed unit hypercube orthogonal to the segment from $x$ to $y$ and bisecting it at its center. For a given configuration $\sigma_\Lambda$, we consider the boundary of the regions of constant spins consisting of the union $\partial(\sigma_\Lambda)$ of all hypercubes that are dual to nearest-neighbor bonds $\langle x, y\rangle$ for which $\sigma_x \neq \sigma_y$. The *contours corresponding to* $\sigma_\Lambda$ are now defined as the connected components of $\partial(\sigma_\Lambda)$. Notice that, under the fixed boundary condition, there is a one-to-one correspondence between configurations $\sigma_\Lambda$ and sets $\Gamma$ of mutually compatible (disconnected) contours in $\Lambda$.

Observing that the number of faces in $\partial(\sigma_\Lambda)$ is just the sum of the areas $|\gamma|$ of the contours $\gamma \in \Gamma$, we get the polymer representation

$$Z_\Lambda^+(\beta) = e^{\beta|E(\Lambda)|} \sum_\Gamma \exp\left(-\beta \sum_{\gamma\in\Gamma} |\gamma|\right) \qquad [51]$$

where the sum is over all collections of disjoint contours in $\Lambda$. Here $E(\Lambda)$ is the set of all bonds $\langle x, y\rangle$ with at least one endpoint $x, y$ in $\Lambda$.

The condition [24] with $r(\gamma) = \epsilon^\gamma$ yields a similar bound on the weights $w(\gamma) = e^{-\beta|\gamma|}$ as in the high-temperature expansion. To verify it, for $\beta$ sufficiently large, boils down to the evaluation of number of contours of size $n$ that contain a fixed site.

As a result, we can employ the cluster expansion theorem to get

$$\log Z_\Lambda^+(\beta) = \beta|E(\Lambda)| + \sum_{X:X\in\mathcal{X}(\mathcal{C}(\Lambda))} a(X)w^X \qquad [52]$$

with an explicit formula for the limit

$$\beta p(\beta) = \beta d + \sum_{X:A(X)\ni 0} \frac{a(X)}{|A(X)|} w^X \qquad [53]$$

Here, $A(X)$ is the set of sites attached to contours from supp $X$,

$$A(X) = \cup_{\gamma\in \text{supp}\, X} A(\gamma) \qquad [54]$$

with

$$A(\gamma) = \{x \in \mathbb{Z}^d \mid \text{such that } \text{dist}(x,\gamma) \le 1/2\} \qquad [55]$$

As a consequence of the fact that [53] is, for large $\beta$, an absolutely convergent sum of analytic terms $a(X)w^X = a(X)e^{-\beta\sum_\gamma X(\gamma)|\gamma|}$ (considered as functions of $\beta$), the function $\beta p(\beta)$ is, for large $\beta$, analytic in $\beta$.

The fact that one can explicitly express the difference $\log Z_\Lambda^+(\beta) - |\Lambda|\beta p(\beta)$ (cf. [28]) found numerous applications in situations where one needs an accurate evaluation of the influence of the boundary of the region $\Lambda$ on the partition function. One such example is a study of microscopic behavior of interfaces. The main idea is to use the explicit expression in the form

$$\begin{aligned} Z_\Lambda^+(\beta) &= \exp\{\beta p(\beta)|\Lambda|\} \exp\left\{\sum_{X:A(X)\cap\Lambda^c\neq\emptyset} a(X)w^X \frac{|A(X)\cap\Lambda|}{|A(X)|}\right\} \\ &= \exp\{\beta p(\beta)|\Lambda|\} \prod_{X:A(X)\cap\Lambda^c\neq\emptyset} (1+f_X) \end{aligned} \qquad [56]$$

Noticing that

$$f_X = \exp\left\{a(X)w^X \frac{|A(X)\cap\Lambda|}{|A(X)|}\right\} - 1$$

does not vanish only if $A(X)\cap\Lambda \neq \emptyset$, we can expand the product to obtain "decorations" of the boundary $\partial\Lambda$ by clusters $f_X$. In the case of interface these clusters can be incorporated into the weight of interface, while on a fixed boundary they yield a "wall free energy."

The possibility of the (low-temperature) polymer representation of the partition function in terms of contours is based on the $+ \leftrightarrow -$ symmetry of the Ising model. In absence of such a symmetry, cluster expansions can still be used, but in the framework of Pirogov–Sinai theory (*see* Pirogov–Sinai Theory).

## Bibliographical Notes

Cluster expansions originated from the works of Ursell, Yvon, Mayer, and others and were first studied in terms of formal power series. The combinatorial and enumeration problems considered in this framework were summarized in Uhlenbeck and Ford (1962). For related topics in modern language, see Bergeron *et al.* (1998). The convergence results for Mayer and virial expansions for dilute gas were first proved in the works of Penrose, Lebowitz, Groenveld, and Ruelle (see Ruelle (1969) for a detailed survey). General polymer models on lattice were discussed by Gruber and Kunz (1971) (see also Simon (1993) for discussion of high-temperature and low-temperature cluster expansions of lattice models). Abstract polymer models were introduced in Kotecký and Preiss (1986). An elegant proof of a general claim presented by Dobrushin (1996) was further extended and summarized by Scott and Sokal (2005). We follow their reformulation of the Dobrushin condition. Cluster expansions with a view on applications in quantum field theory are reviewed in Brydges (1986).

# Coherent States

**S T Ali**, Concordia University, Montreal, QC, Canada

## Introduction

Very generally, a family of coherent states is a set of continuously labeled quantum states, with specific mathematical and physical properties, in terms of which arbitrary quantum states can be expressed as linear superpositions. Since coherent states are continuously labeled, they form overcomplete sets of vectors in the Hilbert space of states. Originally these states were introduced into physics by Schrödinger (1926), as a family of quantum states in terms of which the transition from quantum to classical mechanics could be conveniently studied. These states have the minimal uncertainty property, in the sense that they saturate the Heisenberg uncertainty relations. The name coherent state was applied when these states were rediscovered in the context of quantum optical radiation by Glauber, Klauder, and Sudarshan. It was demonstrated that in these states the correlation functions of the quantum optical field factorize as they do in classical optics, so that the optical field has a near-classical behavior, with the optical beam being coherent. In this article, we shall refer to these originally studied coherent states as canonical coherent states (CCS).

The canonical coherent states, apart from their use in quantum optics, have also been found to be extremely useful in computations in atomic and molecular physics, in quantum statistical mechanics, and in certain areas of mathematics and mathematical physics, including harmonic analysis, symplectic geometry, and quantization theory. Their wide applicability has prompted the search for other families of states sharing similar mathematical and physical properties. These other families of states are usually called generalized coherent states, even when there is no link to optical coherence in such studies.

## Some Properties of CCS

In addition to the minimal uncertainty property, the canonical coherent states have a number of analytical and group-theoretical properties which are taken as starting points in looking for generalizations. We now define the canonical coherent states mathematically and enumerate a few of these properties.

Suppose that the vectors $|0\rangle, |1\rangle, \ldots, |n\rangle, \ldots,$ correspond to quantum states of $0, 1, \ldots, n, \ldots,$ excitons, respectively. The Hilbert space of these states, in which they form an orthonormal basis, is often known as Fock space. The canonical coherent states are then defined in terms of this basis, for each complex number $z$, by the analytic expansion:

$$|z\rangle = \mathrm{e}^{-|z|^2/2} \sum_{n=0}^{\infty} \frac{z^n}{\sqrt{n!}} |n\rangle \qquad [1]$$

The states $|z\rangle$ are normalized to unity: $\langle z|z\rangle = 1$. They satisfy the formal eigenvalue equation

$$a|z\rangle = z|z\rangle \qquad [2]$$

where $a$ is the annihilation operator for excitons, which acts on the basis vectors (Fock states) $|n\rangle$ as follows:

$$a|n\rangle = \sqrt{n}|n-1\rangle \qquad [3]$$

Its adjoint $a^\dagger$ has the action

$$a^\dagger|n\rangle = \sqrt{n+1}|n+1\rangle \qquad [4]$$

and

$$[a, a^\dagger] = aa^\dagger - a^\dagger a = I \qquad [5]$$

$I$ being the identity operator on Fock space. Introducing the self-adjoint operators $Q$ and $P$, of position and momentum, respectively,

$$Q = \frac{a + a^\dagger}{\sqrt{2}}, \qquad P = \frac{a - a^\dagger}{\mathrm{i}\sqrt{2}} \qquad [6]$$

it is possible to demonstrate the minimal uncertainty property referred to above (we take $\hbar = 1$):

$$\langle \Delta Q\rangle\langle \Delta P\rangle = \tfrac{1}{2} \qquad [7]$$

where for any observable $A$,

$$\langle \Delta A\rangle = \left[\langle z|A^2|z\rangle - \langle z|A|z\rangle^2\right]^{1/2}$$

is its dispersion in the state $|z\rangle$.

One can also prove the resolution of the identity,

$$\int_{\mathbb{C}} |z\rangle\langle z| \frac{\mathrm{d}q\ \mathrm{d}p}{2\pi} = I \qquad [8]$$

where $z = (1/\sqrt{2})(q - \mathrm{i}p)$ has been written in terms of its real and imaginary parts $(1/\sqrt{2})q$ and $(1/\sqrt{2})p$, respectively. The above operator integral is to be understood in the weak sense, as will be explained later. Equation [8] incorporates the mathematical fact that the set of vectors $|z\rangle$ is overcomplete in the Hilbert space. Indeed, using [8] any vector $|\phi\rangle$ in the Hilbert space can be written as a linear (integral) superposition of these states:

$$|\phi\rangle = \int_{\mathbb{C}} \overline{\Psi(z)}|z\rangle \frac{\mathrm{d}q\ \mathrm{d}p}{2\pi}$$

where $\Psi$ is the component function, $\Psi(z) = \langle\phi|z\rangle$. Thus, the coherent states $|z\rangle$ form a continuously labeled total set of vectors in the Hilbert space and since this space is separable, they are an overcomplete set.

Analytic properties of the vectors $|z\rangle$ emerge when the scalar product $\langle\phi|z\rangle$ is taken with respect to an arbitrary vector $|\phi\rangle$ in Fock space. From [1] it is clear that

$$F(z) = \langle\phi|z\rangle = \mathrm{e}^{-|z|^2/2} f(z)$$

where $f$ is an entire analytic function in the complex variable $z$. Moreover, the mapping $\phi \mapsto f$ is an isometric embedding of the Fock space onto the Hilbert space of analytic functions, with respect to the norm

$$\|f\| = \left[\int_{\mathbb{C}} |f(z)|^2 \mathrm{d}\mu(z, \bar{z})\right]^{1/2} \qquad [9]$$

defined by the measure $\mathrm{d}\mu(z,\bar{z}) = (1/2\pi)\mathrm{e}^{-|z|^2}\,\mathrm{d}q\,\mathrm{d}p$.

Group-theoretical properties of the CCS can be demonstrated by noting that

$$|n\rangle = \frac{(a^\dagger)^n}{\sqrt{n!}}|0\rangle \text{ and } a|0\rangle = 0$$

using which [1] can be recast into the form

$$|z\rangle = \mathrm{e}^{-|z|^2/2}\mathrm{e}^{za^\dagger}|0\rangle = U(z)|0\rangle$$
$$U(z) = \mathrm{e}^{za^\dagger} - \bar{z}a \qquad [10]$$

The vectors $|z\rangle$ and the unitary operator $U(z)$ can be reexpressed in terms of the real variables $q$, $p$ and the operators Q, $P$ as

$$|z\rangle = |q,p\rangle = U(q,p)|0\rangle$$
$$U(q,p) = \mathrm{e}^{\mathrm{i}(pQ - qP)} \qquad [11]$$

The operators $U(q,p)$ realize a (projective) unitary, irreducible representation of the Weyl–Heisenberg group, which is the group whose Lie algebra has the generators $Q$, $P$, and $I$, obeying the commutation relations $[Q,P] = \mathrm{i}I$. The existence of the resolution of the identity [8] is the statement of the fact that this representation is square integrable (a notion which will be elaborated upon in the section "Some examples") which gives us the next paradigm for building coherent states, namely by the action, on a fixed vector, of the unitary operators of a square-integrable representation of a locally compact group.

The above range of properties, which are enjoyed by the CCS, cannot all be expected to hold when looking for generalizations. It then becomes necessary to adopt one or other of these properties as the starting point and to proceed from there. In so doing, it is best first to set down a general definition of coherent states, involving a minimal mathematical structure. Motivated more by possible applications to physics, we do this in the following section.

## General Definition

Let $\mathfrak{H}$ be an abstract, separable Hilbert space over the complexes, $X$ a locally compact space and $\mathrm{d}\nu$ a measure on $X$. Let $|x,i\rangle$ be a family of vectors in $\mathfrak{H}$, defined for each $x$ in $X$ and $i = 1, 2, 3, \ldots, N$, where $N$ is usually a finite integer, although it could also be infinite. We assume that this set of vectors possesses the following properties:

1. For each $i$, the mapping $x \mapsto |x,i\rangle$ is weakly continuous, that is, for each vector $|\phi\rangle$ in $\mathfrak{H}$, the function $\Psi_i(x) = \langle x,i|\phi\rangle$ is continuous (in the topology of $X$).
2. For each $x$ in $X$, the vectors $|x,i\rangle, i = 1, 2, \ldots, N$, are linearly independent.
3. The resolution of the identity

$$\sum_{i=1}^{N} \int_X |x,i\rangle\langle x,i| \mathrm{d}\nu(x) = I_{\mathfrak{H}} \qquad [12]$$

holds in the weak sense on the Hilbert space $\mathfrak{H}$, that is, for any two vectors $|\phi\rangle, |\psi\rangle$ in $\mathfrak{H}$, the following equality holds:

$$\sum_{i=1}^{N} \int_X \langle\phi|x,i\rangle\langle x,i|\psi\rangle \mathrm{d}\nu(x) = \langle\phi|\psi\rangle$$

A set of vectors $|x,i\rangle$ satisfying the above three properties is called a family of generalized vector coherent states. In case $N = 1$, the set is called a family of generalized coherent states. Sometimes the resolution of the identity condition is replaced by a weaker

condition, with the vectors $|x, i\rangle$ simply forming a total set in $\mathfrak{H}$ and the functions $F_i(x) = \langle x, i|\phi\rangle$, as $|\phi\rangle$ runs through $\mathfrak{H}$, forming a reproducing kernel Hilbert space. Alternatively, the identity on the right-hand side of [12] could also be replaced by a bounded, positive operator $T$ with bounded inverse. In this case, the term frame is also used for the family of generalized coherent states. For physical applications, however, the resolution of the identity condition is always assumed to hold, although the measure $d\nu$ could be of a very general nature (possibly also singular). The objective in all these cases is to ensure that an arbitrary vector $|\phi\rangle$ be expressible as a linear (integral) combination of these vectors. Indeed, [12] is immediately seen to imply that

$$|\phi\rangle = \sum_{i=1}^{N} \int_X \Psi_i(x)|x, i\rangle \mathrm{d}\nu(x) \qquad [13]$$

where $\Psi_i(x) = \langle x, i|\phi\rangle$.

Associated to a family of generalized coherent states on a Hilbert space $\mathfrak{H}$, there is an intrinsic isomorphism between this space and a Hilbert space of (in general, vector valued) continuous functions over $X$. Using this isomorphism, it is always possible to look upon coherent states as a family of continuous functions which are square integrable with respect to the measure $d\nu$. To demonstrate this, we note that, in view of [12], for each vector $|\phi\rangle$ in $\mathfrak{H}$, the vector-valued function $\boldsymbol{\Psi}(x)$ on $x$, with components $\Psi_i(x) = \langle x, i|\phi\rangle$, $i = 1, 2, \ldots, N$, satisfies the norm condition

$$\sum_{i=1}^{N} \int_X |\Psi_i(x)|^2 \mathrm{d}\nu(x) = \|\phi\|^2_{\mathfrak{H}}$$

This means that the set of vectors $\boldsymbol{\Psi}$, as $|\phi\rangle$ runs through $\mathfrak{H}$, is a closed subspace of the Hilbert space $L^2_{\mathbb{C}^N}(X, d\nu)$ of $N$-vector-valued functions on $x$. Let us denote this subspace by $\mathfrak{H}_K$ and note that this space is a reproducing kernel Hilbert space with a matrix-valued kernel $\boldsymbol{K}(x, y)$ having matrix elements

$$K(x, y)_{ij} = \langle x, i|y, j\rangle, \quad i, j = 1, 2, \ldots, N \qquad [14]$$

and enjoying the properties

$$K(x, y)_{ij} = \overline{K(y, x)_{ji}}, \quad K(x, x)_{ii} > 0 \qquad [15]$$

and

$$\sum_{\ell=1}^{N} \int_X K(x, z)_{i\ell} K(z, y)_{\ell j} \mathrm{d}\nu(z) = K(x, y)_{ij} \qquad [16]$$

If $\boldsymbol{e}^i$, $i = 1, 2, \ldots, N$, are the vectors constituting the canonical basis of $\mathbb{C}^N$, then for each $x$ in $X$ and $i = 1, 2, \ldots, N$, the vector-valued function $\boldsymbol{\xi}^i_x$ on $X$, defined by $\boldsymbol{\xi}^i_x(y) = \boldsymbol{K}(y, x)\boldsymbol{e}^i$, is the image in $\mathfrak{H}_K$ of the generalized vector coherent state $|x, i\rangle$, under the above-mentioned isometry. The vectors $\boldsymbol{\xi}^i_x$ span the space $\mathfrak{H}_K$ and for an arbitrary element $\boldsymbol{\Psi}$ of this Hilbert space, the reproducing property [16] of the kernel implies the relation

$$\int_X \boldsymbol{K}(x, y)\boldsymbol{\Psi}(y)\mathrm{d}\nu(y) = \boldsymbol{\Psi}(x) \qquad [17]$$

Conversely, given any reproducing kernel Hilbert space, with a kernel satisfying the relations [15] and [16], generalized coherent states can be constructed as above in terms of this kernel. Mathematically, therefore, generalized coherent states are just the set of vectors naturally defined by the kernel in a reproducing kernel Hilbert space.

## Some Examples

We present in this section some of the more commonly used types of coherent states, as illustrations of the general structure given above.

A large class of generalizations of the canonical coherent states [1] is obtained by a simple modification of their analytic structure. Let $x_1 \leq x_2 \leq \cdots \leq x_n \leq \cdots$ be an infinite sequence of positive numbers ($x_1 \neq 0$). Define $x_n! = x_1 x_2 \cdots x_n$ and by convention set $x_0! = 1$. In the same Fock space in which the CCS were described, we now define the related deformed or nonlinear coherent states via the analytic expansion

$$|z\rangle = \mathcal{N}(|z|^2)^{-1/2} \sum_{n=0}^{\infty} \frac{z^n}{\sqrt{x_n!}} |n\rangle \qquad [18]$$

The normalization factor $\mathcal{N}(|z|^2)$ is chosen so that $\langle z\,|\,z\rangle = 1$. These generalized coherent states are overcomplete in the Fock space and satisfy a resolution of the identity of the type

$$\int_{\mathcal{D}} |z\rangle\langle z|\mathcal{N}(|z|^2)\mathrm{d}\nu(z, \overline{z}) = I \qquad [19]$$

$\mathcal{D}$ being an open disk in the complex plane of radius $L$, the radius of convergence of the series $\sum_{n=0}^{\infty}(z^n/\sqrt{x_n!})$. (In the case of the CCS, $L = \infty$.) The measure $d\nu$ is generically of the form $\mathrm{d}\theta\, \mathrm{d}\lambda(r)$ (for $z = r e^{i\theta}$), where $d\lambda$ is related to the $x_n!$ through the moment condition

$$\frac{x_n!}{2\pi} = \int_0^L r^{2n}\, \mathrm{d}\lambda(r), \quad n = 0, 1, 2, \ldots \qquad [20]$$

This means that once the quantities $x_n!$ are specified, the measure $d\lambda$ is to be determined by solving the

moment problem [20], which of course may not always have a solution. This puts a constraint on the type of sequences $\{x_n\}$ which may be used in the construction.

Once again, we see that for an arbitrary vector $|\phi\rangle$ in the Fock space, the function $F(z) = \langle\phi\,|\,z\rangle$, of the complex variable $z$, is of the form $F(z) = \mathcal{N}(|z|^2)^{-1/2} f(z)$, where $f$ is an analytic function on the domain $\mathcal{D}$. The reproducing kernel associated to these coherent states is

$$\begin{aligned} K(\bar{z}, z') &= \langle z|z'\rangle \\ &= \left[\mathcal{N}(|z|^2)\mathcal{N}(|z'|^2)\right]^{-1/2} \sum_{n=0}^{\infty} \frac{(\bar{z}z')^n}{x_n!} \end{aligned} \qquad [21]$$

By analogy with [2], one can define a generalized annihilation operator $A$ by its action on the vectors $|z\rangle$,

$$A|z\rangle = z|z\rangle \qquad [22]$$

and its adjoint operator $A^\dagger$. These act on the Fock states $|n\rangle$ as follows:

$$\begin{aligned} A|n\rangle &= \sqrt{x_n}|n-1\rangle \\ A^\dagger|n\rangle &= \sqrt{x_{n+1}}|n+1\rangle \end{aligned} \qquad [23]$$

Depending on the exact values of the quantities $x_n$, these two operators, together with the identity $I$ and all their commutators, could generate a wide range of algebras including various deformed quantum algebras. The term nonlinear, as often applied to these generalized coherent states, comes again from quantum optics, where many such families of states are used in studying the interaction between the radiation field and atoms, and the strength of the interaction itself depends on the frequency of radiation. Of course, these coherent states will not in general have either the group-theoretical or the minimal uncertainty properties of the CCS.

The following is an example of generalized coherent states of the above type, built over the unit disk, $\mathcal{D} = \{z \in \mathbb{C} \,|\, |z| < 1\}$: on the Fock space, we define the states

$$|z\rangle = (1-r^2)^\kappa \sum_{n=0}^{\infty} \left[\frac{(2\kappa)_n}{n!}\right]^{1/2} z^n|n\rangle \quad r = |z| \qquad [24]$$

where $\kappa = 1,\ 3/2,\ 2,\ 5/2, \ldots$, and

$$\begin{aligned} (a)_m &= \frac{\Gamma(a+m)}{\Gamma(a)} \\ &= a(a+1)(a+2)\cdots(a+m-1) \end{aligned}$$

Comparing [24] with [18] we see that $x_n = n/(2\kappa + n - 1)$ so that $\lim_{n\to\infty} x_n = 1$. Thus, the infinite sum is convergent for any $z$ lying in the unit disk. These generalized coherent states arise from representations of the group SU(1, 1) belonging to the discrete series, each irreducible representation being labeled by a specific value of the index $\kappa$. The associated Hilbert space of functions, analytic on the unit disk, is a subspace of $L^2(\mathcal{D}, \mathrm{d}\mu_\kappa)$, with

$$\begin{aligned} \mathrm{d}\mu_\kappa(z, \bar{z}) &= (2\kappa - 1)\frac{(1-r^2)^{2\kappa-2}}{\pi} r\, \mathrm{d}r\, \mathrm{d}\theta \\ z &= r e^{\mathrm{i}\theta} \end{aligned}$$

which can be obtained by solving the moment problem [20]. The resolution of the identity satisfied by these states is

$$\frac{2\kappa - 1}{\pi} \int_{\mathcal{D}} |z\rangle\langle z| \frac{r\,\mathrm{d}r\,\mathrm{d}\theta}{(1-r^2)^2} = I \qquad [25]$$

The associated generalized creation and annihilation operators are

$$\begin{aligned} A|n\rangle &= \sqrt{\frac{n}{2\kappa + n - 1}}|n-1\rangle \\ A^\dagger|n\rangle &= \sqrt{\frac{n+1}{2\kappa + n}}|n+1\rangle \end{aligned} \qquad [26]$$

so that, clearly, $[A, A^\dagger] \neq I$.

Operators $A$ and $A^\dagger$ of the general type defined in [23] are also known as ladder operators. When such operators appear as generators of representations of Lie algebras, their eigenvectors (see [22]) are usually called Barut–Girardello coherent states. As an example, the representation of the Lie algebra of SU(1,1) on the Fock space is generated by the three operators $K_+, K_-$, and $K_3$, which satisfy the commutation relations

$$[K_3, K_\pm] = \pm K_\pm, \quad [K_-, K_+] = 2K_3 \qquad [27]$$

They act on the vectors $|n\rangle$ as follows:

$$\begin{aligned} K_-|n\rangle &= \sqrt{n(2\kappa + n - 1)}|n-1\rangle \\ K_+ &= K_-^\dagger \\ K_3|n\rangle &= (\kappa + n)|n\rangle \end{aligned} \qquad [28]$$

Thus, $K_-|0\rangle = 0$ and

$$|n\rangle = \frac{1}{\sqrt{n!(2\kappa)_n}} K_+^n|0\rangle$$

The Barut–Girardello coherent states $|z\rangle$ are now defined as the formal eigenvectors of the ladder operator $K_-$:

$$K_-|z\rangle = z|z\rangle, \quad z \in \mathbb{C} \qquad [29]$$

They have the analytic form

$$|z\rangle = \frac{|z|^{2\kappa-1}}{\sqrt{I_{2\kappa-1}(2|z|)}} \sum_{n=0}^{\infty} \frac{z^n}{\sqrt{n!(2\kappa + n - 1)!}}|n\rangle \qquad [30]$$

where $I_\nu(x)$ is the order-$\nu$ modified Bessel function of the first kind. These coherent states satisfy the resolution of the identity,

$$\frac{2}{\pi}\int_{\mathbb{C}} |z\rangle\langle z| K_{2\kappa-1}(2r) I_{2\kappa-1}(2r) r\, \mathrm{d}r\, \mathrm{d}\theta = I \qquad z = r\mathrm{e}^{\mathrm{i}\theta} \qquad [31]$$

where again, $K_\nu(x)$ is the order-$\nu$ modified Bessel function of the second kind.

A nonanalytic extension of the expression [18] is often used to define generalized coherent states associated to physical Hamiltonians having pure point spectra. These coherent states, known as Gazeau–Klauder coherent states, are labeled by action–angle variables. Suppose that we are given the physical Hamiltonian $H = \sum_{n=0}^{\infty} E_n |n\rangle\langle n|$, with $E_0 = 0$, that is, it has the energy eigenvalues $E_n$ and eigenvectors $|n\rangle$, which we assume to form an orthonormal basis for the Hilbert space of states $\mathfrak{H}$. Let us write the eigenvalues as $E_n = \omega\epsilon_n$ by introducing a sequence of dimensionless quantities $\{\epsilon_n\}$ ordered as: $0 = \epsilon_0 < \epsilon_1 < \epsilon_2 < \cdots$. Then, for all $J \geq 0$ and $\gamma \in \mathbb{R}$, the Gazeau–Klauder coherent states are defined as

$$|J,\gamma\rangle = \mathcal{N}(J)^{-1/2} \sum_{k=0}^{\infty} \frac{J^{n/2}\mathrm{e}^{-\mathrm{i}\epsilon_n\gamma}}{\sqrt{\epsilon_n!}} |n\rangle \qquad [32]$$

where again $\mathcal{N}$ is a normalization factor, which turns out to be dependent on $J$ only. These coherent states satisfy the temporal stability condition

$$\mathrm{e}^{-\mathrm{i}Ht}|J,\gamma\rangle = |J,\gamma+\omega t\rangle \qquad [33]$$

and the action identity

$$\langle J,\gamma|H|J,\gamma\rangle_{\mathfrak{H}} = \omega J \qquad [34]$$

While these generalized coherent states do form an overcomplete set in $\mathfrak{H}$, the resolution of the identity is generally not given by an integral relation of the type [12].

For the second set of examples of generalized coherent states, we take the group-theoretical structure of the CCS as the point of departure. Let $G$ be a locally compact group and suppose that it has a continuous, irreducible representation on a Hilbert space $\mathfrak{H}$ by unitary operators $U(g)$, $g \in G$. This representation is called square integrable if there exists a nonzero vector $|\psi\rangle$ in $\mathfrak{H}$ for which the integral

$$c(\psi) = \int_G |\langle\psi|U(g)\psi\rangle|^2 \,\mathrm{d}\mu(g) \qquad [35]$$

converges. Here $\mathrm{d}\mu$ is a Haar measure of $G$, which for definiteness, we take to be the left-invariant measure. (The value of the above integral is independent of whether the left- or the right-invariant measure is used, so we could just as well have used the right-invariant measure.) A vector $|\psi\rangle$, satisfying [35], is said to be admissible, and it can be shown that the existence of one such vector guarantees the existence of an entire dense set of such vectors in $\mathfrak{H}$. Moreover, if the group $G$ is unimodular, that is, if the left- and the right-invariant measures coincide, then the existence of one admissible vector implies that every vector in $\mathfrak{H}$ is admissible. Given a square-integrable representation and an admissible vector $|\psi\rangle$, let us define the vectors

$$|g\rangle = \frac{1}{\sqrt{c(\psi)}} U(g)|\psi\rangle \qquad [36]$$

for all $g$ in the group $G$. These vectors are to be seen as the analogs of the canonical coherent states [11], written there in terms of the representation of the Weyl–Heisenberg group. Next, it can be shown that the resolution of the identity

$$\int_G |g\rangle\langle g| \mathrm{d}\mu(g) = I_{\mathfrak{H}} \qquad [37]$$

holds on $\mathfrak{H}$. Thus, the vectors $|g\rangle$ constitute a family of generalized coherent states. The functions $F(g) = \langle g|\phi\rangle$ for all vectors $|\phi\rangle$ in $\mathfrak{H}$ are square integrable with respect to the measure $\mathrm{d}\mu$ and the set of such functions, which in fact are continuous in the topology of $G$, forms a closed subspace of $L^2(G, \mathrm{d}\mu)$. Furthermore, the mapping $\phi \mapsto F$ is a linear isometry between $\mathfrak{H}$ and $L^2(G, \mathrm{d}\mu)$ and under this isometry the representation U gets mapped to a subrepresentation of the left regular representation of $G$ on $L^2(G, \mathrm{d}\mu)$.

A typical example of the above construction is provided by the affine group, $G_{\mathrm{Aff}}$. This is the group of all $2 \times 2$ matrices of the type

$$g = \begin{pmatrix} a & b \\ 0 & 1 \end{pmatrix} \qquad [38]$$

$a$ and $b$ being real numbers with $a \neq 0$. We shall also write $g = (b, a)$. This group is nonunimodular, with the left-invariant measure being given by $\mathrm{d}\mu(b,a) = (1/a^2)\, \mathrm{d}b\, \mathrm{d}a$. (The right-invariant measure is $(1/a)\, \mathrm{d}b\, \mathrm{d}a$.) The affine group has a unitary irreducible representation on the Hilbert space $L^2(\mathbb{R}, dx)$. Vectors in $L^2(\mathbb{R}, \mathrm{d}x)$ are measurable functions $\phi(x)$ of the real variable $x$ and the (unitary) operators $U(b,a)$ of this representation act on them in the manner

$$(U(b,a)\phi)(x) = \frac{1}{\sqrt{|a|}}\phi\left(\frac{x-b}{a}\right) \qquad [39]$$

If $\psi$ is a function in $L^2(\mathbb{R}, dx)$ such that its Fourier transform $\widehat{\psi}$ satisfies the condition

$$\int_{\mathbb{R}} \frac{|\widehat{\psi}(k)|^2}{|k|}\, \mathrm{d}k < \infty \qquad [40]$$

then it can be shown to be an admissible vector, that is,

$$c(\psi) = \int_{G_{\mathrm{Aff}}} |\langle \psi | U(b,a)\psi\rangle|^2 \frac{\mathrm{d}b\ \mathrm{d}a}{a^2} < \infty$$

Thus, following the general construction outlined above, the vectors

$$|b,a\rangle = \frac{1}{\sqrt{c(\psi)}} U(b,a)\psi, \quad (b,a) \in G_{\mathrm{Aff}} \qquad [41]$$

define a family of generalized coherent states and one has the resolution of the identity

$$\int_{G_{\mathrm{Aff}}} |b,a\rangle\langle b,a| \frac{\mathrm{d}b\,\mathrm{d}a}{a^2} = I \qquad [42]$$

on $L^2(\mathbb{R}, \mathrm{d}x)$.

In the signal-analysis literature a vector satisfying the admissibility condition [40] is called a mother wavelet and the generalized coherent states [41] are called wavelets. Signals are then identified with vectors $|\phi\rangle$ in $L^2(\mathbb{R}, \mathrm{d}x)$ and the function

$$F(b,a) = \langle b,a|\phi\rangle \qquad [43]$$

is called the continuous wavelet transform of the signal $\phi$.

There exist alternative ways of constructing generalized coherent states using group representations. For example, the Perelomov method is based on the observation that the vector $|0\rangle$, appearing in the construction of the canonical coherent states in [10] and [11] using the representation of the Weyl–Heisenberg group, is invariant up to a phase, under the action of its center. Consequently, the coherent states $|z\rangle$, as written in [10], are labeled, not by elements of the group itself, but only by the points in the quotient space of the group by its (central) phase subgroup. Generally, let $G$ be a locally compact group and $U$ a unitary irreducible representation of it on the Hilbert space $\mathfrak{H}$. We do not assume $U$ to be square integrable. We fix a vector $|\psi\rangle$ in $\mathfrak{H}$, of unit norm and denote by $H$ the subgroup of $G$ consisting of all elements $h$ for which

$$U(h)|\psi\rangle = \mathrm{e}^{\mathrm{i}\omega(h)}|\psi\rangle \qquad [44]$$

where $\omega$ is a real-valued function of $h$. Let $X = G/H$ be the left-coset space and $x$ an arbitrary element in $X$. Choosing a coset representative $g(x) \in G$, for each coset $x$, we define the vectors

$$|x\rangle = U(g(x))|\psi\rangle \qquad [45]$$

in $\mathfrak{H}$. The dependence of these vectors on the specific choice of the coset representative $g(x)$, is only through a phase. Thus, if instead of $g(x)$ we took a different representative $g(x)' \in G$ for the same coset $x$, then since $g(x)' = g(x)h$ for some $h \in H$, in view of [44] we would have $U(g(x)')|\psi\rangle = \mathrm{e}^{\mathrm{i}\omega(h)}|x\rangle$. Hence, quantum mechanically, both $|x\rangle$ and $U(g(x)')|\psi\rangle$ represent the same physical state and in particular, the projection operator $|x\rangle\langle x|$ depends only on the coset. Vectors $|x\rangle$, defined in this manner, are called Gilmore–Perelomov coherent states. Since $U$ is assumed to be irreducible, the set of all these vectors as $x$ runs through $G/H$ is dense in $\mathfrak{H}$. In this definition of generalized coherent states, no resolution of the identity is postulated. However, if $X$ carries an invariant measure, under the natural action of $G$, and if the formal operator $B$ defined as

$$B = \int_X |x\rangle\langle x|\, \mathrm{d}\mu(x)$$

is bounded, then it is necessarily a multiple of the identity and a resolution of the identity is again retrieved.

The Perelomov construction can be used to define coherent states for any locally compact group. On the other hand, there exist other constructions of generalized coherent states, using group representations, which generalize the notion of square integrability to homogeneous spaces of the group. Briefly, in this approach one starts with a unitary irreducible representation $U$ and attempts to find a vector $|\psi\rangle$, a subgroup $H$ and a section $\sigma : G/H \longrightarrow G$ such that

$$\int_{G/H} |x\rangle\langle x|\, \mathrm{d}\mu(x) = T \qquad [46]$$

where $|x\rangle = U(\sigma(x))|\psi\rangle$, $T$ is a bounded, positive operator with bounded inverse and $\mathrm{d}\mu$ is a quasi-invariant measure on $X = G/H$. It is not assumed that $|\psi\rangle$ be invariant up to a phase under the action of $H$ and clearly, the best situation is when $T$ is a multiple of the identity. Although somewhat technical, this general construction is of enormous versatility for semidirect product groups of the type $\mathbb{R}^n \rtimes K$, where $K$ is a closed subgroup of $\mathrm{GL}(n, \mathbb{R})$. Thus, it is useful for many physically important groups, such as the Poincaré or the Euclidean group, which do not have square-integrable representations in the sense of the earlier definition (see eqn [35]). The integral condition [46] ensures that any vector $|\phi\rangle$ in $\mathfrak{H}$ can be written in terms of the $|x\rangle$. Indeed, it

is easy to see that one has the integral representation of a vector,

$$|\phi\rangle = \int_X \Psi(x)|x\rangle \, \mathrm{d}\mu(x)$$
$$\Psi(x) = \langle x|T^{-1}\phi\rangle$$

in terms of the generalized coherent states.

The canonical coherent states satisfy the minimal uncertainty relation [7]. It is possible to build families of coherent states by generalizing from this condition. To do this, one typically starts with two self-adjoint generators in the Lie algebra of a particular group representation and then looks for appropriate eigenvectors of a complex combination of these two generators. For two self-adjoint operators $B$ and $C$ on a Hilbert space $\mathfrak{H}$, satisfying the commutation relation $[B, C] = \mathrm{i}D$ and any normalized vector $\phi$ in $\mathfrak{H}$, one can prove the Heisenberg uncertainty relation

$$(\Delta B)^2(\Delta C)^2 \geq \frac{\langle D\rangle^2}{4} \qquad [47]$$

where $\langle X\rangle = \langle\phi|X\phi\rangle$ and $(\Delta X)^2 = \langle X^2\rangle - \langle X\rangle^2$, for any operator $X$ on $\mathfrak{H}$. More generally, one can prove the Schrödinger–Robertson uncertainty relation

$$(\Delta B)^2(\Delta C)^2 \geq \frac{1}{4}\left[\langle D\rangle^2 + \langle F\rangle^2\right] \qquad [48]$$

where $\langle F\rangle = \langle BC + CB\rangle - 2\langle B\rangle\langle C\rangle$ measures the correlation between $B$ and $C$ in the state $\phi$. If $\langle F\rangle = 0$, the above relation reduces to the Heisenberg uncertainty relation. On the other hand, if $\langle D\rangle = 0$, the Heisenberg uncertainty relations become redundant. Suppose now that $B$ and $C$ are two self-adjoint elements of the Lie algebra in the unitary irreducible representation of a Lie group and we look for states $|\phi\rangle$ which minimize the uncertainty relation [48], that is, for which the equality holds. It turns out that such states can be found by considering the linear combination $B + \mathrm{i}\lambda C$, for a fixed complex number $\lambda$, and solving the formal eigenvalue equation

$$[B + \mathrm{i}\lambda C]|z, \lambda\rangle = z|z, \lambda\rangle$$
$$\text{with} \quad z = \langle B\rangle + \mathrm{i}\lambda\langle C\rangle \qquad [49]$$

Solutions to this equation for which $|\lambda| = 1$ are called squeezed states, since in this case $\Delta B \neq \Delta C$. Generally, the states $|z, \lambda\rangle$ are known as intelligent states. As an example, for the operators $Q$ and $P$ in [6], for which one has

$$(\Delta Q)^2(\Delta P)^2 \geq \frac{1}{4}\left[1 + \langle F\rangle^2\right]$$

taking the combination $Q + \mathrm{i}\lambda P$, one obtains the minimal uncertainty states,

$$|z, \lambda\rangle = \mathcal{N}(z, \lambda)^{-1/2} \, \mathrm{e}^{-w(a^\dagger)^2/2} \, \mathrm{e}^{(z/\sqrt{2})(1+w)a^\dagger}|0\rangle \qquad [50]$$

$\mathcal{N}(z, \lambda)$ being a normalization constant and $w = (1-\lambda)/(1+\lambda)$. The case $\lambda = -1$ does not lead to any solutions, while $\lambda = 1$ gives the canonical coherent states [10]. For real $\lambda \neq 1$ the above states are the well-known squeezed states of quantum optics.

Our final example is that of a family of vector coherent states, which will be obtained essentially by replacing the complex variable $z$ in [18] by a matrix variable. We choose the domain $\Omega = \mathbb{C}^{2\times 2}$ (all $2\times 2$ complex matrices), equipped with the measure

$$\mathrm{d}\nu(\mathfrak{z}, \mathfrak{z}^\dagger) = \frac{\mathrm{e}^{-\mathrm{tr}[\mathfrak{z}\mathfrak{z}^\dagger]}}{\pi^4} \prod_{k,j=1}^{2} \mathrm{d}x_{kj} \wedge \mathrm{d}y_{kj}$$

where $\mathfrak{z}$ is an element of $\Omega$ and $z_{kj} = x_{kj} + \mathrm{i}y_{kj}$ are its entries. One can then prove the matrix orthogonality relation

$$\begin{aligned}\int_\Omega & \mathfrak{z}^k \mathfrak{z}^{\dagger\ell} \, \mathrm{d}\nu(\mathfrak{z}, \mathfrak{z}^\dagger) \\ &= \frac{1}{2}\int_\Omega \mathrm{tr}[\mathfrak{z}^k \mathfrak{z}^{\dagger\ell}] \, \mathrm{d}\nu(\mathfrak{z}, \mathfrak{z}^\dagger)\mathbb{I}_2 \\ &= b(k)\mathbb{I}_2, \quad k, \ell = 0, 1, 2, \ldots, \infty\end{aligned} \qquad [51]$$

$\mathbb{I}_2$ being the $2\times 2$ identity matrix and

$$b(k) = \frac{(k+3)!}{2(k+1)(k+2)}$$
$$k = 1, 2, 3, \ldots, \quad b(0) = 1 \qquad [52]$$

Consider the Hilbert space $\tilde{\mathfrak{H}} = L^2_{\mathbb{C}^2}(\Omega, \mathrm{d}\nu)$ of square integrable, two-component vector-valued functions on $\Omega$ and in it consider the vectors $|\boldsymbol{\Psi}^i_k\rangle$, $i = 1, 2$, $k = 0, 1, 2, \ldots, \infty$, defined by the $\mathbb{C}^2$-valued functions,

$$\boldsymbol{\Psi}^i_k(\mathfrak{z}^\dagger) = \frac{1}{\sqrt{b(k)}}\mathfrak{z}^{\dagger k}\chi^i \qquad [53]$$

where the vectors $\chi^i, i = 1, 2$, form an orthonormal basis of $\mathbb{C}^2$. By virtue of [51], the vectors $|\boldsymbol{\Psi}^i_k\rangle$ constitute an orthonormal set in $\tilde{\mathfrak{H}}$, that is,

$$\langle\boldsymbol{\Psi}^i_k|\boldsymbol{\Psi}^j_\ell\rangle_{\tilde{\mathfrak{H}}} = \delta_{k\ell}\,\delta_{ij}$$

Denote by $\mathfrak{H}_K$ the Hilbert subspace of $\tilde{\mathfrak{H}}$ generated by this set of vectors. This can be shown to be a reproducing kernel Hilbert space of analytic

functions in the variable $\mathfrak{z}^\dagger$, with the matrix valued kernel $K : \Omega \times \Omega \longmapsto C^{2\times 2}$:

$$K(\mathfrak{z}'^\dagger, \mathfrak{z}) = \sum_{i=1}^{2}\sum_{k=0}^{\infty} \mathbf{\Psi}^i_k(\mathfrak{z}'^\dagger)\mathbf{\Psi}^i_k(\mathfrak{z}^\dagger)^\dagger = \sum_{i=1}^{2}\sum_{k=0}^{\infty} \frac{\mathfrak{z}'^{\dagger k}\mathfrak{z}^k}{b(k)} \quad [54]$$

Vector coherent states in $\mathfrak{H}_K$ are then naturally associated to this kernel and are given by

$$|\mathfrak{z}, i\rangle = \sum_{j=1}^{2}\sum_{k=0}^{\infty} \frac{\chi^{j\dagger}\mathfrak{z}^k\chi^i}{\sqrt{b(k)}}|\mathbf{\Psi}^j_k\rangle$$
$$\text{that is,}\ \ |\mathfrak{z}, i\rangle(\mathfrak{z}'^\dagger) = K(\mathfrak{z}'^\dagger, \mathfrak{z})\chi^i \quad [55]$$

for $i = 1, 2$ and all $\mathfrak{z}$ in $\Omega$. They satisfy the resolution of the identity

$$\sum_{i=1}^{2}\int_\Omega |\mathfrak{z}, i\rangle\langle\mathfrak{z}, i| \mathrm{d}\nu(\mathfrak{z}, \mathfrak{z}^\dagger) = I_{\mathfrak{H}_K} \quad [56]$$

The expression for the $|\mathfrak{z}, i\rangle$ in [55], involving the sum, should be compared to [18], of which it is a direct analog.

## Some Applications of Coherent States

Generalized coherent states have many applications in physics, signal analysis, and mathematics, of which we mention a few here. As an example of an application of deformed coherent states, we take

$$x_n = \left[\frac{q^n - q^{-n}}{q - q^{-1}}\right]^{1/2}, \quad q > 0 \quad [57]$$

in the definition of these states in [18]. It is then easy to see that the operators $A$ and $A^\dagger$, defined in [23], satisfy the $q$-deformed commutation relation

$$AA^\dagger - qA^\dagger A = q^{-N} \quad [58]$$

where $N$ is the usual number operator, which acts on the Fock states as $N|n\rangle = n|n\rangle$. Clearly, in the limit as $q \to 1$, these $q$-deformed coherent states go over to the canonical coherent states, with the operators $A$ and $A^\dagger$ becoming the usual creation and annihilation operators $a$ and $a^\dagger$, respectively. The operators $A$ and $A^\dagger$ and the commutation relation [58] describe a system of $q$-deformed oscillators, which have been used to describe, for example, the vibrations of polyatomic molecules. The potential energy between the atoms of such a molecule has anharmonic terms, leading to a deformation of the usual oscillator algebra, generated by the operators $a$ and $a^\dagger$.

As already mentioned, generalized coherent states are widely used in signal analysis. The wavelet transform $F(b, a) = \langle b, a|\phi\rangle$, introduced in [43], is a time–frequency transform, in which the parameter $b$ is identified with time and $1/a$ with frequency. Wavelet transforms are used extensively to analyze, encode, and reconstruct signals arising in many different branches of physics, engineering, seismography, electronic data processing, etc. Similarly, the canonical coherent states, as written in [11], give rise to the transform $F(q, p) = \langle q, p \mid \phi\rangle$. Again, if $q$ is interpreted as time and $p$ as frequency, then this is just the windowed Fourier transform, also used extensively in signal processing. More general wavelets, from higher-dimensional affine groups, are used to analyze higher-dimensional signals, while wavelet like transforms from other groups have been used to study signals exhibiting different geometries. In particular, wavelet transforms from spherical geometries have been applied to the study of brain signals and to astrophysical data.

Our final example is taken from quantization theory. A quantization technique is a method for performing the transition from a given classical mechanical system to its quantum counterpart. Many methods have been developed to accomplish this and the use of coherent states is one of them. Suppose that we are given a family of coherent states $|x\rangle$ in a Hilbert space $\mathfrak{H}$, where the set $X$ from which $x$ is taken is a classical phase space. This means that $X$ is a symplectic manifold with an associated 2-form $\omega$, which defines a Poisson bracket on the set of observables of the classical system, which are real-valued functions on $X$. There is a natural measure $\mathrm{d}\omega$, defined on $X$ by the 2-form $\omega$. Let us assume that the coherent states $|x\rangle$ satisfy a resolution on the identity with respect to this measure:

$$\int_X |x\rangle\langle x| \mathrm{d}\omega(x) = I_{\mathfrak{H}}$$

In this case, the coherent states may be used to quantize the observables of the classical system in the following way: let $f$ be a real-valued function on $X$, representing a classical observable and suppose that the formal operator

$$\widehat{f} = \int_X f(x)|x\rangle\langle x| \mathrm{d}\omega(x) \quad [59]$$

is well defined as a self-adjoint operator on $\mathfrak{H}$. Then we may take the operator $\widehat{f}$ to be the quantized observable corresponding to the classical observable $f$. Suppose that we have two such operators, $\widehat{f}$ and $\widehat{g}$,

corresponding to the two classical observables $f$ and $g$, which have the Poisson bracket $\{f, g\}$, defined via the 2-form $\omega$. We then check if the quantization condition

$$\widehat{\{f, g\}} = \frac{2\pi}{\mathrm{i}h}[\widehat{f}, \widehat{g}] \qquad [60]$$

where $h$ is Planck's constant, is satisfied. Generally this will be the case for a certain number of classical observables. This method of quantization has been most successfully used for manifolds $X$ which have a (complex) Kähler structure. Over such a manifold, one can define a Hilbert space of analytic functions, which has a reproducing kernel and hence a naturally associated set of coherent states. As a specific example, we take the case of canonical coherent states [11]. We can identify the complex plane $\mathbb{C}$ with the phase space $\mathbb{R}^2$ of a free classical particle having a single degree of freedom. The measure $\mathrm{d}\omega$ in this case is just $(1/2\pi)\mathrm{d}q\,\mathrm{d}p$. If we now quantize the classical observables $f(q,p) = q$ and $f(q,p) = p$, of position and momentum, respectively, using the canonical coherent states, we obtain the two operators

$$\begin{aligned} Q &= \int_{\mathbb{R}^2} q|q,p\rangle\langle q,p| \frac{\mathrm{d}q\,\mathrm{d}p}{2\pi} \\ P &= \int_{\mathbb{R}^2} p|q,p\rangle\langle q,p| \frac{\mathrm{d}q\,\mathrm{d}p}{2\pi} \end{aligned} \qquad [61]$$

It can be verified that these two operators satisfy the canonical commutation relations $[Q, P] = \mathrm{i}I_{\mathfrak{H}}$, as required.

# Cohomology Theories

**U Tillmann**, University of Oxford, Oxford, UK

## Introduction

The origins of cohomology theory are found in topology and algebra at the beginning of the last century but since then it has become a tool of nearly every branch of mathematics. It's a way of life! Naturally, this article can only give a glimpse at the rich subject. We take here the point of view of algebraic topology and discuss only the cohomology of spaces.

Cohomology reflects the global properties of a manifold, or more generally of a topological space. It has two crucial properties: it only depends on the homotopy type of the space and is determined by local data. The latter property makes it in general computable.

To illustrate the interplay between the local and global structure, consider the Euler characteristic of a compact manifold; as will be explained below, cohomology is a refinement of the Euler characteristic. For simplicity, assume that the manifold $M$ is a surface and that we have chosen a way of dividing the surface into triangles. The Euler characteristic is then defined to be

$$\chi(M) = F - E + V$$

where $F$ denotes the number of faces, $E$ the number of edges, and $V$ the number of vertices in the triangulation. Remarkably, this number does not depend on the triangulation. Yet, this simple, easy to compute number can already distinguish the different types of closed, oriented surfaces: for the sphere we have $\chi = 2$, the torus $\chi = 0$, and in general for any surface $M_g$ of genus $g$

$$\chi(M_g) = 2 - 2g$$

The Euler characteristic also tells us something about the geometry and analysis of the manifold. For example, the total curvature of a surface is equal to its Euler characteristic. This is the Gauss–Bonnet theorem and an analogous result holds in higher dimensions. Another striking result is the Poincaré–Hopf theorem which equates the Euler characteristic with the total index of a vector field and thus gives strong restrictions on what kind of vector fields can exist on a manifold. This interplay between global analysis and topology has been one of the most exciting and fruitful research areas and is most powerfully expressed in the celebrated Atiyah–Singer index theorem, which determines the analytic index of an elliptic operator, such as the Dirac operator on a spin manifold, in terms of cohomology classes.

## Chain Complexes and Homology

There are several different geometric definitions of the cohomology of a topological space. All share some basic algebraic structure which we will explain first.

A "chain complex" $(C_*, \partial_*)$

$$\cdots C_{i+1} \xrightarrow{\partial_{i+1}} C_i \xrightarrow{\partial_i} C_{i-1} \cdots \xrightarrow{\partial_1} C_0 \qquad [1]$$

is a collection of vector spaces (or $R$-modules more generally) $C_i, i \geq 0$, and linear maps ($R$-module maps) $\partial_i : C_i \to C_{i-1}$ with the property that for all $i$

$$\partial_i \circ \partial_{i+1} = 0 \qquad [2]$$

The scalar fields one tends to consider are the rationals $\mathbb{Q}$, reals $\mathbb{R}$, complex numbers $\mathbb{C}$, or a primary field $\mathbb{Z}_{\mathrm{p}}$, while the most important ring $R$ is the ring of integers $\mathbb{Z}$ though we will also consider localizations such as $\mathbb{Z}[1/p]$, which has the effect of suppressing any $p$-primary torsion information.

Of particular interest are the elements in $C_i$ that are mapped to zero by $\partial_i$, the $i$-dimensional "cycles," and those that are in the image of $\partial_{i+1}$, the $i$-dimensional "boundaries." Because of [2], every boundary is a cycle, and we may define the quotient vector space ($R$-module), the $i$th-dimensional homology,

$$H_i(C_*; \partial_*) := \frac{\ker \partial_i}{\mathrm{im} \partial_{i+1}} \qquad [3]$$

$(C_*, \partial_*)$ is "exact" if all its cycles are boundaries. Homology thus measures to what extent the sequence [1] fails to be exact.

### Simplicial Homology

A triangulation of a surface gives rise to its "simplicial" chain complex: Taking coefficients in $\mathbb{Z}, \mathbb{C}_2, \mathbb{C}_1, \mathbb{C}_0$ are the free abelian groups generated by the set of faces, edges, and vertices, respectively; $C_i = \{0\}$ for $i \geq 3$. The map $\partial_2$ assigns to a triangle the sum of its edges; $\partial_1$ maps an edge to the sum of its endpoints. If we are working with $\mathbb{Z}_2$ coefficients, this defines for us a chain complex as [2] is clearly satisfied; in general, one needs to keep track of the orientations of the triangles and edges and take sums with appropriate signs (cf. [6] below). An easy calculation shows that for an oriented, closed surface $M_g$ of genus $g$, we have

$$\begin{aligned} H_0(M_g, \mathbb{Z}) &= \mathbb{Z} \\ H_1(M_g; \mathbb{Z}) &= \mathbb{Z}^{2g} \\ H_2(M_g; \mathbb{Z}) &= \mathbb{Z} \\ H_i(M_g; \mathbb{Z}) &= 0 \quad \text{for } i \geq 3 \end{aligned} \qquad [4]$$

Note that the Euler characteristic can be recovered as the alternating sum of the rank of the homology groups:

$$\chi(M) = \sum_{i=0}^{\dim M} (-1)^i \operatorname{rk} H_i(M; \mathbb{Z}) \qquad [5]$$

Every smooth manifold $M$ has a triangulation, so that its simplicial homology can be defined just as above. More generally, simplicial homology can be defined for any simplicial space, that is, a space that is built up out of points, edges, triangles, tetrahedra, etc. Formula [5] remains valid for any compact manifold or simplicial space.

### Singular Homology

Let $X$ be any topological space, and let $\triangle^n$ be the oriented $n$-simplex $[v_0, \ldots, v_n]$ spanned by the standard basis vectors $v_i$ in $\mathbb{R}^{n+1}$. The set of singular $n$-chains $S_n(X)$ is the free abelian group on the set of continuous maps $\sigma : \triangle^n \longrightarrow X$. The boundary of $\sigma$ is defined by the alternating sum of the restriction of $\sigma$ to the faces of $\triangle^n$:

$$\partial_n(\sigma) := \sum_{i=0}^{n} (-1)^{-i} \sigma|_{[v_0, \ldots, \hat{v}_i, \ldots, v_n]} \qquad [6]$$

One easily checks that the boundary of a boundary is zero, and hence $(S_*(X), \partial_*)$ defines a chain complex. Its homology is by definition the singular homology $H_*(X; \mathbb{Z})$ of $X$. For any simplicial space, the inclusion of the simplicial chains into the singular chains induces an isomorphism of homology groups. In particular, this implies that the simplicial homology of a manifold, and hence its Euler characteristic do not depend on its triangulation.

If in the definition of simplicial and singular homology we take free $R$-modules (where $R$ may

also be a field) instead of free abelian groups, we get the homology $H_*(X;R)$ of $X$ with coefficients in $R$. The "universal-coefficient theorem" describes the homology with arbitrary coefficients in terms of the homology with integer coefficients. In particular, if $R$ is a field of characteristic zero,

$$\dim H_n(X;R) = \operatorname{rk} H_n(X;\mathbb{Z})$$

### Basic Properties of Singular Homology

While simplicial homology (and the more efficient cellular homology which we will not discuss) is easier to compute and easier to understand geometrically, singular homology lends itself more easily to theoretical treatment.

1. *Homotopy invariance*. Any continuous map $f:X\to Y$ induces a map on homology $f_*:H_*(X;R)\to H_*(Y;R)$ which only depends on the homotopy class of $f$.

In particular, a homotopy equivalence $f:X\to Y$ induces an isomorphism in homology. So, for example, the inclusion of the circle $S^1$ into the punctured plane $\mathbb{C}\backslash\{0\}$ is a homotopy equivalence, and thus

$$\begin{aligned} H_i(\mathbb{C}\backslash\{0\};R) &\simeq H_i(S^1;R) \\ &= \begin{cases} \mathbb{Z} & \text{for } i=0,1 \\ 0 & \text{for } i\geq 2 \end{cases} \end{aligned}$$

For the one point space we have $H_0(\text{pt};R)=R$. Define reduced homology by $\tilde{H}_*(X;R):=\ker(H_*(X;R)\to H_*(\text{pt};R))$.

2. *Dimension axiom*. $\tilde{H}_i(\text{pt};R)=0$ for all $i$.

More generally, it follows immediately from the definition of simplicial homology that the homology of any $n$-dimensional manifold is zero in dimensions larger than $n$.

We mentioned in the introduction that homology depends only on local data. This is made precise by the

3. *Mayer–Vietoris theorem. Let $X=A\cup B$ be the union of two open subspaces. Then the following sequence is exact*:

$$\begin{aligned} \cdots \longrightarrow H_n(A\cap B;R) &\longrightarrow H_n(A;R)\oplus H_n(B;R) \\ &\longrightarrow H_n(X;R) \xrightarrow{\partial} H_{n-1}(A\cap B;R) \\ &\longrightarrow \cdots \longrightarrow H_0(X;R)\to 0 \end{aligned}$$

On the level of chains, the first map is induced by the diagonal inclusion, while the second map takes the difference between the first and second summands. Finally, $\partial$ takes a cycle $c=a+b$ in the chains of $X$ that can be expressed as the sum of a chain $a$ in $A$ and $b$ in $B$ to $\partial c:=\partial_n a=-\partial_n b$. For example, consider two cones, $A$ and $B$, on a space $X$ and identify them at the base $X$ to define the suspension $\Sigma X$ of $X$. Then $\Sigma X=A\cup B$ with $A,B\simeq \text{pt}$ and $A\cap B\simeq X$. The boundary map $\partial$ is then an isomorphism:

$$\tilde{H}_n(X;R)\simeq H_{n+1}(\Sigma X;R) \quad \text{for all } n\geq 0 \qquad [7]$$

From this one can easily compute the homology of a sphere. First note that

$$\tilde{H}_0(X;\mathbb{Z})=\mathbb{Z}^{k-1}$$

where $k$ is the number of connected components in $X$. Also, $S^n\simeq \Sigma S^{n-1}\simeq\cdots\simeq\Sigma^n S^0$. Thus, by [7],

$$H_n(S^n;\mathbb{Z})\simeq\mathbb{Z} \quad \text{and} \quad \tilde{H}_*(S^n;\mathbb{Z})=0 \quad \text{for } *\neq n \qquad [8]$$

If $Y$ is a subspace of $X$, relative homology groups $H_*(X,Y;R)$ can be defined as the homology of the quotient complex $S_*(X)/S_*(Y)$. When $Y$ has a good neighborhood in $X$ (i.e., it is a neighborhood deformation retract in $X$), then, by the "excision theorem,"

$$H_*(X,Y;R)\simeq\tilde{H}_*(X/Y;R)$$

where $X/Y$ denotes the quotient space of $X$ with $Y$ identified to a point. There is a long exact sequence

$$\begin{aligned} \cdots\longrightarrow H_n(Y;R)\longrightarrow H_n(X;R)\longrightarrow H_n(X,Y;R) \\ \xrightarrow{\partial} H_{n-1}(Y;R)\longrightarrow\cdots\longrightarrow H_0(X,Y;R)\longrightarrow 0 \end{aligned}$$

This and the Mayer–Vietoris sequence give two ways of breaking up the problem of computing the homology of a space into computing the homology of related spaces. An iteration of this process leads to the powerful tool of spectral sequences (*see* Spectral Sequences).

### Relation to Homotopy Groups

Let $\pi_1(X,x_0)$ denote the fundamental group of $X$ relative to the base point $x_0$. These are the based homotopy classes of based maps from a circle to $X$.

$$\text{If } X \text{ is connected, then } H_1(X;\mathbb{Z}) \text{ is the abelianization of } \pi_1(X,x_0) \qquad [9]$$

Indeed, every map from a (triangulated) sphere to $X$ defines a cycle and hence gives rise to a homology class. This defines the Hurewicz map $h:\pi_*(X;x_0)\to H_*(X;\mathbb{Z})$. In general there is no good description of its image. However, if $X$ is $k$-connected with $k\geq 1$, then $h$ induces an isomorphism in dimension $k+1$ and an epimorphism in dimension $k+2$.

Though [9] indicates that homology cannot distinguish between all homotopy types, the fundamental group is in a sense the only obstruction to this. A simple form of the "Whitehead theorem" states:

**Theorem** *If a map $f: X \to Y$ between two simplicial complexes with trivial fundamental groups induces an isomorphism on all homology groups, then it is a homotopy equivalence.*

*Warning*: This does not imply that two simply connected spaces with isomorphic homology groups are homotopic! The existence of the map $f$ inducing this isomorphism is crucial and counterexamples can easily be constructed.

## Dual Chain Complexes and Cohomology

The process of dualizing itself cannot be expected to yield any new information. Nevertheless, the cohomology of a space, which is obtained by dualizing its simplicial chain complex, carries important additional structure: it possesses a product, and moreover, when the coefficients are a primary field, it is an algebra over the rich Steenrod algebra. As with homology we start with the algebraic setup.

Every chain complex $(C_*, \partial_*)$ gives rise to a dual chain complex $(C^*, \partial^*)$ where $C^i = \hom_R(C_i, R)$ is the dual $R$-module of $C_i$; because of [2], the composition of two dual boundary morphisms $\partial^{i+1}: C^i \to C^{i+1}$ is trivial. Hence we may define the $i$th dimensional cohomology group as

$$H^i(C^*, \partial^*) := \frac{\ker \partial^{i+1}}{\operatorname{im} \partial^i} \qquad [10]$$

Evaluation $(\sigma, \phi) \mapsto \phi(\sigma)$ descends to a dual pairing

$$H_n(C_*, \partial_*) \otimes_R H^n(C^*, \partial^*) \longrightarrow R$$

and when $R$ is a field, this identifies the cohomology groups as the duals of the homology groups. More generally, the universal-coefficient theorem relates the two. A simple version states: let $(C_*, \partial_*)$ be a chain complex of free abelian groups (such as the simplicial or singular chain complexes) with finitely generated homology groups. Then,

$$H^i(C^*, \partial^*) \simeq H_i^{\text{free}}(C_*, \partial_*) \oplus H_{i-1}^{\text{tor}}(C_*, \partial) \qquad [11]$$

where $H_*^{\text{tor}}$ denotes the torsion subgroup of $H_*$ and $H_*^{\text{free}}$ denotes the quotient group $H_*/H_*^{\text{tor}}$.

### Singular Cohomology

The dual $S^*(X)$ of the singular chain complex of a space $X$ carries a natural pairing, the cup product, $\cup: S^p(X) \otimes S^q(X) \to S^{p+q}(X)$ defined by

$$(\phi_1 \cup \phi_2)(\sigma) := \phi_1(\sigma|_{[v_0, \ldots, v_p]})\phi_2(\sigma|_{[v_p, \ldots, v_{p+q}]})$$

This descends to a multiplication on cohomology groups and makes $H^*(X; R) := \bigoplus_{n \geq 0} H^n(X; R)$ into an associative, graded commutative ring: $u \cup v = (-1)^{\deg u \deg v} v \cup u$.

The "Künneth theorem" gives some geometric intuition for the cup product. A simple version states: for spaces $X$ and $Y$ with $H^*(Y; R)$ a finitely generated free $R$-module, the cup product defines an isomorphism of graded rings

$$H^*(X; R) \otimes_R H^*(Y; R) \longrightarrow H^*(X \times Y; R)$$

For example, for a sphere, all products are trivial for dimension reasons. Hence,

$$H^*(S^n; \mathbb{Z}) = \bigwedge\nolimits^*(x) \qquad [12]$$

is an exterior algebra on one generator $x$ of degree $n$. On the other hand, the cohomology of the $n$-dimensional torus $T^n$ is an exterior algebra on $n$ degree-1 generators,

$$H^*(T^n; \mathbb{Z}) = \bigwedge\nolimits^*(x_1, \ldots, x_n) \qquad [13]$$

The dual pairing can be generalized to the slant or cap product

$$\cap : H_n(X; R) \otimes_R H^i(X; R) \longrightarrow H_{n-i}(X; R)$$

defined on the chain level by the formula $(\sigma, \phi) \mapsto \phi(\sigma|_{[v_0, \ldots, v_i]})\sigma|_{[v_i, \ldots, v_n]}$.

### Steenrod Algebra

The cup product on the chain level is homotopy commutative, but not commutative. Steenrod used this defect to define operations

$$Sq^i : H^n(X; \mathbb{Z}_2) \longrightarrow H^{n+i}(X; \mathbb{Z}_2)$$

for all $i \geq 0$ which refine the cup-squaring operation: when $n = i$, then $Sq^n(x) = x \cup x$. These are natural group homomorphisms which commute with suspension. Furthermore, they satisfy the Cartan and Adem Relations

$$Sq^n(x \cup y) = \sum_{i+j=n} Sq^i(x) \cup Sq^j(y)$$

$$Sq^i Sq^j = \sum_{k=0}^{[i/2]} \binom{j-k-1}{i-2k} Sq^{i+j-k} Sq^k$$

for $i \leq 2j$

The mod-2 Steenrod algebra $\mathcal{A}$ is then the free $\mathbb{Z}_2$-algebra generated by the Steenrod squares $Sq^i, i \geq 0$, subject only to the Adem relations. With the help of Adem's relations, Serre and Cartan found a $\mathbb{Z}_2$-basis for $\mathcal{A}$:

$$\{Sq^I := Sq^{i_1} \cdots Sq^{i_n} | i_j \geq 2i_{j+1} \quad \text{for all } j\}$$

The Steenrod algebra is also a Hopf algebra with a commutative comultiplication $\Delta : \mathcal{A} \to \mathcal{A} \otimes \mathcal{A}$ induced by

$$\Delta(Sq^n) := \sum_{i+j=n} Sq^i \otimes Sq^j$$

The Cartan relation implies that the mod-2 cohomology of a space is compatible with the comultiplication, that is, $H^*(X; \mathbb{Z}_2)$ is an algebra over the Hopf algebra $\mathcal{A}$. There are odd primary analogs of the Steenrod algebra based on the reduced $p$th power operations

$$P^i : H^n(X; \mathbb{Z}_p) \to H^{n+2i(p-1)}(X; \mathbb{Z}_p)$$

with similar properties to $\mathcal{A}$.

One of the most striking applications of the Steenrod algebra can be found in the work of Adams on the "vector fields on spheres problem": for each $n$, find the greatest number $k$, denoted $K(n)$, such that there is a $k$-field on the $(n-1)$-sphere $S^{n-1}$. Recall that a $k$-field is an ordered set of $k$ pointwise linear independent tangent vector fields. If we write $n$ in the form $n = 2^{4a+b}(2s+1)$ with $0 \le b < 4$, Adams proved that $K(n) = 2^b + 8a - 1$. In particular, when $n$ is odd, $K(n) = 0$. We give an outline of the proof for this special case in the next section.

- The failure of associativity of the cup product at the chain level gives rise to secondary operations, the so-called "Massey products."

## Cohomology of Smooth Manifolds

A smooth manifold $M$ of dimension $n$ can be triangulated by smooth simplices $\sigma : \Delta^n \to M$. If $M$ is compact, oriented, without boundary, the sum of these simplices define a homology cycle $[M]$, the fundamental class of $M$. The most remarkable property of the cohomology of manifolds is that they satisfy "Poincaré duality": taking cap product with $[M]$ defines an isomorphism:

$$D := [M] \cap : H^k(M; \mathbb{Z}) \xrightarrow{\simeq} H_{n-k}(M; \mathbb{Z}) \quad \text{for all } k \qquad [14]$$

In particular, for connected manifolds, $H^n(M; \mathbb{Z}) \simeq \mathbb{Z}$; and every map $f : M' \to M$ between oriented, compact closed manifolds of the same dimension has a degree: $f^* : H^*(M; \mathbb{Z}) \to H^*(M'; \mathbb{Z})$ is multiplication by an integer $\deg(f)$, the degree of $f$. For smooth maps, the degree is the number of points in the inverse image of a generic point $p \in M$ counted with signs:

$$\deg(f) = \sum_{p' \in f^{-1}(p)} \text{sign}(p')$$

where $\text{sign}(p')$ is +1 or –1 depending on whether $f$ is orientation preserving or reversing in a neighborhood of $p'$. For example, a complex polynomial of degree $d$ defines a map of the two-dimensional sphere to itself of degree $d$: a generic point has $n$ points in its inverse image and the map is locally orientation preserving. On the other hand, a map of $S^{n-1}$ induced by a reflection of $\mathbb{R}^n$ reverses orientation and has degree –1. Thus, as degrees multiply on composing maps, the antipodal map $x \mapsto -x$ has degree $(-1)^n$. As an application we prove:

*Every tangent vector field on an even-dimensional sphere $S^{n-1}$ has a zero.*

**Proof** Assume $v(x)$ is a vector field which is nonzero for all $x \in S^{n-1}$. Then $x$ is perpendicular to $v(x)$, and after rescaling, we may assume that $v(x)$ has length 1. The function $F(x,t) = \cos(t)x + \sin(t)\, v(x)$ is a well-defined homotopy from the identity map $(t=0)$ to the antipodal map $(t=\pi)$. But this is impossible as homotopic maps induce the same map in (co)homology and we have already seen that the degree of the identity map is 1 while the degree of the antipodal map is $(-1)^n = -1$ when $n$ is odd.

- It is well known that two self-maps of a sphere of any dimension are homotopic if and only if they have the same degree, that is, $\pi_n(S^n) \simeq \mathbb{Z}$ for $n \ge 1$.
- When $M$ is not orientable, $[M]$ still defines a cycle in homology with $\mathbb{Z}_2$-coefficients, and $[M]\cap$ defines an isomorphism between the cohomology and homology with $\mathbb{Z}_2$ coefficients.
- As $[M]$ represents a homology class, so does every other closed (orientable) submanifold of $M$. It is however not the case that every homology class can be represented by a submanifold or linear combinations of such.

Cohomology is a contravariant functor. Poincaré duality however allows us to define, for any $f : M' \to M$ between oriented, compact, closed manifolds of arbitrary dimensions, a "transfer" or "Umkehr map,"

$$f^! := D^{-1} f_* D' : H^*(M'; \mathbb{Z}) \to H^{*-c}(M; \mathbb{Z})$$

which lowers the degree by $c = \dim M' - \dim M$. It satisfies the formula

$$f^!(f^*(x) \cup y) = x \cup f^!(y)$$

for all $x \in H^*(M; \mathbb{Z})$ and $y \in H^*(M'; \mathbb{Z})$. When $f$ is a covering map then $f^!$ can be defined on the chain level by

$$f^!(x)(\sigma) := x\Big(\sum_{f(\tilde{\sigma})=\sigma} \tilde{\sigma}\Big)$$

where $x \in C^*(M')$ and $\sigma \in C_*(M)$.

### de Rham Cohomology

If $x_1, \dots, x_n$ are the local coordinates of $\mathbb{R}^n$, define an algebra $\Omega^*$ to be the algebra generated by symbols $dx_1, \dots, dx_n$ subject to the relations $dx_i dx_j = -dx_j dx_i$ for all $i, j$. We say $dx_{i_1} \cdots dx_{i_q}$ has degree $q$. The differential forms on $\mathbb{R}^n$ are the algebra

$$\Omega^*(\mathbb{R}^n) := \{C^\infty \text{functions on } \mathbb{R}^n\} \otimes_{\mathbb{R}} \Omega^*$$

The algebra $\Omega^*(\mathbb{R}^n) = \bigoplus_{q=0}^n \Omega^q(\mathbb{R}^n)$ is naturally graded by degree. There is a differential operator $d : \Omega^q(\mathbb{R}^n) \to \Omega^{q+1}(\mathbb{R}^n)$ defined by

1. if $f \in \Omega^0(\mathbb{R}^n)$, then $df = \sum (\partial f / \partial x_i) dx_i$
2. if $\omega = \sum f_I dx_I$, then $d\omega = \sum df_I dx_I$

$I$ stands here for a multi-index. For example, in $\mathbb{R}^3$ the differential assigns to 0-forms ( = functions) the gradient, to 1-forms the curl, and to 2-forms the divergence. An easy exercise shows that $d^2 = 0$ and the $q$th de Rham cohomology of $\mathbb{R}^n$ is the vector space

$$H^q_{\text{de R}}(\mathbb{R}^n) = \frac{\ker d : \Omega^q(\mathbb{R}^n) \to \Omega^{q+1}(\mathbb{R}^n)}{\text{im } d : \Omega^{q-1}(\mathbb{R}^n) \to \Omega^q(\mathbb{R}^n)}$$

More generally, the de Rham complex $\Omega^*(M)$ and its cohomology $H^*_{\text{de R}}(M)$ can be defined for any smooth manifold $M$.

Let $\sigma$ be a smooth, singular, real $(q+1)$-chain on $M$, and let $\omega \in \Omega^q(M)$. Stokes theorem then says

$$\int_{\partial\sigma} \omega = \int_\sigma d\omega$$

and therefore integration defines a pairing between the $q$th singular homology and the $q$th de Rahm cohomology of $M$. This pairing is exact and thus de Rahm cohomology is isomorphic to singular cohomology with real coefficients:

$$H^*_{\text{de R}}(M) \simeq (H_*(M; \mathbb{R}))^* \simeq H^*(M; \mathbb{R})$$

Let $\Omega^*_c(M)$ denote the subcomplex of compactly supported forms and $H^*_c(M)$ its cohomology. Integration with respect to the first $i$ coordinates defines a map

$$\Omega^*_c(\mathbb{R}^n) \to \Omega^{*-i}_c(\mathbb{R}^{n-i})$$

which induces an isomorphism in cohomology; note in particular $H^n_c(\mathbb{R}^n) = \mathbb{R}$. More generally, when $E \to M$ is an $i$-dimensional orientable, real vector bundle over a compact, orientable manifold $M$, integration over the fiber gives the "Thom isomorphism":

$$H^*_c(E) \simeq H^{*-i}_c(M) \simeq H^{*-i}_{\text{de R}}(M)$$

For orientable fiber bundles $F \to M' \xrightarrow{f} M$ with compact, orientable fiber $F$, integration over the fiber provides another definition of the transfer map

$$f^! : H^*_{\text{de R}}(M') \to H^{*-i}_{\text{de R}}(M)$$

### Hodge Decomposition

Let $M$ be a compact oriented Riemannian manifold of dimension $n$. The Hodge star operator, $*$, associates to every $q$-form an $(n-q)$-form. For $\mathbb{R}^n$ and any orthonormal basis $\{e_1, \dots, e_n\}$, it is defined by setting

$$*(e_1 \wedge \cdots \wedge e_q) := \pm e_{p+1} \wedge \cdots \wedge e_n$$

where one takes $+$ if the orientation defined by $\{e_1, \dots, e_n\}$ is the same as the given one, and $-$ otherwise. Using local coordinate charts this definition can be extended to $M$. Clearly, $*$ depends on the chosen metric and orientation of $M$. If $M$ is compact, we may define an inner product on the $q$-forms by

$$(\omega, \omega') := \int_M \omega \wedge *\omega'$$

With respect to this inner product $*$ is an isometry. Define the codifferential via

$$\delta := (-1)^{np+n+1} * d* : \Omega^q(M) \to \Omega^{q-1}(M)$$

and the Laplace–Beltrami operator via

$$\Delta := \delta d + d\delta$$

The codifferential satisfies $\delta^2 = 0$ and is the adjoint of the differential. Indeed, for $q$-forms $\omega$ and $(q+1)$-forms $\omega'$:

$$(d\omega, \omega') = (\omega, \delta\omega') \qquad [15]$$

It follows easily that $\Delta$ is self-adjoint, and furthermore,

$$\Delta\omega = 0 \quad \text{if and only if} \quad d\omega = 0 \text{ and } \delta\omega = 0 \qquad [16]$$

A form $\omega$ satisfying $\Delta\omega = 0$ is called "harmonic." Let $\mathcal{H}^q$ denote the subspace of all harmonic $q$-forms. It is not hard to prove the "Hodge decomposition theorem":

$$\Omega^q = \mathcal{H}^q \oplus \text{im}\, d \oplus \text{im}\, \delta$$

Furthermore, by adjointness [15], a form $\omega$ is closed only if it is orthogonal to $\text{im}\,\delta$. On calculating the de Rham cohomology we can also ignore the summand $\text{im}\, d$ and find that:

*Each de Rham cohomology class on a compact oriented Riemannian manifold M contains a unique harmonic representative, that is,* $H^q_{\text{de R}}(M) \simeq \mathcal{H}^q$.

*Warning*: This is an isomorphism of vector spaces and in general does not extend to an isomorphism of algebras.

## Examples

We list the cohomology of some important examples.

#### Projective Spaces

Let $\mathbb{R}P^n$ be real projective space of dimension $n$. Then,

$$H^*(\mathbb{R}P^n;\mathbb{Z}_2)=\mathbb{Z}_2[x]/(x^{n+1})$$

is a stunted polynomial ring on a generator $x$ of degree 1.

Similarly, let $\mathbb{C}P^n$ and $\mathbb{H}P^n$ denote complex and quaternionic projective space of real dimensions $2n$ and $4n$, respectively. Then,

$$H^*(\mathbb{C}P^n;\mathbb{Z})=\mathbb{Z}[y]/(y^{n+1})$$
$$H^*(\mathbb{H}P^n;\mathbb{Z})=\mathbb{Z}[z]/(z^{n+1})$$

are stunted polynomial rings with $\deg(y)=2$ and $\deg(z)=4$.

#### Lie Groups

Let $G$ be a compact, connected Lie group of rank $l$, that is, the dimension of the maximal torus of $G$ is $l$. Then,

$$H^*(G,\mathbb{Q})\simeq \bigwedge_{\mathbb{Q}}^{*}[a_{2d_1-1},a_{2d_2-1},\ldots,a_{2d_l-1}]$$

where $|a_i|=i$ and $d_1,\ldots,d_l$ are the fundamental degrees of $G$ which are known for all $G$. Often this structure lifts to the integral cohomology. In particular we have:

$$H^*_{\text{free}}(SO(2k+1);\mathbb{Z}))\simeq \bigwedge_{\mathbb{Z}}^{*}[a_3,a_7,\ldots,a_{4k-1}]$$
$$H^*_{\text{free}}(SO(2k);\mathbb{Z}))\simeq \bigwedge_{\mathbb{Z}}^{*}[a_1,a_7,\ldots,a_{4k-5},a_{2k-1}]$$
$$H^*(U(k);\mathbb{Z})\simeq \bigwedge_{\mathbb{Z}}^{*}[a_1,a_3,\ldots,a_{2k-1}]$$

#### Classifying Spaces

For any group $G$ there exists a classifying space $BG$, well defined up to homotopy. Classifying spaces are of central interest to geometers and topologists for the set of isomorphism classes of principal $G$-bundles over a space $X$ is in one-to-one correspondence with the set of homotopy classes of maps from $X$ to $BG$. In particular, every cohomology class $c\in H^*(BG;R)$ defines a characteristic class of principle $G$-bundles $E$ over $X$: if $E$ corresponds to the map $f_E:X\to BG$, then $c(E):=f_E^*(c)$.

$BG$ can be constructed as the space of $G$-orbits of a contractible space $EG$ on which $G$ acts freely. Thus, for example,

$$B\mathbb{Z}=\mathbb{R}/\mathbb{Z}\simeq S^1$$
$$B\mathbb{Z}_2=(\lim_{n\to\infty}S^n)/\mathbb{Z}_2\simeq\mathbb{R}P^\infty$$
$$BS^1=(\lim_{n\to\infty}S^{2n+1})/S^1\simeq\mathbb{C}P^\infty$$

and more generally, infinite Grassmannian manifolds are classifying spaces for linear groups. When $G$ is a compact connected Lie group,

$$H^*(BG;\mathbb{Q})\simeq\mathbb{Q}[x_{2d_1},\ldots,x_{2d_l}]$$

with $d_i$ as above and $|x_i|=i$. In particular,

$$H^*(BSO(2k+1);\mathbb{Z}[1/2])\simeq\mathbb{Z}[1/2][p_1,p_2,\ldots,p_k]$$
$$H^*(BSO(2k);\mathbb{Z}[1/2])\simeq\mathbb{Z}[1/2][p_1,p_2,\ldots,p_{k-1},e_k]$$
$$H^*(BU(k);\mathbb{Z})\simeq\mathbb{Z}[c_1,c_2,\ldots,c_k]$$

where the Pontryagin, Euler, and Chern classes have degree $|p_i|=4i$, $|e_k|=2k$, and $|c_i|=2i$, respectively.

#### Moduli Spaces

Let $\mathcal{M}_g^n$ be the space of Riemann surfaces of genus $g$ with $n$ ordered, marked points. There are naturally defined classes $\kappa_i$ and $e_1,\ldots,e_n$ of degree $2i$ and 2, respectively. By Harer–Ivanov stability and the recent proof of the Mumford conjecture (Madsen–Weiss, preprint 2004), there is an isomorphism up to degree $*<3g/2$ of the rational cohomology of $\mathcal{M}_g^n$ with

$$\mathbb{Q}[\kappa_1,\kappa_2,\ldots]\otimes\mathbb{Q}[e_1,\ldots,e_n]$$

The rational cohomology vanishes in degrees $*>4g-5$ if $n=0$, and $*>4g-4+n$ if $n>0$. Though the stable part of the cohomology is now well understood, the structure of the unstable part, as proposed by Faber (Viehweg 1999), remains conjectural.

## Generalized Cohomology Theories

The three basic properties of singular homology appropriately dualized, hold of course also for cohomology. Furthermore, they (essentially) determine (co)homology uniquely as a functor from the category of simplicial spaces and continuous functions to the category of abelian groups. If we drop the dimension axiom (2), we are left with homotopy invariance (1), and the Mayer–Vietoris sequence (3). Abelian group valued functors satisfying (1) and (3) are so called “generalized (co)homology theories.”

$K$-theory and cobordism theory are two well-known examples but there are many more.

### *K*-Theory

The geometric objects representing elements in complex $K$-theory $K^0(X)$ are isomorphism classes of finite dimensional complex vector bundles $E$ over $X$. Vector bundles $E, E'$ can be added to form a new bundle $E \oplus E'$ over $X$, and $K^0(X)$ is just the group completion of the arising monoid. Thus, for example, for the point space we have $K^0(\mathrm{pt}) = \mathbb{Z}$. Tensor product of vector bundles $E \otimes E'$ induces a multiplication on $K$-theory making $K^*(X)$ into a graded commutative ring.

In many ways $K$-theory is easier than cohomology. In particular, the groups are 2-periodic: all even degree groups are isomorphic to the reduced $K$-theory group $\tilde{K}^0(X) := \mathrm{coker}(K^0(\mathrm{pt}) = \mathbb{Z} \to K^0(X))$, and all odd degree groups are isomorphic to $K^{-1}(X) := \tilde{K}^0(\Sigma X)$.

The theory of characteristic classes gives a close relation between the two cohomology theories. The Chern character map, a rational polynomial in the Chern classes, defines

$$\begin{aligned} \mathrm{ch} : K^0(X) \otimes_{\mathbb{Z}} \mathbb{Q} &\to H^{\mathrm{even}}(X; \mathbb{Q}) \\ &:= \bigoplus_{k \geq 0} H^{2k}(X; \mathbb{Q}) \end{aligned}$$

an isomorphism of rings. Thus, the $K$-theory and cohomology of a space carry the same rational information. But they may have different torsion parts. This became an issue in string theory when D-brane charges which had formerly been thought of as differential forms (and hence cohomology classes) were later reinterpreted more naturally as $K$-theory classes by Witten 1998)

- There are real and quaternionic $K$-theory groups which are 8-periodic.

### Cobordism Theory

The geometric objects representing an element in the oriented cobordism group $\Omega^n_{SO}(X)$ are pairs $(M, f)$ where $M$ is a smooth, orientable $n$-dimensional manifold and $f: M \to X$ is a continuous map. Two pairs $(M, f)$ and $(M', f')$ represent the same cobordism class if there exists a pair $(W, F)$ where $W$ is an $(n+1)$-dimensional, smooth, oriented manifold with boundary $\partial W = M \cup -M'$ such that $F: W \to X$ restricts to $f$ and $f'$ on the boundary $\partial W$. Disjoint union and Cartesian product of manifolds define an addition and multiplication so that $\Omega^*_{SO}(X)$ is a graded, commutative ring.

- Similarly, unoriented, complex, or spin cobordism groups can be defined.

### Elliptic Cohomology

Quillen proved that complex cobordism theory is universal for all complex oriented cohomology theories, that is, those cohomology theories that allow a theory of Chern classes. In a complex oriented theory, the first Chern class of the tensor product of two line bundles can be expressed in terms of the first Chern class of each of them via a two-variable power series: $c_1(E \otimes E') = F(c_1(E), c_1(E'))$. $F$ defines a formal group law and Quillen's theorem asserts that the one arising from complex cobordism theory is the universal one.

Vice versa, given a formal group law, one may try to construct a complex oriented cohomology theory from it. In particular, an elliptic curve gives rise to a formal group law and an elliptic cohomology theory. Hopkins *et al.* have described and studied an inverse limit of these elliptic theories, which they call the theory of topological modular forms, tmf, as the theory is closely related to modular forms. In particular, there is a natural map from the groups $\mathrm{tmf}_{2n}(\mathrm{pt})$ to the group of modular forms of weight $n$ over $\mathbb{Z}$. After inverting a certain element (related to the discriminant), the theory becomes periodic with period $24^2 = 576$.

Witten (1998) showed that the purely theoretically constructed elliptic cohomology theories should play an important role in string theory: the index of the Dirac operator on the free loop space of certain manifolds should be interpreted as an element of it. But unlike for ordinary cohomology, $K$-theory, and cobordism theory we do not (yet) know a good geometric object representing elements in this theory without which its use for geometry and analysis remains limited. Segal speculated some 20 years ago that conformal field theories should define such geometric objects. Though progress has been made, the search for a good geometric interpretation of elliptic cohomology (and tmf) remains an active and important research area.

### Infinite Loop Spaces

Brown's representability theorem implies that for each (reduced) generalized cohomology theory $h^*$ we can find a sequence of spaces $E_*$ such that $h^n(X)$ is the set of homotopy classes $[X, E_n]$ from the space $X$ to $E_n$ for all $n$. Recall that the Mayer–Vietoris sequence implies that $h^n(X) \simeq h^{n+1}(\Sigma X)$. The suspension functor $\Sigma$ is adjoint to the based loop space functor $\Omega$ which takes a space $X$ to the space of based maps from the circle to $X$. Hence,

$$\begin{aligned} h^n(X) &= [X, E_n] = [\Sigma X, E_{n+1}] \\ &= [X, \Omega E_{n+1}] \end{aligned}$$

and it follows that every generalized cohomology theory is represented by an infinite loop space

$$E_0 \simeq \Omega E_1 \simeq \cdots \simeq \Omega^n E_n \simeq \cdots$$

Vice versa, any such infinite loop space gives rise to a generalized cohomology theory.

One may think of infinite loop spaces as the abelian groups up to homotopy in the strongest sense. Indeed, ordinary cohomology with integer coefficients is represented by

$$\mathbb{Z} \simeq \Omega S^1 \simeq \Omega^2 \mathbb{C}P^\infty \simeq \cdots \simeq \Omega^n K(n, \mathbb{Z}) \simeq \cdots$$

where by definition the Eilenberg–MacLane space $K(n, \mathbb{Z})$ has trivial homotopy groups for all dimensions not equal to $n$ and $\pi_n K(n, \mathbb{Z}) = \mathbb{Z}$. Complex $K$-theory is represented by

$$\mathbb{Z} \times BU \simeq \Omega(U) \simeq \Omega^2(BU) \simeq \Omega^3(U) \simeq \cdots$$

This is Bott's celebrated "periodicity theorem." Finally, oriented cobordism theory is represented by

$$\Omega^\infty MSO := \lim_{n\to\infty} \Omega^n \mathrm{Th}(\gamma_n)$$

where $\gamma_n \to BSO_n$ is the universal $n$-dimensional vector space over the Grassmannian manifold of oriented $n$-planes in $\mathbb{R}^\infty$, and $\mathrm{Th}(\gamma_n)$ denotes its Thom space.

A good source of infinite loop spaces are symmetric monoidal categories. Indeed every infinite loop space can be constructed from such a category: the symmetric monoidal structure gives the corresponding homotopy abelian group structure. For example, the category of finite-dimensional, complex vector spaces and their isomorphisms gives rise to $\mathbb{Z} \times BU$. To give another example, in quantum field theory, one considers the $(d+1)$-dimensional cobordism category with objects the compact, oriented $d$-dimensional manifolds, and their $(d+1)$-dimensional cobordisms as morphisms. Disjoint union of manifolds makes this category into a symmetric monoidal category. The associated infinite loop space and hence generalized cohomology theory has recently been identified as a $(d+1)$-dimensional slice of oriented cobordism theory (Galatius *et al.* preprint 2005).

# Combinatorics: Overview

**C Krattenthaler**, Universität Wien, Vienna, Austria

## Introduction

Combinatorics is a vast field which enters particularly in a crucial way in statistical physics. There, it is particularly the enumerative problems that are of importance. Therefore, in this article, we shall mainly concentrate on the enumerative aspects of combinatorics. We first recall the basic terminology, in particular the basic combinatorial objects and numbers, together with the simplest facts about them. We then provide introductions into the most important techniques of enumeration: the generating function technique, Redfield–Pólya theory, methods of solving functional equations of combinatorial origin, methods of asymptotic enumeration, the theory of heaps, and the transfer matrix method. The subsequent sections then discuss specific problem circles with relation to statistical physics more closely. We discuss lattice path problems, explain Kasteleyn's method of enumerating perfect matchings and tilings, present the fundamental theorems on nonintersecting paths, and provide an introduction into the research field involving vicious walkers, plane partitions, rhombus tilings, alternating sign matrices, six-vertex configurations, and fully packed loop configurations. Finally, we explain how one should treat binomial and hypergeometric series, which frequently arise in enumeration problems.

## Basic Combinatorial Terminology

In this section we review basic combinatorial notions and facts. The reader can find a more detailed treatment and further results, for example, in chapter 1 of Stanley (1986).

The basic combinatorial choice problems and their solutions are: there are $2^n$ subsets of an $n$-element set. There are $\binom{n}{k}$ $k$-element subsets of an $n$-element set. Given an alphabet $\mathcal{A} = \{a_1, a_2, \ldots\}$, a word is a (finite or infinite) sequence of elements of $\mathcal{A}$. Usually, a finite word is written in the form $w_1 w_2 \ldots w_n$ (with $w_i \in \mathcal{A}$). Out of the letters $\{1, 2, \ldots, k\}$, one can build $k^n$ words of length $n$. Out of the letters $\{1, 2, \ldots, k\}$, one can build $\binom{n+k-1}{n}$ increasing sequences of length $n$. The number of permutations of an $n$-element set is $n!$. The set of permutations of $\{1, 2, \ldots, n\}$ is denoted by $\mathfrak{S}_n$. The number of permutations of an $n$-element set with exactly $k$ cycles is the Stirling number of the first kind, $s(n, k)$. These numbers are given as the expansion coefficients of falling factorials,

$$x(x-1)\cdots(x-n+1) = \sum_{k=0}^{n} (-1)^{n-k} s(n,k) x^k$$

or in form of the double (formal) power series

$$\sum_{n,k \geq 0} s(n,k) x^k \frac{y^n}{n!} = (1+y)^x$$

A partition of a set is a collection of pairwise disjoint subsets the union of which is the complete set. The subsets in the collection are called the blocks of the partition. The total number of partitions of an $n$-element set is the Bell number $B_n$. These numbers are given by

$$\sum_{n \geq 0} B_n \frac{x^n}{n!} = \mathrm{e}^{\mathrm{e}^x - 1}$$

The number of partitions of an $n$-element set into exactly $k$ blocks is the Stirling number of the second kind, $S(n, k)$. These numbers are given by

$$\sum_{n,k \geq 0} S(n,k) x^k \frac{y^n}{n!} = \mathrm{e}^{x(\mathrm{e}^y - 1)}$$

or, explicitly, by

$$S(n,k) = \frac{1}{k!} \sum_{j=0}^{k} (-1)^{k-j} \binom{k}{j} j^n$$

A composition of a positive integer $n$ is a representation of $n$ as a sum $n = s_1 + s_2 + \cdots + s_k$ of other positive integers $s_i$, where the order of the summands matters. The total number of compositions of $n$ is $2^{n-1}$. The number of compositions of $n$ with exactly $k$ summands is $\binom{n-1}{k-1.}$ A partition of a positive integer $n$ is a representation of $n$ as a sum $n = \lambda_1 + \lambda_2 + \cdots + \lambda_k$ of other positive integers $\lambda_i$, where the order of the summands does matter. Thus, we may assume that the summands are ordered, $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_k > 0$. This is the motivation to write partitions most often in the form of tuples $(\lambda_1, \lambda_2, \ldots, \lambda_k)$ the entries of which are weakly decreasing. The summands of a partition are called the parts of the partition. Let $p(n)$ denote the number of partitions of $n$. These numbers are given by

$$\sum_{n=0}^{\infty} p(n) x^n = \frac{1}{\prod_{i=1}^{\infty} (1 - x^i)}$$

If $p(n, k)$ denotes the number of partitions of $n$ into at most $k$ parts, then we have

$$\sum_{n=0}^{\infty} p(n,k) x^n = \frac{1}{\prod_{i=1}^{k} (1 - x^i)}$$

Finally, if $p(n, k, m)$ denotes the number of partitions of $n$ into at most $k$ parts, all of which are at most $m$, then

$$\sum_{n \geq 0} p(n,k,m) x^n = \frac{(1 - x^{k+m})(1 - x^{k+m-1}) \cdots (1 - x^{m+1})}{(1 - x^k)(1 - x^{k-1}) \cdots (1 - x)}$$

The expression on the right-hand side is called q-binomial coefficient, and is denoted by $\left[ \begin{matrix} k+m \\ k \end{matrix} \right]_x$.

Partitions are frequently encoded in terms of their Ferrers diagrams. The Ferrers diagram of a partition $\lambda = (\lambda_1, \lambda_2, \ldots, \lambda_\ell)$ is an array of cells with $\ell$ left-justified rows and $\lambda_i$ cells in row $i$. For example, the diagram in **Figure 1** is the Ferrers diagram of the partition $(3, 3, 2)$.

A lattice path P in $\mathbb{Z}^d$ (where $\mathbb{Z}$ denotes the set of integers) is a path in the $d$-dimensional integer lattice $\mathbb{Z}^d$ which uses only points of the lattice, that is, it is a sequence $(P_0, P_1, \ldots, P_l)$, where $P_i \in \mathbb{Z}^d$ for all $i$. The vectors $\overrightarrow{P_0 P_1}, \overrightarrow{P_1 P_2}, \ldots, \overrightarrow{P_{l-1} P_l}$ are called the steps of $P$. The number of steps, $l$, is called the length of $P$. **Figure 2** shows a lattice path in $\mathbb{Z}^2$ of length 11.

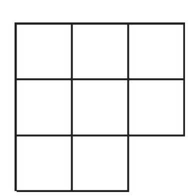

**Figure 1** A Ferrers diagram.

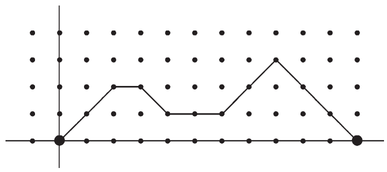

**Figure 2** A Motzkin path.

A Dyck path is a lattice path in the integer plane $\mathbb{Z}^2$ consisting of up-steps $(1,1)$ and down-steps $(1,-1)$, which starts at the origin, never passes below the $x$-axis, and ends on the $x$-axis. See Figure 3 for an example.

The number of Dyck paths of length $2n$ is the Catalan number

$$C_n = \frac{1}{n+1}\binom{2n}{n}$$

The generating function (see the next section for an introduction to the theory of generating functions) for these numbers is

$$\sum_{n=0}^{\infty} C_n x^n = \frac{1-\sqrt{1-4x}}{2x} \qquad [1]$$

The reader is referred to exercise 6.19 in Stanley (1999) for countless occurrences of the Catalan numbers.

A Motzkin path is a lattice path in the integer plane $\mathbb{Z}^2$ consisting of up-steps $(1,1)$, level steps $(1,0)$, and down-steps $(1,-1)$, which starts at the origin, never passes below the $x$-axis, and ends on the $x$-axis. The path in Figure 2 is in fact a Motzkin path. The number of Motzkin paths of length $n$ is the Motzkin number

$$M_n = \sum_{k\geq 0} \frac{1}{k+1}\binom{2k}{k}\binom{n}{2k}$$

The generating function for these numbers is

$$\sum_{n=0}^{\infty} M_n x^n = \frac{1-x-\sqrt{1-2x-3x^2}}{2x^2} \qquad [2]$$

The reader is referred to exercise 6.38 in Stanley (1999) for numerous occurrences of the Motzkin numbers.

A Schröder path is a lattice path in the integer plane $\mathbb{Z}^2$ consisting of horizontal steps $(1,0)$ and

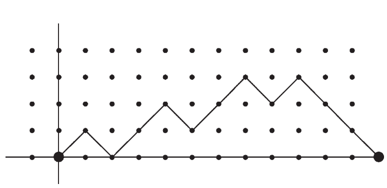

**Figure 3** A Dyck path.

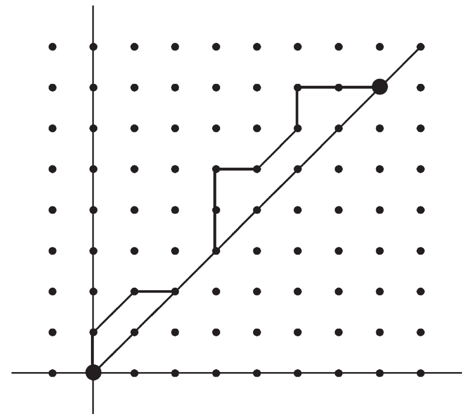

**Figure 4** A Schröder path.

vertical steps $(0,1)$, which starts at the origin, never passes below the diagonal $x=y$, and ends on the diagonal $x=y$. See Figure 4 for an example.

The number of Schröder paths of length $n$ is the (large) Schröder number

$$S_n = \sum_{k\geq 0} \frac{1}{k+1}\binom{2k}{k}\binom{n+k}{2k}$$

The generating function for these numbers is

$$\sum_{n=0}^{\infty} S_n x^n = \frac{1-x-\sqrt{1-6x+x^2}}{2x} \qquad [3]$$

The reader is referred to exercise 6.39 in Stanley (1999) for numerous occurrences of the Schröder numbers.

There is another famous sequence of numbers which we did not touch yet, the Fibonacci numbers $F_n$. They are given by

$$F_n = \frac{1}{\sqrt{5}}\left(\frac{1+\sqrt{5}}{2}\right)^{n+1}$$

with generating function

$$\sum_{n=0}^{\infty} F_n x^n = \frac{1}{1-x-x^2} \qquad [4]$$

They also occur in numerous places. For example, the number $F_n$ counts all paths on the integers $\mathbb{Z}$ from 0 to $n$ with steps $(1,0)$ and $(2,0)$.

An undirected graph G consists of vertices and edges. An edge is a two-element subset of the vertices, which, however, is thought of as a line or curve connecting the two vertices. See Figure 5a for an example. The usual notation for a graph $G$ is $G=(V,E)$, where $V$ is the set of vertices and $E$ is the set of edges of $G$. A graph is planar if it is

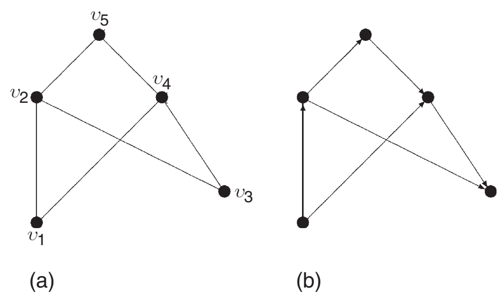

**Figure 5** (a) An undirected graph. (b) A directed graph.

embedded in the plane (sphere) in such a way that the curves which mark the edges do not intersect in their interiors. There can be several different ways to embed the same graph in the plane (or in another surface). When we speak of a planar graph then we assume the graph already to be embedded in a given way. For example, the graph in Figure 5 is not a planar graph, by its drawing. However, there is a different embedding which is planar (namely, all embeddings which put the vertex $v_3$ above the vertex $v_5$ and leave the other vertices as they are). A tree is a graph without any cycles.

A directed graph (or digraph) $G$ consists of vertices and arcs (which are sometimes also called directed edges). An arc is a pair of vertices, which, however, is thought of an arrow pointing from the first vertex of the pair to the second. See Figure 5b for an example. The usual notation for a directed graph $G$ is again $G=(V,E)$, where $V$ is the set of vertices and $E$ is the set of arcs of $G$. All other notions explained for undirected graphs have analogous meanings for directed graphs.

Graphs can be labeled, in which case each vertex is assigned a label, or unlabeled. The (undirected) graph in Figure 5a is labeled, whereas the (directed) graph in Figure 5b is unlabeled.

## Generating Functions

Generating functions are the very basic tools of enumeration. For introductions to this technique, from different points of view, the reader is referred to Bergeron *et al.* (1998), Flajolet and Sedgewick (chapter 1 in the reference listed in "Further reading" section), and Stanley (1998, chapter 1; 1999, chapter 4).

Let $\mathcal{A}$ be a set of (unlabeled) objects. Each object $a$ in $\mathcal{A}$ has a certain size, $|a|$, which is a non-negative integer. Let us also assume that there is only a finite number of objects from $\mathcal{A}$ of a given size. Let $a_n$ be the number of objects from $\mathcal{A}$ of size $n$. The (ordinary) generating function for $\mathcal{A}$ is the formal power series

$$F_{\mathcal{A}}(x) = \sum_{a\in\mathcal{A}} x^{|a|} = \sum_{n=0}^{\infty} a_n x^n$$

("formal" means that $x$ is just an indeterminate, not a real or complex number. One can compute with formal power series in the same way as with analytic series, only that convergence issues do not arise, respectively that "convergence" has a different meaning; cf. Stanley (1998, section 1.1)) Typical examples are **`Sets`** (the collection containing all "unlabeled sets," that is, all objects of the form $\{\bullet,\bullet,\ldots,\bullet\}$, including the empty set, where the size of $\{\bullet,\bullet,\ldots,\bullet\}$ is the number of $\bullet$'s), **`Sequences`** (the collection containing all "unlabeled sequences," that is, all objects of the form $(\bullet,\bullet,\ldots,\bullet)$, including the empty sequence), **`Cycles`** (unlabeled cycles), with respective generating function

$$F_{\texttt{Sets}}(x) = F_{\texttt{Sequences}}(x) = \frac{1}{1-x} \qquad F_{\texttt{Cycles}}(x) = \frac{x}{1-x} \tag{5}$$

or **`Trees`** (unlabeled trees).

If $\mathcal{A}$ and $\mathcal{B}$ are two sets of objects, one can define several other sets of objects using them. The union of $\mathcal{A}$ and $\mathcal{B}$, written $\mathcal{A}\cup\mathcal{B}$, has as a groundset the disjoint union of $\mathcal{A}$ and $\mathcal{B}$, and the size of an element from $\mathcal{A}$ is its size in $\mathcal{A}$, while the size of an element from $\mathcal{B}$ is its size in $\mathcal{B}$. We have

$$F_{\mathcal{A}\cup\mathcal{B}}(x) = F_{\mathcal{A}}(x) + F_{\mathcal{B}}(x) \tag{6}$$

The product of $\mathcal{A}$ and $\mathcal{B}$, written $\mathcal{A}\times\mathcal{B}$, has as a groundset the set of pairs $\mathcal{A}\times\mathcal{B}$, and the size of an element $(a,b)$ from $\mathcal{A}\times\mathcal{B}$ is the sum of the sizes of $a$ (in $\mathcal{A}$) and of $b$ (in $\mathcal{B}$). We have

$$F_{\mathcal{A}\times\mathcal{B}}(x) = F_{\mathcal{A}}(x)\cdot F_{\mathcal{B}}(x) \tag{7}$$

The substitution of two sets $\mathcal{A}$ and $\mathcal{B}$ of objects can only be defined in certain circumstances, and only in certain more restrictive circumstances the generating function for the substitution can be computed by substituting the generating functions for $\mathcal{A}$ and $\mathcal{B}$. Let us assume that any object $a$ from $\mathcal{A}$ of size $n$, by its structure, has $n$ atoms (nodes). For example, if $\mathcal{A}$ is a certain set of trees, where the size of a tree is the number of leaves in the tree, then we may take, as the atoms, the leaves of the tree. In this situation, the substitution of $\mathcal{B}$ *in* $\mathcal{A}$, denoted by $\mathcal{A}(\mathcal{B})$, is the set of objects which arises by replacing the atoms of objects from $\mathcal{A}$ by objects from $\mathcal{B}$ in all possible ways. The size of an object from $\mathcal{A}(\mathcal{B})$ is the sum of the sizes of the objects from $\mathcal{B}$ that it

contains. In order that $\mathcal{A}(\mathcal{B})$ contains only a finite number of objects of a given size, we must assume that $\mathcal{B}$ contains no elements of size 0. If, in addition, the atoms of any element $a$ from $\mathcal{A}$ inherit an order (e.g., if $\mathcal{A}$ is a set of binary trees, then the leaves of a binary tree are ordered in a natural way from "left" to "right"), then we have

$$F_{\mathcal{A}(\mathcal{B})}(x) = F_{\mathcal{A}}(F_{\mathcal{B}}(x)) \qquad [8]$$

However, this equation is not true in general. The general formula comes out of Redfield–Pólya theory (see [21] and [24]) and requires the notion of cycle index series. For example, if $\mathcal{B}$ is the set of connected (unlabeled) graphs, $\mathcal{A}$ is **Sets**, so that $\mathcal{A}(\mathcal{B})$ is the set of all (connected and disconnected) graphs, then [8] is not true, but what is true is

$$F_{\texttt{Sets}(\mathcal{B})} = \exp\left(F_{\mathcal{B}}(x) + \tfrac{1}{2}F_{\mathcal{B}}(x^2) + \tfrac{1}{3}F_{\mathcal{B}}(x^3) + \cdots\right) \qquad [9]$$

This holds, in fact, for any set $\mathcal{B}$ of unlabeled objects. (This is seen by combining [24], [17], and [21].)

Next we deal with the enumeration of labeled objects. Let $\mathcal{A}$ be a set of labeled objects, again, each object $a$ with a certain size $|a|$ which is a nonnegative integer. "Labeled" means that each object of size $n$, by its structure, comes with $n$ atoms (nodes) which are labeled $1, 2, \ldots, n$. For example, $\mathcal{A}$ may be the set of all labeled graphs, where the size of a graph is the number of its vertices, and where the vertices are labeled $1, 2, \ldots, n$. Again, we assume that there is only a finite number of objects from $\mathcal{A}$ of a given size. Let $a_n$ be the number of objects from $\mathcal{A}$ of size $n$. The exponential generating function for $\mathcal{A}$ is the formal power series

$$E_{\mathcal{A}}(x) = \sum_{a \in \mathcal{A}} \frac{x^{|a|}}{|a|!} = \sum_{n=0}^{\infty} a_n \frac{x^n}{n!}$$

Typical examples are **Sets** (the collection containing all "labeled sets," that is all objects of the form $\{1, 2, \ldots, n\}$, including the empty set), **Permutations**, **Cycles** (labeled cycles), with respective generating functions

$$E_{\texttt{Sets}}(x) = \exp(x) \qquad [10]$$

$$E_{\texttt{Permutations}}(x) = \frac{1}{1-x} \qquad [11]$$

$$E_{\texttt{Cycles}}(x) = \log \frac{1}{1-x} \qquad [12]$$

or **Trees** (labeled trees). The explicit form of the generating function for **Trees** is discussed in the section "Solving equations for generating functions: the Lagrange inversion formula and the kernel method."

If $\mathcal{A}$ and $\mathcal{B}$ are two sets of objects, one defines again several other sets of objects using them. The union of $\mathcal{A}$ and $\mathcal{B}$, written $\mathcal{A} \cup \mathcal{B}$, has as a groundset the disjoint union of $\mathcal{A}$ and $\mathcal{B}$, and the size of an element from $\mathcal{A}$ is its size in $\mathcal{A}$, while the size of an element from $\mathcal{B}$ is its size in $\mathcal{B}$. We have

$$E_{\mathcal{A} \cup \mathcal{B}}(x) = E_{\mathcal{A}}(x) + E_{\mathcal{B}}(x) \qquad [13]$$

To define the product of $\mathcal{A}$ and $\mathcal{B}$, written $\mathcal{A} \times \mathcal{B}$, we cannot simply take $\mathcal{A} \times \mathcal{B}$ as a groundset, we must also say something about the labeling of the objects. So, as a groundset we take all pairs $(a, b)$ with $a \in \mathcal{A}$ and $b \in \mathcal{B}$, but labeled in all possible ways by $1, 2, \ldots, |a| + |b|$ such that the order of labels assigned to $a$ respects the original order of labels of $a$, and the same for $b$. The size of such an element $(a,b)$ is again the sum of the sizes of $a$ (in $\mathcal{A}$) and of $b$ (in $\mathcal{B}$). We have

$$E_{\mathcal{A} \times \mathcal{B}}(x) = E_{\mathcal{A}}(x) \cdot E_{\mathcal{B}}(x) \qquad [14]$$

Since, in the labeled world, objects come automatically with atoms, the substitution of two sets $\mathcal{A}$ and $\mathcal{B}$ of objects can now always be defined. The substitution of $\mathcal{B}$ in $\mathcal{A}$, denoted by $\mathcal{A}(\mathcal{B})$, is the set of objects which arises by replacing the atoms of objects from $\mathcal{A}$ by objects from $\mathcal{B}$ in all possible ways, and labeling the substituted objects in all possible ways by $1, 2, \ldots, \sum_b |b|$ (the sum being over the objects from $\mathcal{B}$ which were put in the places of the atoms) that are consistent with the original labelings of the objects from $\mathcal{B}$. The size of an object from $\mathcal{A}(\mathcal{B})$ is the sum of the sizes of the objects from $\mathcal{B}$ that it contains. In order that $\mathcal{A}(\mathcal{B})$ contains only a finite number of objects of a given size, we must assume that $\mathcal{B}$ contains no elements of size 0. Then we have

$$E_{\mathcal{A}(\mathcal{B})}(x) = E_{\mathcal{A}}(E_{\mathcal{B}}(x)) \qquad [15]$$

An example of a composition is

$$\texttt{Permutations} = \texttt{Sets}(\texttt{Cycles})$$

Thus, from [15] we have

$$E_{\texttt{Permutations}}(x) = E_{\texttt{Sets}}(E_{\texttt{Cycles}}(x))$$

corresponding to the identity

$$\frac{1}{1-x} = \exp(\log 1/(1-x))$$

Another manifestation of the composition rule is, for example, the fact (which is sometimes called the "exponential principle") that, if one takes the log of the partition function for some maps, the result is the partition function for the connected maps among them.

All of the above can be generalized to a weighted setting. Namely, if $\mathcal{A}$ is a set of objects (labeled or unlabeled), and if $w:\mathcal{A}\to R$ is a weight function from $\mathcal{A}$ into some ring $R$, then all of the above remains true, if we replace the definitions of $F_{\mathcal{A}}(x)$ and $E_{\mathcal{A}}(x)$ above by the weighted sums

$$F_{\mathcal{A}}(x) = \sum_{a\in\mathcal{A}} w(a)x^{|a|}$$

and

$$E_{\mathcal{A}}(x) = \sum_{a\in\mathcal{A}} w(a)\frac{x^{|a|}}{|a|!}$$

respectively, if in the definition of the union of $\mathcal{A}$ and $\mathcal{B}$ we define the weight of an object to be its weight in $\mathcal{A}$, respectively $\mathcal{B}$, if in the definition of the product of $\mathcal{A}$ and $\mathcal{B}$ we define the weight of an object $(a, b)$ to be the product of the weights of $a$ and $b$, and if in the definition of the substitution we define the weight of an object in $\mathcal{A}(\mathcal{B})$ as the product of the weights of the objects from $\mathcal{B}$ that were put in place of the atoms.

## Redfield–Pólya Theory of Colored Enumeration

The natural and uniform environment for the separate treatment of generating functions for unlabeled and labeled objects in the last section is the theory for counting colored objects founded by Redfield and Pólya, in the modern treatment through cycle index series due to Joyal. We refer the reader to Bergeron *et al.* (1998, appendix 1), de Bruijn (1981), and Stanley (1999, chapter 7) for further reading.

Let $\mathcal{A}$ be a set of labeled objects with the constraint that there is only a finite number of objects of a given size. The cycle index series for $\mathcal{A}$ is the formal multivariable series

$$Z_{\mathcal{A}}(x_1,x_2,\ldots) = \sum_{n=0}^{\infty}\frac{1}{n!}\sum_{\sigma\in\mathfrak{S}_n}\mathrm{fix}_\sigma(\mathcal{A})x_1^{c_1(\sigma)}x_2^{c_2(\sigma)}x_3^{c_3(\sigma)}\cdots \qquad [16]$$

where $\mathrm{fix}_\sigma(\mathcal{A})$ is the number of objects $a$ from $\mathcal{A}$ that remain invariant when the labels are permuted according to the permutation $\sigma$ (in particular, if $\sigma\in\mathfrak{S}_n$, the size of $a$ must be $n$ in order that $\sigma$ can be applied to the labels), and where $c_i(\sigma)$ denotes the number of cycles of length $i$ of $\sigma$.

In most cases, it is difficult to obtain compact expressions for the cycle index series. However, for our familiar families of objects, compact expressions are available:

$$Z_{\mathtt{Sets}}(x_1,x_2,\ldots) = \exp\left(x_1+\frac{x_2}{2}+\frac{x_3}{3}+\cdots\right) \qquad [17]$$

$$Z_{\mathtt{Permutations}}(x_1,x_2,\ldots) = \prod_{i=1}^{\infty}\frac{1}{1-x_i} \qquad [18]$$

$$Z_{\mathtt{Cycles}}(x_1,x_2,\ldots) = \sum_{i=1}^{\infty}\frac{\Phi(i)}{i}\log\frac{1}{1-x_i} \qquad [19]$$

where $\Phi(i)$ is the Euler totient function (the number of positive integers $j\le i$ relatively prime to $i$).

What makes the cycle index series so fundamental is the fact that the generating functions from the last section are specializations of it. Namely, the exponential generating function for $\mathcal{A}$ is equal to

$$E_{\mathcal{A}}(x) = Z_{\mathcal{A}}(x,0,0,\ldots) \qquad [20]$$

If, given the set of labeled objects $\mathcal{A}$, we produce a set of unlabeled objects $\tilde{\mathcal{A}}$ by taking all the objects from $\mathcal{A}$ but forgetting the labels, then the ordinary generating function for $\tilde{\mathcal{A}}$ is another specialization of the cycle index series,

$$F_{\tilde{\mathcal{A}}}(x) = Z_{\mathcal{A}}(x,x^2,x^3,\ldots) \qquad [21]$$

The cycle index series satisfies the following properties with respect to union, product and composition of sets of objects:

$$Z_{\mathcal{A}\cup\mathcal{B}}(x_1,x_2,\ldots) = Z_{\mathcal{A}}(x_1,x_2,\ldots) + Z_{\mathcal{B}}(x_1,x_2,\ldots) \qquad [22]$$

$$Z_{\mathcal{A}\times\mathcal{B}}(x_1,x_2,\ldots) = Z_{\mathcal{A}}(x_1,x_2,\ldots) \times Z_{\mathcal{B}}(x_1,x_2,\ldots) \qquad [23]$$

$$Z_{\mathcal{A}(\mathcal{B})}(x_1,x_2,\ldots) = Z_{\mathcal{A}}(Z_{\mathcal{B}}(x_1,x_2,x_3,\ldots), Z_{\mathcal{B}}(x_2,x_4,x_6\ldots), Z_{\mathcal{B}}(x_3,x_6,x_9,\ldots),\ldots) \qquad [24]$$

Similar to the theory of generating functions surveyed in the last section, one can also develop a weighted version of the cycle index series. Given a set of labeled objects $\mathcal{A}$, where each object $a$ is assigned a weight $w(a)$, one changes the definition [16] insofar as $\mathrm{fix}_\sigma(\mathcal{A})$ gets replaced by the weighted sum $\sum_{\sigma(a)=a} w(a)$, where $\sigma(a)$ means the object arising from $a$ by permuting the labels according to $\sigma$. Then all the above formulas remain true in this weighted setting.

Cycle index series are instrumental in the enumeration of colored objects. The basic situation is that we have given a set $\tilde{\mathcal{A}}$ of unlabeled objects so that every object of size $n$ comes with $n$ atoms (nodes). For example, we may think of $\tilde{\mathcal{A}}$ as the set of cycles. We are now going to color each atom by a

color from the set of colors $C$. The question that we pose is: *how many different colored objects of a given size are there?* In our example, if $C$ consists of the two colors "black" and "white," then we are asking the question of how many necklaces one can make out of $n$ pearls that can be black or white. In terms of generating functions, we want to compute

$$\Gamma_{\tilde{\mathcal{A}}}(x) = \sum_{c} x^{|c|}$$

where the sum is over all colored objects $c$ that one can obtain by coloring the objects from $\tilde{\mathcal{A}}$.

The central result of Redfield–Pólya theory is that, if $\mathcal{A}$ is the set of labeled objects that one obtains from $\tilde{\mathcal{A}}$ by labeling the objects of $\tilde{\mathcal{A}}$ in all possible ways, then

$$\Gamma_{\tilde{\mathcal{A}}}(x) = Z_{\mathcal{A}}(|C|x, |C|x^2, |C|x^3, \ldots)$$

There is again a weighted version. One allows the objects $a$ from $\tilde{\mathcal{A}}$ to have weight $w(a) \in R$. Moreover, one assumes a weight function $f: C \to R$ on the colors with values in the ring $R$. One defines the weight of a colored object obtained by coloring the atoms of $a$ to be $w(a)$ multiplied by the product of all $f(\gamma)$, where $\gamma$ ranges over all the colors of the atoms (including repetitions of colors). Let $\Gamma_{\tilde{\mathcal{A}}}(w, f)$ denote the sum of all the weights of all colored objects obtained from $\tilde{\mathcal{A}}$. Then

$$\Gamma_{\tilde{\mathcal{A}}}(w,f) = Z_{\mathcal{A}}\left(\sum_{c\in C} f(c), \sum_{c\in C} f(c)^2, \sum_{c\in C} f(c)^3, \ldots\right)$$

We remark that these results cover also the case of enumeration of objects under a group action. This includes the enumeration of objects on which we impose certain symmetries. See Bergeron *et al.* (1998, appendix 1), de Bruijn (1981), and Stanley (1999, chapter 7) for more details. The enumeration of asymmetric objects is the subject of an ongoing research program (cf. Labelle and Lamathe (2004)).

## Solving Equations for Generating Functions: The Lagrange Inversion Formula and the Kernel Method

In this section, we describe two methods to solve functional equations for generating functions. The Lagrange inversion makes it possible (in some situations) to find explicit expressions for the coefficients of an implicitly given series. The kernel method (and its extensions), on the other hand, is a powerful method to obtain an explicit expression for an implicitly given function. We refer the reader to Flajolet and Sedgewick, (section VII.5 of the reference in "Further reading" section) for further reading.

In many situations it will happen that, when we apply the methods from the last section, we end up with a functional equation for the generating function $f(x) = \sum_{n=0}^{\infty} f_n x^n$ that we wanted to compute. For example, if $t_n$ denotes the number of labeled rooted trees with $n$ nodes, and if we write $T(x) = \sum_{n=1}^{\infty} t_n x^n/n!$, then, by applying a straightforward decomposition of a tree into its root and its set of subtrees attached to the root, we obtain the equation

$$T(z) = z\exp(T(z)) \qquad [25]$$

How does one solve such an equation? As a matter of fact, for $T(z)$, there is no expression in terms of known functions. However, the Lagrange inversion formula enables one to find the coefficients $t_n/n!$ of $T(z)$ explicitly. The theorem reads as follows.

**Theorem** *Let $g(x)$ be a formal Laurent series containing only a finite number of negative powers of $x$, and let $f(x)$ be a formal power series without constant term. If we expand $g(x)$ in powers of $f(x)$,*

$$g(x) = \sum_{k} c_k f^k(x) \qquad [26]$$

*then the coefficients $c_n$ are given by*

$$c_n = \frac{1}{n}[x^{-1}]g'(x)f^{-n}(x) \quad \text{for } n \neq 0 \qquad [27]$$

*or, alternatively, by*

$$c_n = [x^{-1}]g(x)f'(x)f^{-n-1}(x) \qquad [28]$$

*Here, $[x^n]h(x)$ denotes the coefficient of $x^n$ in the power series $h(x)$.*

With this theorem in hand, eqn [25] is easy to solve. We write it in the form

$$T(x)\exp(-T(x)) = x \qquad [29]$$

We want to know the coefficients in the expansion $T(x) = \sum_{n=0}^{\infty} t_n x^n/n!$. Since, by [29], $T(x)$ is the compositional inverse of $x\exp(-x)$, substitution of $x\exp(-x)$ instead of $x$ gives

$$x = \sum_{n=0}^{\infty} \frac{t_n}{n!}(x\exp(-x))^n$$

This equation is in the form [26] with $f(x) = x\exp(-x)$ and $g(x) = x$. Hence, by [27], we obtain

$$\frac{t_n}{n!} = \frac{1}{n}[x^{-1}](x\exp(-x))^{-n} = \frac{1}{n}[x^{n-1}]\exp(nx) = \frac{n^{n-1}}{n!}$$

and, thus, $t_n = n^{n-1}$.

The second method to solve functional equations which we explain in this section is the kernel method. We illustrate the method by an example. Let us consider the problem of counting Dyck paths of length $2n$ (see the section "Basic combinatorial terminology"). Rather than attempting to arrive at a solution of the problem directly, we consider the more general problem of counting the number $a_{n,k}$ of paths consisting of steps (1, 1) and (1, −1), which start at the origin, never drop below $y=0$, have length $n$, and end at height $k$. We then form the bivariate generating function $F(u,x)=\sum_{n,k\geq 0} a_{n,k}x^n u^k$. We then have the functional equation

$$F(u,x)=1+xuF(u,x)+\frac{x}{u}(F(u,x)-F(0,x)) \quad [30]$$

since a path can be empty (this explains the term 1), it can end by a step (1,1) (this explains the term $xuF(u)$), or it can end by a step (1,−1). The latter can only happen if the path before that last step did not end at height 0. The generating function for these paths is $F(u,x)-F(0,x)$, and this explains the third term in the eqn [30]. In fact, we may replace [30] by

$$F(u,x)=1+xuF(u,x)+\frac{x}{u}(F(u,x)-F_1(x)) \quad [31]$$

because [31] implies that $F_1(x)=F(0,x)$.

The idea of the kernel method is to get rid of the unknown series $F(u,x)$. This is possible because $F(u,x)$ occurs linearly in [31], which can be rewritten as

$$F(u,x)\left(1-xu-\frac{x}{u}\right)=1-\frac{x}{u}F_1(x) \quad [32]$$

We simply equate the coefficient of $F(u,x)$ in this equation to zero,

$$1-xu-\frac{x}{u}=0$$

solve this for $u$,

$$u=\frac{1-\sqrt{1-4x^2}}{2x}$$

(the other solution for $u$ makes no sense in [31]), and substitute this back in [32], to obtain

$$F_1(x)=\frac{1-\sqrt{1-4x^2}}{2x^2}$$

the familiar generating function [2] for the Catalan numbers. Now, by substituting this result in [31], we can even compute the full series $F(u,x)$.

While this was certainly a complicated, and unusual, way to compute the Catalan numbers, this approach generalizes when one considers paths with different step sets (see section VII.5 of the Flajolet and Sedgewick reference in "Further reading" section). In a more general situation, one has a functional equation

$$P(F(u,x),F_1(x),\ldots,F_k(x),x,u)=0 \quad [33]$$

where $F(u,x)$ appears linearly, as well as the unknown series $F_1(x),\ldots,F_k(x)$, whereas $x$ and $u$ appear rationally. It is clear that one can apply the same technique, namely collecting all the terms involving $F(u,x)$, equating the coefficient of $F(u,x)$ to zero, solving for $u$ and substituting back in [33]. If there is more than one function $F_i(x)$, then this will only give one equation for $F_i(x)$. However, when equating the coefficient of $F(u,x)$, which was a polynomial equation, there can be more solutions. (That was actually also the case in our example, although only one solution could be used.) All these solutions can be substituted in [33] to give many more equations for $F_i(x)$. The kernel method will work if we have enough equations to determine the unknown functions $F_i(x)$ (see the Flajolet and Sedgewick reference, section VII.5 for further details). In the variant of the "obstinate kernel method," more equations are produced in more sophisticated ways. The method has been largely extended by Bousquet–Mélou and co-workers to cover equations of the form [33], where $P$ is a polynomial such that eqn [33] determines all involved series uniquely. This extension covers in particular the so-called quadratic method due to Brown, which is of great significance in the work of Tutte on the enumeration of maps. We refer the reader to Bousquet–Mélou and Jehanne (2005) and the references given there for these extensions.

## Extracting Asymptotic Information from Generating Functions

There is powerful machinery available to extract the asymptotic behavior of the coefficients of a power series out of analytic properties of the power series. We describe the corresponding methods, singularity analysis and the saddle point method in this section. The survey by Odlyzko (1995) and the Flajolet and Sedgewick reference in "Further reading" are excellent sources for further reading, which, in particular, contain several other methods which we cannot cover here for reasons of limited space.

Let us suppose that we are interested in the asymptotic behavior of the sequence $(f_n)_{n\geq 0}$ of real (or complex) numbers as $n$ tends to infinity. Let us suppose that the power series $f(z)=\sum_{n=0}^{\infty} f_n z^n$ converges in some neighborhood of the origin. (If this series converges only at $z=0$, then either one has to try to scale, that is, for example, look at the

power series $f(z) = \sum_{n=0}^{\infty} f_n z^n/n!$ instead, or one must apply methods other than singularity analysis or the saddle point method. In the latter case, depending on the nature of the coefficients $f_n$, this may be the Euler–Maclaurin or the Poisson summation formulas, the Mellin transform technique, or other direct methods. The reader is referred to Odlyzko (1995) and the Flajolet and Sedgewick reference.) The idea is then to consider $f(z)$ as a complex function in $z$ (and extend the range of $f$ beyond the disk of convergence about the origin), and to study the singularities of $f(z)$. (The point at infinity can also be a singularity.) The upshot is that the singularities of $f(z)$ with smallest modulus dictate the asymptotic behavior of the coefficients $f_n$. These singularities of smallest modulus are called the dominating singularities.

If there is an infinite number of dominant singularities, then one has to try the circle method. We refer the reader to Andrews (1976) and Ayoub (1963) for details of this method.

If there is a finite number of dominant singularities, then there can be again two different situations, depending on whether these are "small" or "large" singularities. Roughly speaking, a singularity is small if the function $f(z)$ grows at most polynomially when $z$ approaches the singularity, otherwise it is "large." A typical example of a small singularity is $z = 1/4$ in $(1-4z)^{-1/2}$, whereas a typical example of a large singularity is $z = \infty$ in $\exp(x)$ or $z = 1$ in $\exp(1/(1-z))$.

The method to apply for small singularities is the method of singularity analysis as developed by Flajolet and Odlyzko. (Singularity analysis implies Darboux's method, which occurs frequently in the literature, and, thus, supersedes it.) For the sake of simplicity, we consider first only the case of a unique dominant singularity. We shall address the issue of several dominant singularities shortly. Furthermore, we assume the singularity to be $z = 1$, again for the sake of simplicity of presentation. The general result can then be obtained by rescaling $z$.

The basic idea is the transfer principle:

$$\text{If } f(z) \underset{z\to 1}{=} \sigma(z) + O(\tau(z)) \quad \text{then}$$
$$f_n \underset{n\to\infty}{=} \sigma_n + O(\tau_n) \qquad [34]$$

where $\sigma(z) = \sum_{n=0}^{\infty} \sigma_n z^n$ is a linear combination of standard functions of the form $(1-z)^{-\alpha}$, or logarithmic variants, and $\tau(z) = \sum_{n=0}^{\infty} \tau_n z^n$ also lies in the scale (see sections VI.3,4 of the Flajolet and Sedgewick reference for the exact statement). The expansion for $f(z)$ in [34] is called the singular expansion of $f(z)$. For the above-mentioned standard functions, we have

$$[z^n](1-z)^{-\alpha}\left(\frac{1}{z}\log\frac{1}{1-z}\right)^{\beta} \sim \frac{n^{\alpha-1}}{\Gamma(\alpha)}(\log n)^{\beta}\left(1 + \frac{C_1}{1!}\frac{\beta}{\log n} + \frac{C_2}{2!}\frac{\beta(\beta-1)}{(\log n)^2} + \cdots\right) \qquad [35]$$

where $[z^n]g(z)$ denotes the coefficient of $z^n$ in $g(z)$, and where

$$C_k = \Gamma(\alpha)\frac{d^k}{ds^k}\frac{1}{\Gamma(s)}\bigg|_{s=\alpha}$$

If $\alpha$ is a nonpositive integer, then this expansion has to be taken with care (cf. section VI.2 of the Flajolet and Sedgewick reference).

To see how this works, consider the example $f_n = \sum_{k=0}^{n}\binom{2k}{k}$. We have

$$\sum_{n=0}^{\infty} f_n z^n = \frac{1}{(1-z)\sqrt{1-4z}}$$

The function on the right-hand side is meromorphic in all of $\mathbb{C}$ (where $\mathbb{C}$ denotes the complex numbers), with singularities at $z = 1$ and $z = 1/4$. The dominant singularity is $z = 1/4$. We determine the singular expansion of $f(z)$ about $z = 1/4$,

$$f(z) = \frac{4}{3}(1-4z)^{-1/2} - \frac{4}{9}(1-4z)^{1/2} + \frac{4}{27}(1-4z)^{3/2} + O\left((1-4z)^{5/2}\right)$$

(We stopped the expansion after three terms. The farther we go, the more terms can we compute of the asymptotic expansion for $f_n$.) Hence, we obtain

$$\begin{aligned} f_n &= 4^n\left(\frac{4}{3}\frac{n^{-1/2}}{\Gamma(1/2)}\left(1 - \frac{1}{8n} + \frac{1}{128n^2}\right) - \frac{4}{9}\frac{n^{-3/2}}{\Gamma(-1/2)}\left(1 + \frac{3}{8n}\right) + \frac{4}{27}\frac{n^{-5/2}}{\Gamma(-3/2)} + O\left(n^{-7/2}\right)\right) \\ &= \frac{4^n}{\sqrt{\pi n}}\left(\frac{4}{3} + \frac{1}{18n} + \frac{11}{288n^2} + O\left(\frac{1}{n^3}\right)\right) \end{aligned}$$

If there are several small dominant singularities (but only a finite number of them), then one simply applies the above procedure for all of them and, to obtain the desired asymptotic expansion, one adds up the corresponding contributions.

The method to apply for large singularities is the saddle point method. For the following considerations, we assume that $f(z)$ is analytic in $|z| < R \le \infty$. At the heart of the saddle point method lies Cauchy's formula

$$f_n = [z^n]f(z) = \frac{1}{2\pi\,\mathrm{i}}\int_{\mathcal{C}} \frac{f(z)}{z^{n+1}}\,\mathrm{d}z \qquad [36]$$

for writing the $n$th coefficient in the power series expansion of $f(z)$. Here, $\mathcal{C}$ is some simple closed contour around the origin that stays in the range $|z| < R$. The idea is to exploit the fact that we are free to deform the contour. The aim is to choose a contour such that the main contribution to the integral in [36] comes from a very tiny part of the contour, whereas the contribution of the rest is negligible. This will be possible if we put the contour through a saddle point of the integrand $f(z)/z^{n+1}$. Under suitable conditions, the main contribution will then come from the small passage of the path through the saddle point, and the contribution of the rest will be negligible.

In practice, the saddle point method is not always straightforward to apply, but has to be adapted to the specific properties of the function $f(z)$ that we are encountering. We refer the reader to the corresponding chapters in the Flajolet and Sedgewick reference and Odlyzko (1995) for more details. There is one important exception though, namely the Hayman admissible functions. We will not reproduce the definition of Hayman admissibility because it is cumbersome (cf. section VIII.5 in the Flajolet and Sedgewick reference and definition 12.4 of Odlyzko (1995)). However, in many applications, it is not even necessary to go back to it because of the closure properties of Hayman admissible functions. Namely, it is known (cf. Odlyzko (1995), theorem 12.8) that $\exp(p(z))$ is Hayman admissible in $|z| < \infty$ for any polynomial $p(z)$ with real coefficients as long as the coefficients $a_n$ of the Taylor series of $\exp(p(z))$ are positive for all sufficiently large $n$ (thus, e.g., $\exp(z)$ is Hayman admissible), and it is known that, if $f(z)$ and $g(z)$ are Hayman admissible in $|z| < R \le \infty$, then $\exp(f(z))$ and $f(z)g(z)$ are also (thus, e.g., $\exp(\exp(z) - 1)$ is Hayman admissible).

The central result of Hayman's theory is the following: if $f(z) = \sum_{n\ge 0} f_n z^n$ is Hayman admissible in $|z| < R$, then

$$f_n \sim \frac{f(r_n)}{r_n^n\sqrt{2\pi b(r_n)}} \quad \text{as} \quad n \to \infty \qquad [37]$$

where $r_n$ is the unique solution for large $n$ of the equation $a(r) = n$ in $(R_0, R)$, with $a(r) = rf'(r)/f(r)$, $b(r) = ra'(r)$, and a suitably chosen constant $R_0 > 0$.

This result covers only the first term in the asymptotic expansion. There is an even more sophisticated theory due to Harris and Schoenfeld, which allows one to also find a complete asymptotic expansion. We refer the reader to section VIII.5 of the Flajolet and Sedgewick reference and Odlyzko (1995) for more details.

Methods for the asymptotic analysis of multivariable generating functions are also available (see the corresponding chapters in Flajolet and Sedgewick, Odlyzko (1995) and the recent important development surveyed in the Pemantle and Wilson reference listed in "Further reading"). We add that both the method of singularity analysis and Hayman's theory of admissible functions have been made largely automatic, and that this has been implemented in the Maple program `gdev` (see "Further reading").

## The Theory of Heaps

The theory of heaps, developed by Viennot, is a geometric rendering of the theory of the partial commutation monoid of Cartier and Foata, which is now most often called the Cartier–Foata monoid. Its importance stems from the fact that several objects which appear in statistical physics, such as Motzkin paths, animals, respectively polyominoes, or Lorentzian triangulations (see the Viennot and James reference in "Further reading" and the references therein), are in bijection with heaps.

Informally, a heap is what we would imagine. We take a collection of "pieces," say $B_1, B_2, \ldots$, and put them one upon the other, sometimes also sideways, to form a "heap," see Figure 6.

There, we imagine that pieces can only move vertically, so that the heap in Figure 6 would indeed form a stable arrangement. Note that we allow several copies of a piece to appear in a heap. (This means that they differ only by a vertical translation.) For example, in Figure 6 there appear two copies of $B_2$. Under these assumptions, there are pieces which can move past each other, and others which cannot. For example, in Figure 6, we can move the piece $B_6$ higher up, thus moving it higher than $B_1$ if we wish. However, we cannot move $B_7$ higher than $B_6$,

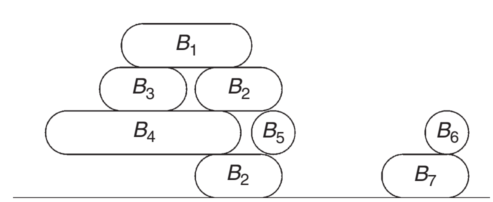

**Figure 6** A heap of pieces.

because $B_6$ blocks the way. On the other hand, we can move $B_7$ past $B_1$ (thus taking $B_6$ with us). Thus, a rigorous way to introduce heaps is by beginning with a set $\mathcal{B}$ of pieces (in our example, $\mathcal{B} = \{B_1, B_2, \ldots, B_7\}$), and we declare which pieces can be moved past another and which cannot. We indicate this by a symmetric relation $\mathcal{R}$: we write $a\mathcal{R}b$ to indicate that a cannot move past $b$ (and vice versa). When we consider a word $a_1a_2\ldots a_n$ of pieces, $a_i \in \mathcal{B}$, we think of it as putting first $a_1$, then putting $a_2$ on top of it (and, possibly, moving it past $a_1$), then putting $a_3$ on top of what we already have, etc. We declare two words to be equivalent if one arises from the other by commuting adjacent letters which are not in relation. A heap is then an equivalence class of words under this equivalence relation. What we have described just now is indeed the original definition of Cartier and Foata.

The class of heaps which occurs most frequently in applications is the class of heaps of monomers and dimers, which we now introduce. Let $\mathcal{B} = M \cup D$, where $\mathcal{M} = \{m_0, m_1, \ldots\}$ is the set of monomers and $\mathcal{D} = \{d_1, d_2, \ldots\}$ is the set of dimers. We think of a monomer $m_i$ as a point, symbolized by a circle, with $x$-coordinate $i$, see Figure 7. We think of a dimer $d_i$ as two points, symbolized by circles, with $x$-coordinates $i-1$ and $i$ which are connected by an edge, see Figure 7. We impose the relations $m_i\mathcal{R}m_i$, $m_i\mathcal{R}d_i$, $m_i\mathcal{R}d_{i+1}$, $i = 0, 1, \ldots, d_i\,\mathcal{R}d_j$, $i-1 \le j \le i$, and extend $\mathcal{R}$ to a symmetric relation. Figure 8 shows two heaps of momomers and dimers.

For example, Motzkin paths are in bijection with heaps of monomers and dimers. To see this, given a Motzkin path, we read the steps of the path from

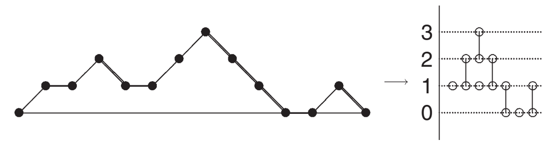

**Figure 9** Bijection between Motzkin paths and heaps of monomers and dimers.

the beginning to the end. Whenever we read a level-step at height $h$, we make it into a monomer with $x$-coordinate $h$, whenever we read a down-step from height $h$ to height $h-1$, we make it into a dimer whose endpoints have $x$-coordinates $h-1$ and $h$. Up-steps are ignored. Figure 9 shows an example. In the figure, the heap is not in "standard" fashion, in the sense that the $x$-axis is not shown as a horizontal line but as a vertical line (cf. Figure 7). But it could be easily transformed into "standard" fashion by a simple reflection with respect to a line of slope 1.

Lattice animals on the triangular lattice and on the quadratic lattice are also in bijection with heaps, this time with heaps consisting entirely out of dimers. Given an animal, one simply replaces each vertex of the animal by a dimer, see Figures 10 and 11. While in the case of animals on the triangular lattice this gives a constraintless bijection (see Figure 10), in the case of the quadratic lattice this sets up a bijection with heaps of dimers in which two dimers of the same type can never be placed directly one over the other (see Figure 11). For example, two dimers $d_5$, one placed directly over the other (as they occur in Figure 10), are forbidden under this rule.

Next we make heaps into a monoid by introducing a composition of heaps. (A monoid is a set with a binary operation which is associative.) Intuitively, given two heaps $H_1$ and $H_2$, the composition of $H_1$ and $H_2$, the heap $H_1 \circ H_2$, is the heap which results

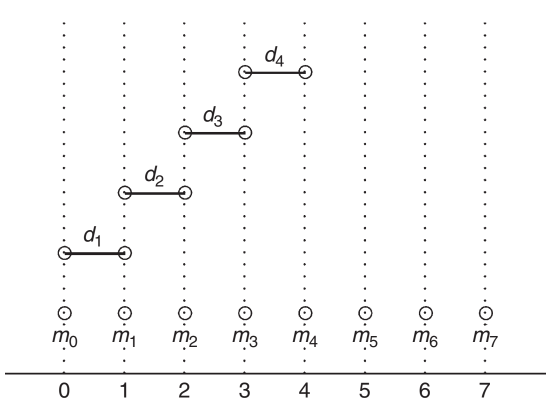

**Figure 7** Monomers and dimers.

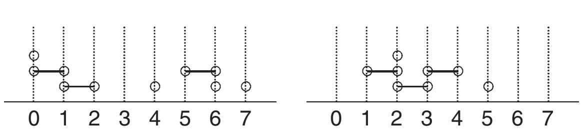

**Figure 8** Two heaps of monomers and dimers.

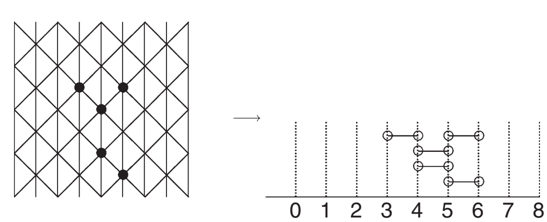

**Figure 10** Bijection between animals and heaps of dimers.

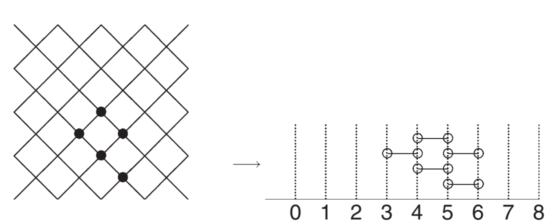

**Figure 11** Bijection between animals and heaps of dimers.

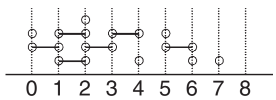

**Figure 12** The composition of the heaps in Figure 8.

by putting $H_2$ on top of $H_1$. In terms of words, the composition of two heaps is the equivalence class of the concatenation $uw$, where $u$ is a word from the equivalence class of $H_1$, and $w$ is a word from the equivalence class of $H_2$.

The composition of the two heaps in Figure 8 is shown in Figure 12.

Given pieces $\mathcal{B}$ with relation $\mathcal{R}$, let $\mathcal{H}(\mathcal{B},\mathcal{R})$ be the set of all heaps consisting of pieces from $\mathcal{B}$, including the empty heap, the latter denoted by $\emptyset$. It is easy to see that the composition makes $(\mathcal{H}(\mathcal{B},\mathcal{R}),\circ)$ into a monoid with unit $\emptyset$.

For the statement of the main theorem in the theory of heaps, we need two more terms. A trivial heap is a heap consisting of pieces all of which are pairwise unrelated. Figure 13a shows a trivial heap consisting of monomers and dimers. A pyramid is a heap with exactly one maximal (= topmost) element. Figure 13a shows a pyramid consisting of monomers and dimers. Finally, if $H$ is a heap, then we write $|H|$ for the number of pieces in $H$.

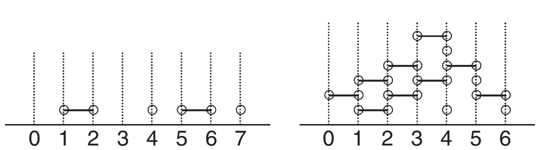
In applications, heaps will have weights, which are defined by introducing a weight $w(B)$ for each piece $B$ in $\mathcal{B}$, and by extending the weight $w$ to all heaps $H$ by letting $w(H)$ denote the product of all weights of the pieces in $H$ (multiplicities of pieces included).

Let $\mathcal{M}$ be a subset of the pieces $\mathcal{B}$. Then, the generating function for all heaps with maximal pieces contained in $\mathcal{M}$ is given by

$$\sum_{\substack{H\in\mathcal{H}(\mathcal{B},\mathcal{R})\\ \text{maximal pieces}\subseteq\mathcal{M}}} w(H)=\frac{\sum_{T\in\mathcal{T}(\mathcal{B}\backslash\mathcal{M},\mathcal{R})}(-1)^{|T|}w(T)}{\sum_{T\in\mathcal{T}(\mathcal{B},\mathcal{R})}(-1)^{|T|}w(T)} \qquad [38]$$

where $\mathcal{T}(\mathcal{B},\mathcal{R})$ denotes the set of all trivial heaps with pieces from $\mathcal{B}$. In particular, the generating function for all heaps is given by

$$\sum_{H\in\mathcal{H}(\mathcal{B},\mathcal{R})} w(H)=\frac{1}{\sum_{T\in\mathcal{T}(\mathcal{B},\mathcal{R})}(-1)^{|T|}w(T)} \qquad [39]$$



(a) (b)

**Figure 13** (a) A trivial heap. (b) A pyramid.

Furthermore, if $\mathcal{P}(\mathcal{B},\mathcal{R})$ denotes the set of all pyramids with pieces from $\mathcal{B}$, then

$$\sum_{P\in\mathcal{P}(\mathcal{B},\mathcal{R})}\frac{w(P)}{|P|}=\log\left(\sum_{H\in\mathcal{H}(\mathcal{B},\mathcal{R})} w(H)\right) \qquad [40]$$

where $|P|$ is the number of pieces of $P$. (As the reader will have guessed, this is a consequence of the "exponential principle" mentioned in the section "generating functions.")

## The Transfer Matrix Method

The transfer matrix method (cf. Stanley (1986), chapter 4 for further reading) applies whenever we are able to build the combinatorial objects that we are interested in by moving on a finite number of states in a step-by-step fashion, where the current step does not depend on the previous ones. (In statistical language, we are considering a finite-state Markov chain.) For example, Motzkin paths which are constrained to stay between two parallel lines, say between $y=0$ and $y=K$, can be described in such a way: the states are the heights $0,1,\ldots,K$, and, if we are in state $h$, then in the next step we are allowed to move to states $h+1, h$, or $h-1$, except that from state 0 we cannot move to $-1$ (there is no state $-1$), and when we are in state $K$ we cannot move to $K+1$ (there is no state $K+1$).

For describing the general situation, let $G=(V,E)$ be a directed graph with vertex set $V$ and edge set $E$. Let $w_n(u,v)$ denote the number of walks from vertex $u$ to vertex $v$ along edges of $G$. To compute these numbers, we consider the adjacency matrix of $G, A(G)$. By definition, using our notation, $A(G)=(w_1(u,v))_{u,v\in V}$. Obviously, $(w_n(u,v))_{u,v\in V}=(A(G))^n$. Thus,

$$\left(\sum_{n=0}^{\infty} w_n(u,v)x^n\right)_{u,v\in V}=\sum_{n=0}^{\infty}(A(G))^n x^n = (I_n-A(G)x)^{-1}$$

where $I_n$ is the $n\times n$ identity matrix. In other words, the generating functions $\sum_{n=0}^{\infty} w_n(u,v)x^n$ for the walk numbers between $u$ and $v$ form the entries of a matrix which is the inverse matrix of $I_n-A(G)x$. By elementary linear algebra,

$$\sum_{n=0}^{\infty} w_n(u,v)\,x^n = \frac{(-1)^{\#u+\#v}\det(I_n-A(G)x)_{v,u}}{\det(I_n-A(G)x)} \qquad [41]$$

where $\det(I_n-A(G)x)_{v,u}$ is the minor of $I_n-A(G)x$ with the row indexed by $v$ and the column indexed

by $u$ omitted, and where $\#u$ denotes the row number of $u$ and similarly for $\#v$. A weighted version could also be developed in the same way, where we put a weight $w(e)$ on each edge, and the weight of a walk is the product of the weights of all its edges.

In particular, the expression [41] is a rational function in $x$. Then, by the basic theorem on rational generating functions (cf. Stanley (1986), section 4.1), the number $w_n(u, v)$ can be expressed as a sum $\sum_{i=1}^{d} P_i(n)\gamma_i^n$, where the $\gamma_i$'s are the different roots of the polynomial $\det(xI_n - A(G))$, and $P_i(n)$ is a polynomial of degree less than the multiplicity of the root $\gamma_i$. (The $P_i(n)$'s depend on $u$ and $v$, whereas the $\gamma_i$'s do not.) If there exists a unique root $\gamma_j$ with maximal modulus, then this implies that, asymptotically as $n \to \infty, w_n(u, v) \sim P_j(n)\gamma_j^n$.

## Lattice Paths

Recall from the section on basic combinatorial terminology that a lattice path P in $\mathbb{Z}^d$ is a path in the $d$-dimensional integer lattice $\mathbb{Z}^d$ which uses only points of the lattice, that is, it is a sequence $(P_0, P_1, \ldots, P_l)$, where $P_i \in \mathbb{Z}^d$ for all $i$. The vectors $\overrightarrow{P_0P_1}, \overrightarrow{P_1P_2}, \ldots, \overrightarrow{P_{l-1}P_l}$ are called the steps of $P$. The number of steps, $l$, is called the length of $P$.

The enumeration of lattice paths has always been an intensively studied topic in statistics, because of their importance in the study of random walks, of rank order statistics for nonparametric testing, and of queueing processes. The reader is referred to Feller (1957) and particularly Mohanty's (1979) book, which is a rich source for enumerative results on lattice paths, albeit in a statistical language. We review the most important results in this section. Most of these concern two-dimensional lattice paths, that is, the case $d = 2$.

To begin with, we consider paths in the integer plane $\mathbb{Z}^2$ consisting of horizontal and vertical unit steps in the positive direction. Clearly, the number of all (unrestricted) paths from the origin to $(n, m)$ is the binomial coefficient $\binom{n+m}{n}$. By the reflection principle, which is commonly attributed to D André (see, e.g., Comtet (1974) p. 22), it follows that the number of paths from the origin to $(n, m)$ which do not pass above the line $y = x + t$, where $m \leq n + t$, is given by

$$\binom{n+m}{n} - \binom{n+m}{n+t+1} \qquad [42]$$

Roughly, the reflection principle sets up a bijection between the paths from the origin to $(n, m)$ which do pass above the line $y = x + t$ and *all* paths from $(-t-1, t+1)$ to $(n, m)$, by reflecting the path portion between the origin and the last touching point on $y = x + t + 1$ in this latter line. Thus, the result of the enumeration problem is the number of all paths from (0, 0) to $(n, m)$, which is given by the binomial coefficient $\binom{n+m}{n}$, minus the number of all paths from $(-t-1, t+1)$ to $(n, m)$, which is given by the binomial coefficient $\binom{n+m}{n+t+1}$, whence the formula [42].

If one considers more generally paths bounded by the line $my = nx + t$, no compact formula is known. It seems that the most conceptual way to approach this problem is through the so-called kernel method (see the section on solving equations for generating functions), which, in combination with the saddle point method, allows one also to obtain strong asymptotic results. There is one special instance, however, which has a "nice" formula. The number of all lattice paths from the origin to $(n, m)$ which never pass above $x = \mu y$, where $\mu$ is a positive integer, is given by

$$\frac{n - \mu m + 1}{n + m + 1}\binom{n+m+1}{m} \qquad [43]$$

The most elegant way to prove this formula is by means of the cycle lemma of Dvoretzky and Motzkin (see Mohanty (1979), p. 9 where the cycle lemma occurs under the name of "penetrating analysis").

Iteration of the reflection principle shows that the number of paths from the origin to $(n, m)$ which stay between the lines $y = x + t$ and $y = x + s$ (being allowed to touch them), where $t \geq 0 \geq s$ and $n + t \geq m \geq n + s$, is given by the finite (!) sum (see, e.g., Mohanty (1979), p. 6)

$$\sum_{k \in \mathbb{Z}} \left( \binom{n+m}{n - k(t-s+2)} - \binom{n+m}{n - k(t-s+2) + t + 1} \right) \qquad [44]$$

The enumeration of lattice paths restricted to regions bounded by hyperplanes has also been considered for other regions, such as quadrants, octants, and rectangles, as well as in higher dimensions. A general result due to Gessel and Zeilberger, and Biane, independently, on the number of lattice paths in a chamber (alcove) of an (affine) reflection group (see Krattenthaler (2003) for the corresponding references and pointers to further results) shows how far one can go when one uses the reflection principle. In particular, this result covers [42] and [44], the enumeration of lattice paths in quadrants, octants, rectangles, and many other results that have

appeared (before and after) in the literature. We present a particularly elegant (and frequently occurring) special case. (In reflection group language, it corresponds to the reflection group of "type $A_{n-1}$." See Humphreys (1990) for terminology and information on reflection groups.)

Let $A=(a_1,a_2,\ldots,a_d)$ and $E=(e_1,e_2,\ldots,e_d)$ be points in $\mathbb{Z}^d$ with $a_1 \geq a_2 \geq \cdots \geq a_d$ and $e_1 \geq e_2 \geq \cdots \geq e_d$. The number of all paths from A to E in the integer lattice $\mathbb{Z}^d$, which consist of positive unit steps and which stay in the region $x_1 \geq x_2 \geq \cdots \geq x_d$, equals

$$\left(\sum_{i=1}^{d}(e_i - a_i)\right)! \det_{1\leq i,j\leq d}\left(\frac{1}{(e_i - a_j - i + j)!}\right) \qquad [45]$$

The counting problem of the theorem is equivalent to numerous other counting problems. It has been originally formulated as an $n$-candidate ballot problem, but it is as well equivalent to counting the number of standard Young tableaux of a given shape. In the case that all $a_j$'s are equal, the determinant does in fact evaluate into a closed-form product. In Young tableaux theory, a particular way to write the result is known as the hook-length formula (see, e.g., Stanley (1999), corollary 7.21.6).

We return to lattice paths in the plane, mentioning some more closely related results. The first is a result of Mohanty (1979, section 4.2), which expresses the number of all lattice paths from the origin to $(n,m)$ which touch the line $y=x+t$ exactly r times, never crossing it, as the difference

$$\binom{n+m-r}{n+t-1} - \binom{n+m-r}{n+t}, \quad r \geq 1 \qquad [46]$$

Not forbidding that the paths cross the bounding line, we arrive at the problem of counting the lattice paths from the origin to $(n,m)$, which cross the main diagonal $y=x$ exactly $r$ times, the answer being

$$\begin{cases} \dfrac{m-n+2r+1}{m+n+1}\dbinom{m+n+1}{n-r} & \text{if } m>n \\[2ex] \dfrac{2r+2}{n}\dbinom{2n}{n-r-1} & \text{if } m=n \end{cases} \qquad [47]$$

Next, we give the number of lattice paths from the origin to $(n,\ n)$ which have $2r$ steps on one side of the line $y=x$, as

$$\binom{2r}{r}\binom{2n-2r}{n-r} \qquad [48]$$

a result due to Sparre Andersen. We refer the reader to Mohanty (1979, chapter 3) for further results in this direction.

Enumerating lattice paths with a fixed number of maximal straight pieces (which correspond to runs), is intimately connected to another basic enumeration problem concerning lattice paths: the enumeration of lattice paths having a fixed number of turns. An effective way to attack the latter problem is by means of two-rowed arrays (see the survey article by Krattenthaler (1997), where in particular analogs of the reflection principle for two-rowed arrays are developed. These imply formulas for the number of lattice paths with fixed starting points and endpoints and a fixed number of north-east (respectively east–north) turns, for unrestricted paths, as well as for paths bounded by lines. (A north–east turn in a lattice path is a point where the direction changes from "north" to "east." An east–north turn is defined analogously.) In particular, analogs of [42]–[44] are known when the number of north–east (respectively east–north) turns is fixed.

These formulas imply for example (see again Krattenthaler (1997, section 3.5)) that the number of lattice paths from the origin to $(n,n)$ which never pass above the line $y=x+t$ and have exactly $2r$ maximal straight pieces is given by

$$2\binom{n-1}{r-1}^2 - \binom{n+t-1}{r-2}\binom{n-t-1}{r} - \binom{n+t-1}{r-1}\binom{n-t-1}{r-1} \qquad [49]$$

with a similar result for the case of $2r+1$ maximal straight pieces. (If $t=0$, the numbers in [49] become

$$\frac{1}{n}\binom{n}{r}\binom{n}{r-1}$$

and they are known as the Narayana numbers.) Furthermore, they imply that the number of lattice paths from the origin to $(n,n)$ which never pass above the line $y=x+t$ and never below the line $y=x-t$ and have exactly $2r$ maximal straight pieces is given by

$$\sum_{k=-\infty}^{\infty}\left\{2\binom{n-2kt-1}{r+k-1}\binom{n+2kt-1}{r-k-1} - \binom{n-2kt+t-1}{r+k-2}\binom{n+2kt-t-1}{r-k} - \binom{n-2kt+t-1}{r+k-1}\binom{n+2kt-t-1}{r-k-1}\right\} \qquad [50]$$

with a similar result for the case of $2r+1$ maximal straight pieces.

The most general boundary for lattice paths that one can imagine is the restriction that it stays

between two given (fixed) paths. Let us assume that the horizontal steps of the upper (fixed) path are at heights $a_1 \leq a_2 \leq \cdots \leq a_n$, whereas the horizontal steps of the lower (fixed) path are at heights $b_1 \leq b_2 \leq \cdots \leq b_n$, $a_i \geq b_i$, $i = 1, 2, \ldots, n$. Then the number of all paths from $(0, b_1)$ to $(n, a_n)$ satisfying the property that for all $i = 1, 2, \ldots, n$ the height of the $i$th horizontal step is between $b_i$ and $a_i$ is given by the determinant

$$\det_{1 \leq i,j \leq n}\left(\binom{a_i - b_j + 1}{j - i + 1}\right) \qquad [51]$$

In the statistical literature, this formula is often known as "Steck's formula," but it is actually a special case of a much more general theorem due to Kreweras. A generalization of [51] to higher-dimensional paths was given by Handa and Mohanty (see Mohanty (1979, section 2.4)).

Next, we consider three-step lattice paths in the integer plane $\mathbf{Z}^2$, that is, paths consisting of up-steps $(1, 1)$, level steps $(1, 0)$, and down-steps $(1, -1)$. The particular problem that we are interested in is to count such three-step paths starting at $(0, r)$ and ending at $(\ell, s)$, which do not pass below the $x$-axis and do not pass above the horizontal line $y = K$. Furthermore, we assign the weight 1 to an up-step, the weight $b_h$ to a level-step at height $h$, and the weight $\lambda_h$ to a down-step from height $h$ to $h - 1$. The weight $w(P)$ of a path $P$ is defined as the product of the weights of all its steps. Then we have the following result, which can be obtained by the transfer matrix method described in the last section.

Define the sequence $(p_n(x))_{n \geq 0}$ of polynomials by

$$xp_n(x) = p_{n+1}(x) + b_n p_n(x) + \lambda_n p_{n-1}(x) \quad \textit{for } n \geq 1 \qquad [52]$$

with initial conditions $p_0(x) = 1$ and $p_1(x) = x - b_0$. Furthermore, define $(\mathrm{S}p_n(x))_{n \geq 0}$ to be the sequence of polynomials which arises from the sequence $(p_n(x))$ by replacing $\lambda_i$ by $\lambda_{i+1}$ and $b_i$ by $b_{i+1}, i = 0, 1, 2, \ldots,$ everywhere in the three-term recurrence [52] and in the initial conditions. Finally, given a polynomial $p(x)$ of degree $n$, we denote the corresponding reciprocal polynomial $x^n p(1/x)$ by $p^*(x)$.

With the weight $w$ defined as before, the generating function $\sum_P w(P)x^{\ell(P)}$, where the sum is over all three-step paths which start at $(0, r)$, terminate at height $s$, do not pass below the $x$-axis, and do not pass above the line $y = K$, is given by

$$\begin{cases} \dfrac{x^{s-r} p_r^*(x) S^{s+1} p_{K-s}^*(x)}{p_{K+1}^*(x)}, & r \leq s \\ \lambda_r \cdots \lambda_{s+1} \dfrac{x^{r-s} p_s^*(x) S^{r+1} p_{K-r}^*(x)}{p_{K+1}^*(x)}, & r \geq s \end{cases} \qquad [53]$$

The sequence of polynomials $(p_n(x))_{n \geq 0}$ is in fact a sequence of orthogonal polynomials (cf. Koekoek and Swarttouw (1998) and Szegő (1959)).

We remark that in the case that $r = s = 0$ there is also an elegant expression for the generating function due to Flajolet (see section V.2 of the Flajolet and Sedgewick reference in "Further reading") in terms of a continued fraction.

In order to solve our problem, we just have to extract the coefficient of $x^\ell$ in [53]. By a partial fraction expansion, a formula of the type

$$\sum_m c_m \xi_m^\ell \qquad [54]$$

results, where the $\xi_m$'s are the zeroes of $p_{K+1}(x)$, and the $c_m$'s are some coefficients, only a finite number of them being nonzero.

It should be noted that, because of the many available parameters (the $b_n$'s and $\lambda_n$'s), by appropriate specializations one can also obtain numerous results about enumerating three-step paths according to various statistics, such as the number of touchings on the bounding lines, etc.

There are two important special cases in which a completely explicit solution in terms of elementary functions can be given.

The first case occurs for $b_i = 0$ and $\lambda_i = 1$ for all $i$. In this case, the polynomials $p_n(x)$ defined by the three-term recurrence [52] are Chebyshev polynomials of the second kind, $p_n(x) = U_n(x/2)$. (The Chebyshev polynomial of the second kind $U_n(x)$ is defined by $U_n(\cos t) = \sin((n+1)t)/\sin t$ (see Koekoek and Swarttouw (1998) for almost exhaustive information on these polynomials and, more generally, on hypergeometric orthogonal polynomials)). The result which is then obtained from the general theorem (clearly, the zeros of $U_n(x)$ are $x = \cos(2k\pi/(n+1)), k = 1, 2, \ldots, n,$ and therefore the partial fraction expansion of [53] is easily determined) is that the number of lattice paths from $(0, r)$ to $(\ell, s)$ with only up- and down-steps, which always stay between the $x$-axis and the line $y = K$, is given by (see also Feller (1957, chapter XIV, eqn [5.7])

$$\frac{2}{K+2}\sum_{k=1}^{K+1}\left(2\cos\frac{\pi k}{K+2}\right)^\ell \times \sin\frac{\pi k(r+1)}{K+2}\sin\frac{\pi k(s+1)}{K+2} \qquad [55]$$

a formula which goes back to Lagrange.

The second case occurs for $b_i = 1$ and $\lambda_i = 1$ for all $i$. In this case, the polynomials $p_n(x)$ defined by the three-term recurrence [52] are again Chebyshev polynomials of the second kind, $p_n(x) = U_n((x-1)/2)$. The result which is then

obtained from the general theorem is that the number of three-step lattice paths from $(0, r)$ to $(\ell, s)$, which always stay between the $x$-axis and the line $y = K$, is given by

$$\frac{2}{K+2}\sum_{k=1}^{K+1}\left(2\cos\frac{\pi k}{K+2}+1\right)^{\ell} \times \sin\frac{\pi k(r+1)}{K+2}\sin\frac{\pi k(s+1)}{K+2} \qquad [56]$$

## Perfect Matchings and Tilings

In this section we consider the problem of counting the perfect matchings of a graph. For an introduction into the problem, and into methods to solve it, as well as for a report on recent developments, we refer the reader to Propp (1999).

Let $G = (V, E)$ be a finite loopless graph with vertex set $V$ and edge set $E$. A matching (also called 1-factor in graph theory) is a subset of the edges with the property that no two edges share a vertex. A matching is perfect if it covers all the edges. Let $M(G)$ denote the number of perfect matchings of the graph $G$. More generally, we could assign a weight $w(e)$ to each edge $e$ of the graph and define the weight of a matching to be the product of the weights of all its edges. Let $M_w(G)$ denote the sum of all weights of all matchings of the graph $G$.

Kasteleyn's method for determining $M(G)$, respectively $M_w(G)$, makes use of determinants and Pfaffians. Recall that the Pfaffian $\mathrm{Pf}(A)$ of a triangular array $A = (a_{i,j})_{1\le i<j\le 2n}$ is defined by

$$\mathrm{Pf}(A) = \sum_m (\mathrm{sgn}\, m) \prod_{\{i,j\}\in m} \alpha_{i,j} \qquad [57]$$

where the sum is over all perfect matchings of the complete graph on vertices $\{1, 2, \ldots, 2n\}$, and where the product is over all edges $\{i, j\}, i < j$, of $m$. The sign $\mathrm{sgn}\, m$ of $m$ is $(-1)^{\#\text{crossings of } m}$, where a crossing is a pair $(\{i, j\}, \{k, l\})$ of edges such that $i < k < j < l$. Usually, one extends the triangular array $A$ to a matrix by setting $a_{j,i} = -a_{i,j}, i < j$, and $a_{i,i} = 0$ for all $i$. Then, abusing notation, we identify the triangular array with the skew-symmetric matrix $A = (a_{i,j})_{1\le i,j\le 2n}$. The Pfaffian satisfies the following useful properties:

$$\mathrm{Pf}(B^t AB) = \det(B)\,\mathrm{Pf}(A)$$

and

$$\mathrm{Pf}(A)^2 = \det(A) \qquad [58]$$

The latter equality shows in particular that Pfaffians are very close to determinants. They do, in fact, generalize determinants since

$$\mathrm{Pf}\begin{pmatrix} 0 & B \\ -B & 0 \end{pmatrix} = \det B \qquad [59]$$

for any square matrix $B$.

Thus, given a graph with vertices $v_1, v_2, \ldots, v_{2n}$, specializing $a_{i,j}$ to the weight of the edge between $v_i$ and $v_j$, if it exists, and setting $a_{i,j} = 0$ otherwise in the definition of the Pfaffian, we obtain almost $M_w(G)$, the only difference is that there could be signs in front of the individual terms of the sum, whereas in $M_w(G)$ the sign in front of each term must be $+$. (The object obtained by omitting the sign in [57] is called Hafnian. Unfortunately, in contrast to the Pfaffian, it does not have any nice properties and it is therefore extremely difficult to compute.) Kasteleyn's idea is to circumvent this problem by orienting the edges of the graph, defining signed weights of the edges, in such a way that the Pfaffian of the array with signed weights produces exactly $M_w(G)$.

More precisely, given a (weighted) graph $G$ with vertices $v_1, v_2, \ldots, v_{2n}$, we make it into an oriented (weighted) graph $\overrightarrow{G}$. That is, if there is an edge between $v_i$ and $v_j$, $e_{i,j}$ say, we orient it either from $v_i$ to $v_j$ or the other way. Now we define the signed adjacency matrix $A(\overrightarrow{G})$ of $\overrightarrow{G}$ by letting its $(i, j)$-entry to be $+w(e_{i,j})$ if there is an edge from $v_i$ to $v_j$ oriented that way, $-w(e_{i,j})$ if there is an edge from $v_j$ to $v_i$ oriented that way, and 0 if there is no edge between $v_i$ and $v_j$. Such an orientation is called Pfaffian if

$$\mathrm{Pf}(A(\overrightarrow{G})) = \pm M_w(G)$$

Clearly, the question remains whether a Pfaffian orientation can be found for a given graph. In general, this is an open question. However, Kasteleyn shows that for planar graphs such a Pfaffian orientation can always be found. Moreover, he shows that any orientation of a planar graph which has the property that around any face bounded by $4k$ edges an odd number of edges is oriented in either direction and that around any face bounded by $4k + 2$ edges an even number of edges is oriented in either direction is Pfaffian.

For bipartite graphs (i.e., for graphs in which the set of vertices can be split into two disjoint sets such that all the edges connect the vertex of one of these sets to a vertex of the other), the situation is even nicer. This is because for a bipartite graph $G$ in which both parts of the bipartition of the vertices are of the same size (otherwise, there is no perfect matching), any signed

adjacency matrix $A(\overrightarrow{G})$ has the block form of the matrix on the left-hand side of [59] and, hence, the Pfaffian reduces to a determinant. More precisely, let $G$ be a bipartite graph with vertex set $V = U \cup W$, $U = \{u_1, u_2, \ldots, u_n\}$ and $W = \{w_1, w_2, \ldots, w_n\}$, with edges connecting some $u_i$ to some $w_j$. Given a Pfaffian orientation $\overrightarrow{G}$, we build the signed bipartite adjacency matrix $B(\overrightarrow{G}) = (b_{i,j})_{1 \le i,j \le n}$ of $\overrightarrow{G}$ by setting $b_{i,j} = +w(e_{i,j})$ if there is an edge from $u_i$ to $w_j$ oriented that way, $-w(e_{i,j})$ if there is an edge from $u_j$ to $w_i$ oriented that way, and 0 if there is no edge between $u_i$ and $w_j$. Then we have

$$\det(B(\overrightarrow{G})) = \pm M_w(G)$$

In particular, this holds for any bipartite planar graph. See Robertson *et al.* (1999) for a structural description about which (not necessarily planar) bipartite graphs admit a Pfaffian orientation.

Kasteleyn's construction in the planar case has been generalized to graphs on surfaces of any genus $g$ in Dolbilin *et al.* (1996), Galluccio and Loebl (1999), and Tesler (2000), independently. As predicted by Kasteleyn, the solution is in terms of a linear combination of $4^g$ Pfaffians.

With the help of his method, Kasteleyn computed the number of dimer coverings of an $m \times n$ rectangle. (A dimer is a $2 \times 1$ rectangle. Thus, this is equivalent to counting the number of perfect matchings on the $m \times n$ grid graph. The formula was independently found by Temperley and Fisher.) The result is

$$\prod_{i=1}^{m} \prod_{j=1}^{n} \left( 2\cos\frac{\pi i}{m+1} + 2\sqrt{-1}\cos\frac{\pi j}{n+1} \right)$$

For even $m$ and $n$, the formula can be rewritten as

$$\prod_{i=1}^{m/2} \prod_{j=1}^{n/2} \left( 4\cos^2\frac{\pi i}{m+1} + 4\cos^2\frac{\pi j}{n+1} \right)$$

There is a similar rewriting if one of $m$ or $n$ is odd. (If both $m$ and $n$ are odd, there is no dimer covering.)

For further reading and references *see* Dimer Problems and Kuperberg (1998).

## Nonintersecting Paths

Let $G = (V, E)$ be a directed acyclic graph with vertices $V$ and directed edges $E$. Furthermore, we are given a function $w$ which assigns a weight $w(x)$ to every vertex or edge $x$. Let us define the weight $w(P)$ of a walk $P$ in the graph by $\prod_e w(e) \prod_v w(v)$, where the first product is over all edges $e$ of the walk $P$ and the second product is over all vertices $v$ of $P$. We denote the set of all walks in $G$ from $u$ to $v$ by $\mathcal{P}(u \to v)$, and the set of all families $(P_1, P_2, \ldots, P_n)$ of walks, where $P_i$ runs from $u_i$ to $v_i, i = 1, 2, \ldots, n$, by $\mathcal{P}(\boldsymbol{u} \to \boldsymbol{v})$, with $\boldsymbol{u} = (u_1, u_2, \ldots, u_n)$ and $\boldsymbol{v} = (v_1, v_2, \ldots, v_n)$. The symbol $\mathcal{P}^+(\boldsymbol{u} \to \boldsymbol{v})$ stands for the set of all families $(P_1, P_2, \ldots, P_n)$ in $\mathcal{P}(\boldsymbol{u} \to \boldsymbol{v})$ with the additional property that no two walks share a vertex. We call such families of walk(er)s "vicious walkers" or, alternatively, "nonintersecting paths." The weight $w(\boldsymbol{P})$ of a family $\boldsymbol{P} = (P_1, P_2, \ldots, P_n)$ of walks is defined as the product $\prod_{i=1}^{n} w(P_i)$ of all the weights of the walks in the family. Finally, given a set $M$ with weight function $w$, we write $\mathrm{GF}(\mathcal{M}; w)$ for the generating function $\sum_{x \in \mathcal{M}} w(x)$.

We need two further notations before we are able to state the Lindström–Gessel–Viennot theorem. (For references and historical remarks, we refer the reader to footnote 5 in Krattenthaler (2005a).) As earlier, the symbol $\mathfrak{S}_n$ denotes the symmetric group of order $n$. Given a permutation $\sigma \in \mathfrak{S}_n$, we write $\boldsymbol{u}_\sigma$ for $(u_{\sigma(1)}, u_{\sigma(2)}, \ldots, u_{\sigma(n)})$. Then

$$\sum_{\sigma \in \mathfrak{S}_n} (\mathrm{sgn}\ \sigma) \cdot \mathrm{GF}(\mathcal{P}^+(\boldsymbol{u}_\sigma \to \boldsymbol{v}); w) = \det_{1 \le i,j \le n} \left( \mathrm{GF}(\mathcal{P}(u_j \to v_i); w) \right) \qquad [60]$$

Most often, this theorem is applied in the case where the only permutation $\sigma$ for which vicious walks exist is the identity permutation, so that the sum on the left-hand side reduces to a single term that counts all families $(P_1, P_2, \ldots, P_n)$ of vicious walks, the $i$th walk $P_i$ running from $A_i$ to $E_i, i = 1, 2, \ldots, n$. This case occurs, for example, if for any pair of walks $(P, Q)$ with $P$ running from $u_a$ to $v_d$ and $Q$ running from $u_b$ to $v_c$, $a < b$ and $c < d$, it is true that $P$ and $Q$ must have a common vertex. Explicitly, in that case we have

$$\mathrm{GF}(\mathcal{P}^+(\boldsymbol{u} \to \boldsymbol{v}); w) = \det_{1 \le i,j \le n} \left( \mathrm{GF}(\mathcal{P}(u_j \to v_i); w) \right) \quad [61]$$

If the starting points or/and the endpoints are not fixed, then the corresponding number is given by a Pfaffian, a result obtained by Okada and Stembridge (see Bressoud (1999) for references). For a set $\mathcal{A}$ of starting points, let $\mathcal{P}^+(\mathcal{A} \to \boldsymbol{v})$ denote the set of all families $(P_1, P_2, \ldots, P_{2n})$ of nonintersecting lattice paths, where $P_i$ runs from some point of $\mathcal{A}$ to $v_i, i = 1, 2, \ldots, 2n$. Furthermore, let us suppose that the elements of $\mathcal{A} = \{u_1, u_2, \ldots\}$ are ordered in such a way that for any pair of walks $(P, Q)$ with $P$ running from $u_a$ to $v_d$ and $Q$ running from $u_b$ to $v_c$, $a < b$ and $c < d$, it is true that $P$ and $Q$ must have a common vertex. (This is the same condition as the one which makes [61] valid, with the only difference that, here,

the number of $u_i$'s could be larger than the number of $v_i$'s.) Then,

$$\mathrm{GF}(\mathcal{P}^+(\mathcal{A}\to \boldsymbol{v});w) = \underset{1\le i,j\le 2n}{\mathrm{Pf}}\left(\sum_{a<b}\left(\mathrm{GF}(\mathcal{P}(u_a\to v_i);w)\mathrm{GF}(\mathcal{P}(u_b\to v_j);w) - \mathrm{GF}(\mathcal{P}(u_b\to v_i);w)\mathrm{GF}(\mathcal{P}(u_a\to v_j);w)\right)\right) \quad [62]$$

If the number of paths is odd, then one can use the same formula by adding an artificial point to the endpoints and to the set of starting points $\mathcal{A}$. There is also a theorem by Okada and Stembridge which covers the case that starting points and endpoints vary. Refinements when the number of turns is fixed can be found in Krattenthaler (1997).

## Vicious Walkers, Plane Partitions, Rhombus Tilings, and Fully Packed Loop Configurations

In this section we describe the interrelations between four frequently appearing objects in statistical mechanics and combinatorics: vicious walkers, plane partitions, rhombus tilings, and fully packed loop configurations.

Given a lattice, vicious walkers, as introduced by Fisher (1984), are particles which move on lattice sites in such a way that two particles never occupy the same lattice site. Models of vicious walkers have been the object of numerous studies from various points of view. Rather than accomplishing the impossible task of providing a complete overview of references, the reader is referred to the basic reference Fisher (1984) and to Krattenthaler (2005a) for further pointers to the literature.

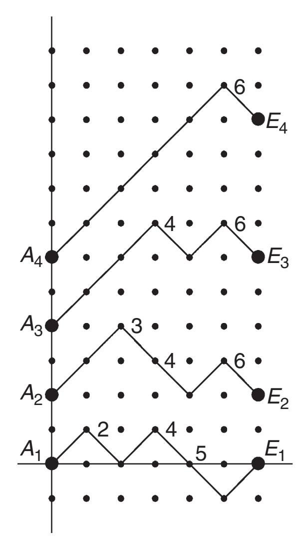
Most of the known results apply for vicious walkers on the line. There are in fact two different models: in the random turns vicious walker model, $n$ walkers move on the integral points of the real line in such a way that at each tick of the clock exactly one walker moves to the right or to the left, whereas in the lock step vicious walker model $n$ walkers move on the integral points of the real line in such a way that at each tick of the clock each walker moves to the right or to the left.

The first model is equivalent to a model of one walker in $\mathbb{Z}^n$ ($\mathbb{Z}$ denoting the set of integers) which at each tick of the clock moves a positive or negative unit step in the direction of one of the coordinate axes, always staying in the wedge $x_1 > x_2 > \cdots > x_n$. This point of view was already put forward by Fisher (1984). However, this problem belongs to the problem of counting paths in chambers of reflection groups discussed in the section "Lattice paths."

The second model could also be realized as a single walker model (cf. Krattenthaler (2003)). However, most often it is realized as a model of $n$ paths in the plane consisting of steps $(1,1)$ and $(1,-1)$ with the property that no two paths have a point in common. In this picture, the $x$-axis becomes the time line, the $k$th path doing an up-step $(1,1)$ from $(t-1,y)$ to $(t,y+1)$ meaning that the $k$th particle moves to the left at time $t$, whereas the $k$th path doing a down-step $(1,-1)$ from $(t-1,y)$ to $(t,y-1)$ meaning that the $k$th particle moves to the right at time $t$.

The reader should consult Figure 14a for an example. (The labelings should be ignored at this point.) Clearly, what we encounter here is a particular instance of the nonintersecting paths of the last section. Therefore, for fixed starting points and endpoints, formula [61] applies, whereas if the starting points vary and the endpoints are fixed, it is formula [62] that applies.

At this point, the links to the other objects, semistandard tableaux and plane partitions (cf. Bressoud (1999)), emerge. A filling of the cells of the Ferrers diagram of $\lambda$ with elements of the set $\{1,2,\ldots\}$, which is weakly increasing along rows and strictly increasing along columns is called a (semistandard) tableau of shape $\lambda$. Figure 14b shows such a semistandard tableau of shape $(4,3,2)$. In fact, vicious walkers and semistandard tableaux are equivalent objects. To see this, first label down-steps by the $x$-coordinate of their endpoint, so that a step from $(a-1,b)$ to $(a,b-1)$ is labeled by $a$, see Figure 14a. Then, out of the labels of the $j$th path, form the $j$th column of the corresponding tableau,



(a)

|---|---|---|---|
| 4 | 4 | 6 | |
| 5 | 6 | | |

(b)

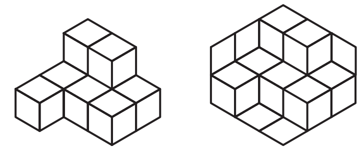
**Figure 14** (a) Vicious walkers. (b) A tableau.

see Figure 14b. The resulting array of numbers is indeed a semistandard tableau. This can be readily seen, since the entries are trivially strictly increasing along columns, and they are weakly increasing along rows because the paths do not touch each other. Thus, problems of enumerating vicious walkers can be translated into tableau enumeration problems, and vice versa.

The significance of semistandard tableaux lies particularly in the representation theory for classical groups, *see* Classical Groups and Homogenous Spaces and Compact Groups and Their Representations. Namely, the irreducible characters for $GL(n,\mathbb{C})$ and $SL(n,\mathbb{C})$, the Schur functions, are generating functions for semistandard tableaux of a given shape. If the entries of the $i$th row of a semistandard tableau are required to be at least $2i-1$, then one speaks of symplectic tableaux, and the irreducible characters for $Sp(2n,\mathbb{C})$ are generating functions for symplectic tableaux of a given shape. We refer the reader to Krattenthaler *et al.* (2000) for more information on these topics.

Objects which are very close to semistandard tableaux are plane partitions. According to MacMahon, a plane partition of shape $\lambda$ is a filling of the Ferrers diagram of $\lambda$ with non-negative integers which is weakly decreasing along rows and columns. See Figure 15b for an example of a plane partition of shape $(3,3,3)$. In particular, semistandard tableaux and plane partitions of rectangular shape are actually equivalent. For, let $T$ be a semistandard tableau of rectangular shape. Then, from each element of the $i$th row we subtract $i$. Finally, the obtained array is rotated by 180°. As a result, we obtain a plane partition. See Figure 15 for a semistandard tableau and a plane partition which correspond to each other under these transformations.

On the other hand, plane partitions can also be realized as three-dimensional objects, by interpreting each entry in the array as a pile of unit cubes of the size of the entry. For example, the plane partition in Figure 15 corresponds to the pile of cubes in Figure 16a. But then, forgetting the three-dimensional view, by embedding the picture in a minimally bounding hexagon, and by filling the emerging empty regions by rhombi of unit length in the unique way this is possible, we obtain a rhombus tiling of a hexagon in which opposite sides have the same length, see Figure 16b.



(a) (b)

**Figure 16** (a) A plane partition; three-dimensional view. (b) A rhombus tiling.

From the rhombus tiling, there is then again an elegant way to go to nonintersecting paths: we mark the mid-points of the edges along two opposite sides, see Figure 17a. Now we draw lattice paths which connect points on different sides, by "following" along the other lozenges, as indicated in Figure 17a by the dashed lines. Clearly, the resulting paths are nonintersecting, that is, no two paths have a common vertex. If we slightly distort the underlying lattice, we get orthogonal paths with horizontal and vertical steps in the positive direction, see Figure 17b.

Rhombus tilings, on their part, are equivalent to perfect matchings of hexagonal graphs. To see this, one places the tiling on the underlying triangular grid, see Figure 18a. Then one places a bond into each rhombus, so that it connects the mid-points of the two triangles out of which the rhombus is composed, see Figure 18b. Finally, one forgets the contour of the tiling, but instead one introduces all the other edges which connect mid-points of adjacent triangles of the triangular grid, see Figure 18c. Thus, one arrives at a perfect matching of the hexagonal graph consisting of the edges connecting mid-points of triangles.

Because of these various connections, enumeration problems for vicious walkers, plane partitions, tableaux, rhombus tilings can be approached by the different methods which are available for the various objects: the determinant theorem from the section "Nonintersecting paths," together with determinant evaluation techniques (cf. the survey Krattenthaler (2005b)), apply, as well as the "Kasteleyn method" from the section "Perfect

matchings and tilings," and also methods from character theory for the classical groups. All of these methods have been applied extensively (see the surveys by Kenyon (2003), Propp (1999), and Krattenthaler *et al.* (2000)), the first and third more frequently for exact enumeration, while the second particularly for asymptotic studies. It should be noted that methods from random matrix theory also apply in certain situations, see Johansson (2002). *See* Growth Processes in Random Matrix Theory and Random Matrix Theory in Physics.

In fact, we missed mentioning a further object, from statistical physics, which in some cases is equivalent to vicious walkers, etc.: fully packed loop configurations. (Fully packed loop configurations are in bijection with six-vertex configurations, see the next section.) If one imposes certain "connectivity constraints" on fully packed loop configurations, then one can construct bijections with rhombus tilings and, hence, with nonintersecting paths and with the other objects discussed in this section. The reader is referred to Di Francesco *et al.* (2004) and references therein.

Having explained the various connections, we cite some fundamental results in the area. (We refer the reader to Bressoud (1999) and Stanley (1999, chapter 7).) MacMahon proved that the number of all plane partitions contained in an $a \times b \times c$ box (when viewed in three dimensions) is equal to

$$\prod_{i=1}^{a}\prod_{j=1}^{b}\prod_{k=1}^{c}\frac{i+j+k-1}{i+j+k-2} \qquad [63]$$

Thus, the number of rhombus tilings of a hexagon with side lengths $a,b,c,a,b,c$ is given by the same number, as well as the number of all vicious walkers $(P_1, P_2, \ldots, P_a)$, where $P_i$ runs from $(0, 2i)$ to $(b+c, b-c+2i), i=1,2,\ldots,a$. More generally, the number of semistandard tableaux of shape $\lambda$ with entries at most $m$ is given by the hook-content formula

$$\prod_{u\in\lambda}\frac{c(u)+m}{h(u)} \qquad [64]$$

where $u$ ranges over all the cells of the Ferrers diagram of $\lambda$, with $c(u)$ being the content of $u$, defined as the difference of the column number and the row number of $u$, and with $h(u)$ being the hook length of $u$, defined as the number of cells in the hook of $u$, the latter consisting of the cells to the right of $u$ in the same row and below $u$ in the same column, including $u$. Thus, this also gives a formula for the number of all vicious walkers $(P_1, P_2, \ldots, P_a)$, where $P_i$ runs from $(0, 2i)$ to $(N, h_i)$. See Krattenthaler *et al.* (2000, section 2) for details. There it is also explained that a Schur function summation formula, together with an analog of the hook-content formula for special orthogonal characters, proves that the number of all vicious walkers $(P_1, P_2, \ldots, P_a)$, where $P_i$ runs from $(0, 2i)$ for $N$ steps is given by

$$\prod_{1\le i\le j\le N}\frac{a+i+j-1}{i+j-1} \qquad [65]$$

The reader is referred to the references given in this section for many more results, in particular, on the enumeration of plane partitions with symmetry, the enumeration of rhombus tilings of regions other than hexagons, and the enumeration of vicious walkers with various starting points and endpoints, under various constraints.

## Six-Vertex Model and Alternating-Sign Matrices

An alternating-sign matrix is a square matrix of 0's, 1's and –1's for which the sum of entries in each row and in each column is 1 and the nonzero entries of each row and of each column alternate in sign. For instance,

$$\begin{pmatrix} 0 & 0 & 1 & 0 & 0 \\ 1 & 0 & -1 & 1 & 0 \\ 0 & 1 & 0 & -1 & 1 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \end{pmatrix}$$

is a $5 \times 5$ alternating-sign matrix. Zeilberger proved that the number of $n \times n$ alternating-sign matrices is given by

$$\prod_{i=0}^{n-1} \frac{(3i+1)!}{(n+i)!} \qquad [66]$$

and he went on to prove the finer version that the number of $n \times n$ alternating-sign matrices with the (unique) 1 in the first row in position $j$ is given by

$$\frac{\binom{n+j-2}{n-1}\binom{2n-j-1}{n-1}}{\binom{3n-2}{n-1}} \prod_{i=0}^{n-1} \frac{(3i+1)!}{(n+i)!} \qquad [67]$$

The first number is also equal to the number of totally symmetric self-complementary plane partitions contained in the $(2n) \times (2n) \times (2n)$ box, but there is no intrinsic explanation why this is so. We refer the reader to Bressoud (1999) for an exposition of these results, and for pointers to the literature containing further unexplained connections between alternating-sign matrices and plane partitions.

While the first result was achieved by a brute-force constant-term approach, the second result is based on the observation that alternating-sign matrices are in bijection with configurations in the six-vertex model on the square grid under domain-wall boundary conditions. This then allowed one to use a formula due to Izergin for the partition function for these six-vertex configurations. Similar formulas for variations of the model have been found by Kuperberg, and by Razumov and Stroganov (see Razumov and Stroganov (2005) and references therein).

A configuration in the six-vertex model is an orientation of edges of a 4-regular graph (i.e., at each vertex there meet exactly four edges) such that at each vertex two edges are oriented towards the vertex and two are oriented away from the vertex. Thus, there are six possible vertex configurations, giving the name of the model, see **Figure 19**. To go from one object to the other, one uses the translation between local configurations at a vertex and entries in alternating-sign matrices indicated in the figure. An example of the correspondence can be found in **Figure 20**.

Another manifestation of alternating-sign matrices and six-vertex configurations are fully packed loop configurations. A fully packed loop configuration on a graph is a collection of edges such that each vertex is

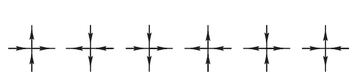

**Figure 19** The six vertex configurations.

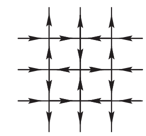
$$\begin{pmatrix} 0 & 1 & 0 \\ 1 & -1 & 1 \\ 0 & 1 & 0 \end{pmatrix}$$



(a) (b)

**Figure 20** (a) An alternating-sign matrix. (b) A six-vertex configuration.

incident to exactly two edges. One obtains a fully packed loop configuration out of a six-vertex configuration by dividing the square lattice into its even and odd sublattice denoted by $A$ and $B$, respectively. Instead of arrows, only those edges are drawn that, on sublattice $A$, point inward and, on sublattice $B$, point outward. The reader is referred to de Gier (2005) and Di Francesco *et al.* (2004) for further reading.

The story of alternating-sign matrices and their connection to the six-vertex model is given a vivid account in Bressoud (1999), with further important results by Kuperberg, Okada, Razumov and Stroganov, referenced in Razumov and Stroganov (2005).

Fully packed loop configurations seem to play an important role in the explicit form of the ground-state vectors of certain Hamiltonians in the dense $O(1)$ loop model. The corresponding conjectures are surveyed in de Gier (2005). There is important progress on these conjectures by Di Francesco and Zinn–Justin (2005, and references therein).

## Binomial Sums and Hypergeometric Series

When dealing with enumerative problems, it is inevitable to deal with binomial sums, that is, sums in which the summands are products/quotients of binomial coefficients and factorials, such as, for example,

$$\sum_{k=0}^{n} \binom{2k}{k}\binom{2n-2k}{n-k}$$

In most cases, the right environment in which one should work is the theory of (generalized) hypergeometric series. These are defined as follows:

$${}_rF_s\left[\begin{matrix} a_1,\ldots,a_r \\ b_1,\ldots,b_s \end{matrix}; z\right] = \sum_{k=0}^{\infty} \frac{(a_1)_k \cdots (a_r)_k}{(b_1)_k \cdots (b_s)_k} \frac{z^k}{k!}$$

where $(\alpha)_k = \alpha(\alpha+1)(\alpha+2)\cdots(\alpha+k-1)$ for $k > 0$, and $(\alpha)_0 = 1$. The symbol $(\alpha)_k$ is called the Pochhammer symbol or shifted factorial. For in-depth treatments of the subject, we refer the reader

to Andrews *et al.* (1999), Gasper and Rahman (2004), and Slater (1966).

Hypergeometric series can be characterized as series in which the quotient of the $(k+1)$st by the $k$th summand is a rational function in $k$. This is also the way to convert binomial sums into their hypergeometric form (respectively to see if this is possible; in most cases it is): form the quotient of the $(k+1)$st by the $k$th summand and read off the parameters $a_1, \ldots, a_r, b_1, \ldots, b_s$, and the argument $z$ from the factorization of the numerator and the denominator polynomials of the rational function, out of these form the corresponding hypergeometric series, and multiply the series by the summand for $k=0$. This is, in fact, a completely routine task, and, indeed, computer algebra programs such as Maple and Mathematica do this automatically.

The reason why hypergeometric series are much more fundamental than the binomial sums themselves is that there are hundreds of ways to write the same sum using binomial coefficients and factorials, whereas there is just one hypergeometric form, that is, hypergeometric series are a kind of normal form for binomial sums. In particular, given a specific binomial sum, it is a hopeless enterprise to scan through all the identities available in the literature for this sum. There may be an identity for it, but perhaps written differently. On the contrary, given a specific hypergeometric series, the list of available identities which apply to this series is usually not large, and tables of such identities can be set up in a systematic way. This has been done (cf. Slater (1966); the most comprehensive table available to this date is contained in the manual of the Mathematica package HYP – see "Further reading"), and scanning through these tables is largely facilitated by the use of the Mathematica package HYP.

We give here some of the most important identities for hypergeometric series. Aside from the binomial theorem, the most important summation formulas are: the Gauß ${}_2F_1$-summation formula

$$ {}_2F_1\left[\begin{matrix} a, b \\ c \end{matrix}; 1\right] = \frac{\Gamma(c)\Gamma(c-a-b)}{\Gamma(c-a)\Gamma(c-b)} $$

provided $\Re(c-a-b) > 0$,
the Pfaff–Saalschütz summation formula

$$ {}_3F_2\left[\begin{matrix} a, b, -n \\ c, 1+a+b-c-n \end{matrix}; 1\right] = \frac{(c-a)_n (c-b)_n}{(c)_n (c-a-b)_n} $$

provided $n$ is a non-negative integer, and
the Dougall summation formula

$$ {}_7F_6\left[\begin{matrix} a, a/2+1, b, c, d, 1+2a-b-c-d+n, -n \\ a/2, 1+a-b, 1+a-c, 1+a-d, \\ -a+b+c+d-n, a+1+n \end{matrix}; 1\right] $$
$$ = \frac{(1+a)_n (1+a-b-c)_n (1+a-b-d)_n (1+a-c-d)_n}{(1+a-b)_n (1+a-c)_n (1+a-d)_n (1+a-b-c-d)_n} $$

provided $n$ is a non-negative integer.

Some of the most important transformation formulas are
the Euler transformation formula

$$ {}_2F_1\left[\begin{matrix} a, b \\ c \end{matrix}; z\right] = (1-z)^{c-a-b} {}_2F_1\left[\begin{matrix} c-a, c-b \\ c \end{matrix}; z\right] $$

provided $|z| < 1$,
the Kummer transformation formula

$$ {}_3F_2\left[\begin{matrix} a, b, c \\ d, e \end{matrix}; 1\right] = \frac{\Gamma(e)\Gamma(d+e-a-b-c)}{\Gamma(e-a)\Gamma(d+e-b-c)} \times {}_3F_2\left[\begin{matrix} a, d-b, d-c \\ d, d+e-b-c \end{matrix}; 1\right] $$

provided both series converge,
and the Whipple transformation formulas

$$ {}_4F_3\left[\begin{matrix} a, b, c, -n \\ e, f, 1+a+b+c-e-f-n \end{matrix}; 1\right] = \frac{(e-a)_n (f-a)_n}{(e)_n (f)_n} \times {}_4F_3\left[\begin{matrix} -n, a, 1+a+c-e-f-n, 1+a+b-e-f-n \\ 1+a+b+c-e-f-n, 1+a-e-n, 1+a-f-n \end{matrix}; 1\right] \quad [68] $$

where $n$ is a non-negative integer, and

$$ {}_7F_6\left[\begin{matrix} a, 1+\frac{a}{2}, b, c, d, e, -n \\ \frac{a}{2}, 1+a-b, 1+a-c, 1+a-d, 1+a-e, 1+a+n \end{matrix}; 1\right] = \frac{(1+a)_n (1+a-d-e)_n}{(1+a-d)_n (1+a-e)_n} \times {}_4F_3\left[\begin{matrix} 1+a-b-c, d, e, -n \\ 1+a-b, 1+a-c, -a+d+e-n \end{matrix}; 1\right] \quad [69] $$

provided $n$ is a non-negative integer.

Since about 1990, for the verification of binomial and hypergeometric series, there are automatic tools available. The book by Petkovšek *et al.* (1996) is an excellent introduction into these aspects. The philosophy is as follows. Suppose we are given a binomial or hypergeometric series $S(n) = \sum_k F(n,k)$. The Gosper–Zeilberger algorithm (see "Further reading") (cf. Petkovšek *et al.* (1996); a simplified version was presented in the reference Zeilberger in "Further reading") will find a linear recurrence

$$A_0(n)S(n) + A_1(n)S(n+1) + \cdots + A_d(n)S(n+d) = C(n) \qquad [70]$$

for some $d$, where the coefficients $A_i(n)$ are polynomials in $n$, and where $C(n)$ is a certain function in $n$, with proof!

If, for example, we suspected that $S(n) = \text{RHS}(n)$, where $\text{RHS}(n)$ is some closed-form expression, then we just have to verify that $\text{RHS}(n)$ satisfies the recurrence [70] and check $S(n) = \text{RHS}(n)$ for sufficiently many initial values of $n$ to have a proof for the identity $S(n) = \text{RHS}(n)$ for all n. On the other hand, if $\text{RHS}(n)$ was a different sum, then we would apply the algorithm to find a recurrence for $\text{RHS}(n)$. If it turns out to be the same recurrence then, again, a check of $S(n) = \text{RHS}(n)$ for a few initial values will provide a full proof of $S(n) = \text{RHS}(n)$ *for all* $n$.

Even in the case that we do not have a conjectured expression $\text{RHS}(n)$, this is not the end of the story. Given a recurrence of the type [70], the Petkovšek algorithm (see "Further reading") (cf. Petkovšek *et al.* (1996)) is able to find a closed-form solution (where "closed form" has a precise meaning), respectively tell that there is no closed-form solution.

The fascinating point about both algorithms is that neither do we have to know what the algorithm does internally nor do we have to check that. For the Petkovšek algorithm, this is obvious anyway because, once the computer says that a certain expression is a solution of [70], it is a routine matter to check that. This is less obvious for the Gosper–Zeilberger algorithm. However, what the Gosper–Zeilberger algorithm does is, for a given sum $S(n) = \sum_k F(n,k)$, it finds polynomials $A_0(n)$, $A_1(n), \ldots, A_d(n)$ and an expression $G(n,k)$ (which is, in fact, a rational multiple of $F(n,k)$), such that

$$A_0(n)F(n,k) + A_1(n)F(n+1,k) + \cdots + A_d(n)F(n+d,k) = G(n,k+1) - G(n,k) \qquad [71]$$

for some $d$. Because of the properties of $F(n,k)$ and $G(n,k)$, which are part of the theory, this is an identity which can be directly verified by clearing all common factors and checking the remaining identity between rational functions in $n$ and $k$. However, we may now sum both sides of [71] over $k$ to obtain a recurrence of the form [70].

Algorithms for multiple sums are also available (see "Further reading"). They follow ideas by Wilf and Zeilberger (1992) (of which a simplified version is presented in a Mohammed and Zeilberger preprint (see "Further reading")); however, they run more quickly in capacity problems. Schneider (2005) is currently developing a very promising new algorithmic approach to the automatic treatment of multisums. *See* q-Special Functions and Statistical Mechanics and Combinatorial Problems.

# Compact Groups and Their Representations

**A Kirillov**, University of Pennsylvania, Philadelphia, PA, USA
**A Kirillov, Jr.**, Stony Brook University, Stony Brook, NY, USA

In this article, we describe the structure and representation theory of compact Lie groups. Throughout the article, $G$ is a compact real Lie group with Lie algebra $\mathfrak{g}$. Unless otherwise stated, $G$ is assumed to be connected. The word "group" will always mean a "Lie group" and the word "subgroup" will mean a closed Lie subgroup. The notation Lie($H$) stands for the Lie algebra of a Lie group $H$. We assume that the reader is familiar with the basic facts of the theory of Lie groups and Lie algebras, which can be found in Lie Groups: General Theory, or in the books listed in the bibliography.

## Examples of Compact Lie Groups

Examples of compact groups include

- finite groups,
- quotient groups $\mathbb{T}^n = \mathbb{R}^n/\mathbb{Z}^n$, or more generally, $V/L$, where $V$ is a finite-dimensional real vector space and $L$ is a lattice in $V$, that is, a discrete subgroup generated by some basis in $V$ – groups of this type are called “tori”; it is known that every commutative connected compact group is a torus;
- unitary groups $\mathrm{U}(n)$ and special unitary groups $\mathrm{SU}(n), n \geq 2$;
- orthogonal groups $\mathrm{O}(n)$ and $\mathrm{SO}(n), n \geq 3$; and
- the groups $U(n, \mathbb{H}), n \geq 1$, of unitary quaternionic transformations, which are isomorphic to $\mathrm{Sp}(n) := \mathrm{Sp}(n, \mathbb{C}) \cap \mathrm{SU}(2n)$.

The groups $\mathrm{O}(n)$ have two connected components, one of which is $\mathrm{SO}(n)$. The groups $\mathrm{SU}(n)$ and $\mathrm{Sp}(n)$ are connected and simply connected.

The groups $\mathrm{SO}(n)$ are connected but not simply connected: for $n \geq 3$, the fundamental group of $\mathrm{SO}(n)$ is $\mathbb{Z}_2$. The universal cover of $\mathrm{SO}(n)$ is a simply connected compact Lie group denoted by $\mathrm{Spin}(n)$. For small $n$, we have isomorphisms: $\mathrm{Spin}(3) \simeq \mathrm{SU}(2), \mathrm{Spin}(4) \simeq \mathrm{SU}(2) \times \mathrm{SU}(2), \mathrm{Spin}(5) \simeq \mathrm{Sp}(4)$, and $\mathrm{Spin}(6) \simeq \mathrm{SU}(4)$.

## Relation to Semisimple Lie Algebras and Lie Groups

### Reductive Groups

A Lie algebra $\mathfrak{g}$ is called

- “simple” if it is nonabelian and has no ideals different from $\{0\}$ and $\mathfrak{g}$ itself;
- “semisimple” if it is a direct sum of simple ideals; and
- “reductive” if it is a direct sum of semisimple and commutative ideals.

We call a connected Lie group $G$ “simple” or “semisimple” if $\mathrm{Lie}(G)$ has this property.

**Theorem 1** *Let $G$ be a connected compact Lie group and $\mathfrak{g} = \mathrm{Lie}(G)$. Then*

(i) *The Lie algebra $\mathfrak{g} = \mathrm{Lie}(G)$ is reductive: $\mathfrak{g} = \mathfrak{a} \oplus \mathfrak{g}'$, where $\mathfrak{a}$ is abelian and $\mathfrak{g}' = [\mathfrak{g}, \mathfrak{g}]$ is semisimple.*
(ii) *The group $G$ can be written in the form $G = (A \times K)/Z$, where $A$ is a torus, $K$ is a connected, simply connected compact semisimple Lie group, and $Z$ is a finite central subgroup in $A \times K$.*
(iii) *If $G$ is simply connected, it is a product of simple compact Lie groups.*

The proof of these results is based on the fact that the Killing form of $\mathfrak{g}$ is negative semidefinite.

**Example 1** The group $\mathrm{U}(n)$ contains as the center the subgroup $C$ of scalar matrices. The quotient group $\mathrm{U}(n)/C$ is simple and isomorphic to $\mathrm{SU}(n)/\mathbb{Z}_n$. The presentation of Theorem 1 in this case is

$$\begin{aligned} \mathrm{U}(n) &= \left(\mathbb{T}^1 \times \mathrm{SU}(n)\right)/\mathbb{Z}_n \\ &= (C \times \mathrm{SU}(n))/(C \cap \mathrm{SU}(n)) \end{aligned}$$

For the group $\mathrm{SO}(4)$ the presentation is $(\mathrm{SU}(2) \times \mathrm{SU}(2))/\{\pm(1 \times 1)\}$.

This theorem effectively reduces the study of the structure of connected compact groups to the study of simply connected compact simple Lie groups.

### Complexification of a Compact Lie Group

Recall that for a real Lie algebra $\mathfrak{g}$, its complexification is $\mathfrak{g}_{\mathbb{C}} = \mathfrak{g} \otimes \mathbb{C}$ with obvious commutator. It is also well known that $\mathfrak{g}_{\mathbb{C}}$ is semisimple or reductive iff $\mathfrak{g}$ is semisimple or reductive, respectively. There is a subtlety in the case of simple algebras: it is possible that a real Lie algebra is simple, but its complexification $\mathfrak{g}_{\mathbb{C}}$ is only semisimple. However, this problem never arises for Lie algebras of compact groups: if $\mathfrak{g}$ is a Lie algebra of a real compact Lie group, then $\mathfrak{g}$ is simple if and only if $\mathfrak{g}_{\mathbb{C}}$ is simple.

The notion of complexification for Lie groups is more delicate.

**Definition 1** Let $G$ be a connected real Lie group with Lie algebra $\mathfrak{g}$. A complexification of $G$ is a connected complex Lie group $G_{\mathbb{C}}$ (i.e., a complex manifold with a structure of a Lie group such that group multiplication is given by a complex analytic map $G_{\mathbb{C}} \times G_{\mathbb{C}} \to G_{\mathbb{C}}$), which contains $G$ as a closed subgroup, and such that $\mathrm{Lie}(G_{\mathbb{C}}) = \mathfrak{g}_{\mathbb{C}}$. In this case, we will also say that $G$ is a real form of $G_{\mathbb{C}}$.

It is not obvious why such a complexification exists at all; in fact, for arbitrary real group it may not exist. However, for compact groups we do have the following theorem.

**Theorem 2** *Let $G$ be a connected compact Lie group. Then it has a unique complexification $G_{\mathbb{C}} \supset G$. Moreover, the following properties hold:*

(i) *The inclusion $G \subset G_{\mathbb{C}}$ is a homotopy equivalence. In particular, $\pi_1(G) = \pi_1(G_{\mathbb{C}})$ and the quotient space $G_{\mathbb{C}}/G$ is contractible.*
(ii) *Every complex finite-dimensional representation of $G$ can be uniquely extended to a complex analytic representation of $G_{\mathbb{C}}$.*

Since the Lie algebra of a compact Lie group $G$ is reductive, we see that $G_{\mathbb{C}}$ must be reductive; if $G$ is semisimple or simple, then so is $G_{\mathbb{C}}$. The natural question is whether every complex reductive group can be obtained in this way. The following theorem gives a partial answer.

**Theorem 3** *Every connected complex semisimple Lie group $H$ has a compact real form: there is a compact real subgroup $K \subset H$ such that $H = K_{\mathbb{C}}$. Moreover, such a compact real form is unique up to conjugation.*

**Example 2**

(i) The unitary group $\mathrm{U}(n)$ is a compact real form of the group $\mathrm{GL}(n, \mathbb{C})$.
(ii) The orthogonal group $\mathrm{SO}(n)$ is a compact real form of the group $\mathrm{SO}(n, \mathbb{C})$.
(iii) The group $\mathrm{Sp}(n)$ is a compact real form of the group $\mathrm{Sp}(n, \mathbb{C})$.
(iv) The universal cover of $\mathrm{GL}(n, \mathbb{C})$ has no compact real form.

These results have a number of important applications. For example, they show that study of representations of a semisimple complex group $H$ can be replaced by the study of representations of its compact form; in particular, every representation is completely reducible (this argument is known as Weyl's unitary trick).

### Classification of Simple Compact Lie Groups

Theorem 1 essentially reduces such classification to classification of simply connected simple compact groups, and Theorems 2 and 3 reduce it to the classification of simple complex Lie algebras. Since the latter is well known, we get the following result.

**Theorem 4** *Let $G$ be a connected, simply connected simple compact Lie group. Then $\mathfrak{g}_{\mathbb{C}}$ must be a simple complex Lie algebra and thus can be described by a Dynkin diagram of one the following types: $A_n, B_n, C_n, D_n, E_6, E_7, E_8, F_4, G_2$.*

*Conversely, for each Dynkin diagram in the above list, there exists a unique, up to isomorphism, simply connected simple compact Lie group whose Lie algebra is described by this Dynkin diagram.*

For types $A_n, \ldots, D_n$, the corresponding compact Lie groups are well-known classical groups shown in the table below:

| $A_n, n \geq 1$ | $B_n, n \geq 2$ | $C_n, n \geq 3$ | $D_n, n \geq 4$ |
|---|---|---|---|
| $\mathrm{SU}(n+1)$ | $\mathrm{Spin}(2n+1)$ | $\mathrm{Sp}(n)$ | $\mathrm{Spin}(2n)$ |

The restrictions on $n$ in this table are made to avoid repetitions which appear for small values of $n$. Namely, $A_1 = B_1 = C_1$, which gives $\mathrm{SU}(2) = \mathrm{Spin}(3) = \mathrm{Sp}(1)$; $D_2 = A_1 \cup A_1$, which gives $\mathrm{Spin}(4) = \mathrm{SU}(2) \times \mathrm{SU}(2)$; $B_2 = C_2$, which gives $\mathrm{SO}(5) = \mathrm{Sp}(4)$; and $A_3 = D_3$, which gives $\mathrm{SU}(4) = \mathrm{Spin}(6)$. Other than that, all entries are distinct.

Exceptional groups $E_6, \ldots, G_2$ also admit explicit geometric and algebraic descriptions which are related to the exceptional nonassociative algebra $\mathbb{O}$ of the so-called octonions (or Cayley numbers). For example, the compact group of type $G_2$ can be defined as a subgroup of $\mathrm{SO}(7)$ which preserves an almost-complex structure on $S^6$. It can also be described as the subgroup of $\mathrm{GL}(7, \mathbb{R})$ which preserves one quadratic and one cubic form, or, finally, as a group of all automorphisms of $\mathbb{O}$.

## Maximal Tori

### Main Properties

In this section, $G$ is a compact connected Lie group.

**Definition 2** A "maximal torus" in $G$ is a maximal connected commutative subgroup $T \subset G$.

The following theorem lists the main properties of maximal tori.

**Theorem 5**

(i) *For every element $g \in G$, there exists a maximal torus $T \ni g$.*
(ii) *Any two maximal tori in $G$ are conjugate.*
(iii) *If $g \in G$ commutes with all elements of a maximal torus $T$, then $g \in T$.*
(iv) *A connected subgroup $H \subset G$ is a maximal torus iff the Lie algebra* $\mathrm{Lie}(H)$ *is a maximal abelian subalgebra in* $\mathrm{Lie}(G)$.

**Example 3** Let $G = \mathrm{U}(n)$. Then the set $T$ of diagonal unitary matrices is a maximal torus in $G$; moreover, every maximal torus is of this form after a suitable unitary change of basis. In particular, this implies that every element in $G$ is conjugate to a diagonal matrix.

**Example 4** Let $G = \mathrm{SO}(3)$. Then the set $D$ of diagonal matrices is a maximal commutative subgroup in $G$, but not a torus. Here $D$ consists of four elements and is not connected.

### Maximal Tori and Cartan Subalgebras

The study of maximal tori in compact Lie groups is closely related to the study of Cartan subalgebras in reductive complex Lie algebras. For convenience of readers, we briefly recall the appropriate definitions

here; details can be found in Serre (2001) or in Lie Groups: General Theory.

**Definition 3** Let $\mathfrak{a}$ be a complex reductive Lie algebra. A Cartan subalgebra $\mathfrak{h} \subset \mathfrak{a}$ is a maximal commutative subalgebra consisting of semisimple elements.

Note that for general Lie algebras Cartan subalgebra is defined in a different way; however, for reductive algebras the definition given above is equivalent to the standard one.

A choice of a Cartan subalgebra gives rise to the so-called root decomposition: if $\mathfrak{h} \subset \mathfrak{a}$ is a Cartan subalgebra in a complex reductive Lie algebra, then we can write

$$\mathfrak{a} = \mathfrak{h} \oplus \left( \bigoplus_{\alpha \in R} \mathfrak{a}_\alpha \right) \qquad [1]$$

where

$$\mathfrak{a}_\alpha = \{x \in \mathfrak{a} |\ \mathrm{ad}\, h.x = \langle \alpha, h \rangle x \, \forall h \in \mathfrak{h}\}$$
$$R = \{\alpha \in \mathfrak{h}^* - \{0\} | \mathfrak{a}_\alpha \neq 0\} \subset \mathfrak{h}^*$$

The set $R$ is called the "root system" of $\mathfrak{a}$ with respect to Cartan subalgebra $\mathfrak{h}$; elements $\alpha \in R$ are called "roots." We will also frequently use elements $\alpha^\vee \in \mathfrak{h}$ defined by $\langle \alpha^\vee, \beta \rangle = 2(\alpha, \beta)/(\alpha, \alpha)$ where $( \, , \, )$ is a nondegenerate invariant bilinear form on $\mathfrak{a}^*$ and $\langle \, , \, \rangle$ is the pairing between $\mathfrak{a}$ and $\mathfrak{a}^*$. It can be shown that so defined $\alpha^\vee$ does not depend on the choice of the form $( \, , \, )$.

**Theorem 6** *Let $G$ be a connected compact Lie group with Lie algebra $\mathfrak{g}$, and let $T \subset G$ be a maximal torus in $G$, $\mathfrak{t} = \mathrm{Lie}(T) \subset \mathfrak{g}$. Let $\mathfrak{g}_\mathbb{C}, G_\mathbb{C}$ be the complexification of $\mathfrak{g}$, $G$ as in Theorem 2.*

*Let $\mathfrak{h} = \mathfrak{t}_\mathbb{C} \subset \mathfrak{g}_\mathbb{C}$. Then $\mathfrak{h}$ is a Cartan subalgebra in $\mathfrak{g}_\mathbb{C}$, and the corresponding root system $R \subset \mathrm{i}\mathfrak{t}^*$. Conversely, every Cartan subalgebra in $\mathfrak{g}_\mathbb{C}$ can be obtained as $\mathfrak{t}_\mathbb{C}$ for some maximal torus $T \subset G$.*

### Weights and Roots

Let $G$ be semisimple. Recall that the root lattice $Q \subset \mathrm{i}\mathfrak{t}^*$ is the abelian group generated by roots $\alpha \in R$, and let the coroot lattice $Q^\vee \subset \mathrm{i}\mathfrak{t}$ be the abelian group generated by coroots $\alpha^\vee, \alpha \in R$. Define also the weight and coweight lattices by

$$P = \{\lambda | \langle \alpha^\vee, \lambda \rangle \in \mathbb{Z} \quad \forall \alpha \in R\} \subset \mathrm{i}\mathfrak{t}^*$$
$$P^\vee = \{t | \langle t, \alpha \rangle \in \mathbb{Z} \quad \forall \alpha \in R\} \subset \mathrm{i}\mathfrak{t},$$

where $\langle \cdot, \cdot \rangle$ is the pairing between $\mathfrak{t}$ and the dual vector space $\mathfrak{t}^*$.

It follows from the definition of root system that we have inclusions

$$Q \subset P \subset \mathrm{i}\mathfrak{t}^*$$
$$Q^\vee \subset P^\vee \subset \mathrm{i}\mathfrak{t} \qquad [2]$$

Both $P, Q$ are lattices in $\mathrm{i}\mathfrak{t}^*$; thus, the index $(P:Q)$ is finite. It can be computed explicitly: if $\alpha_i$ is a basis of the root system, then the fundamental weights $\omega_i$ defined by

$$\langle \alpha_i^\vee, \omega_j \rangle = \delta_{ij}$$

form a basis of $P$. The simple roots $\alpha_i$ are related to fundamental weights $\omega_j$ by the Cartan matrix $A$: $\alpha_i = \sum A_{ij}\omega_j$. Therefore, $(P:Q) = (P^\vee : Q^\vee) = |\det A|$.

Definitions of $P, Q, P^\vee, Q^\vee$ also make sense when $\mathfrak{g}$ is reductive but not semisimple. However, in this case they are no longer lattices: $\mathrm{rk} Q < \dim \mathfrak{t}^*$, and $P$ is not discrete.

We can now give more precise information about the structure of the maximal torus.

**Lemma 1** *Let $T$ be a compact connected commutative Lie group, and $\mathfrak{t} = \mathrm{Lie}(T)$ its Lie algebra. Then the exponential map is surjective and preimage of unit is a lattice $L \subset \mathfrak{t}$. There is an isomorphism of Lie groups*

$$\exp : \mathfrak{t}/L \to T$$

*In particular, $T \simeq \mathbb{R}^r/\mathbb{Z}^r = \mathbb{T}^r, r = \dim T$.*

Let $X(T) \subset \mathrm{i}\mathfrak{t}^*$ be the lattice dual to $(2\pi \mathrm{i})^{-1}L$:

$$X(T) = \{\lambda \in \mathrm{i}\mathfrak{t}^* | \langle \lambda, l \rangle \in 2\pi \mathrm{i}\mathbb{Z} \ \forall l \in L\} \qquad [3]$$

It is called the "character lattice" for $T$ (see the subsection "Examples of representations").

**Theorem 7** *Let $G$ be a compact connected Lie group, and let $T \subset G$ be a maximal torus in $G$.*

*Then $Q \subset X(T) \subset P$. Moreover, the group $G$ is uniquely determined by the Lie algebra $\mathfrak{g}$ and the lattice $X(T) \in \mathrm{i}\mathfrak{t}^*$ which can be any lattice between $Q$ and $P$.*

**Corollary** *For a given complex semisimple Lie algebra $\mathfrak{a}$, there are only finitely many (up to isomorphism) compact connected Lie groups $G$ with $\mathfrak{g}_\mathbb{C} = \mathfrak{a}$.*

*The largest of them is the simply connected group, for which $T = \mathfrak{t}/2\pi \mathrm{i} Q^\vee, X(T) = P$; the smallest is the so-called "adjoint group," for which $T = \mathfrak{t}/2\pi \mathrm{i} P^\vee$, $X(T) = Q$.*

**Example 5** Let $G = \mathrm{U}(n)$. Then $\mathrm{i}\mathfrak{t} = \{$real diagonal matrices$\}$. Choosing the standard basis of matrix

units in it, we identify it $\simeq \mathbb{R}^n$, which also allows us to identify $\mathrm{it}^* \simeq \mathbb{R}^n$. Under this identification,

$$Q = \left\{(\lambda_1, \ldots, \lambda_n) | \lambda_i \in \mathbb{Z}, \sum \lambda_i = 0\right\}$$
$$P = \left\{(\lambda_1, \ldots, \lambda_n) | \lambda_i \in \mathbb{R}, \lambda_i - \lambda_j \in \mathbb{Z}\right\}$$
$$X(T) = \mathbb{Z}^n$$

Note that $Q, P$ are not lattices: $Q \simeq \mathbb{Z}^{n-1}$, $P \simeq \mathbb{R} \times \mathbb{Z}^{n-1}$.

Now let $G = \mathrm{SU}(n)$. Then $\mathrm{it}^* = \mathbb{R}^n / \mathbb{R} \cdot (1, \ldots, 1)$, and $Q, P$ are the images of $Q, P$ for $G = \mathrm{U}(n)$ in this quotient. In this quotient they are lattices, and $(P : Q) = n$. The character lattice in this case is $X(T) = P$, since $\mathrm{SU}(n)$ is simply connected. The adjoint group is $\mathrm{PSU}(n) = \mathrm{SU}(n)/C$, where $C = \{\lambda \cdot \mathrm{id} | \lambda^n = 1\}$ is the center of $\mathrm{SU}(n)$.

### Weyl Group

Let us fix a maximal torus $T \subset G$. Let $N(T) \subset G$ be the normalizer of $T$ in $G$: $N(T) = \{g \in G \,|\, gTg^{-1} = T\}$. For any $g \in N(T)$ the transformation $A(g) : t \mapsto gtg^{-1}$ is an automorphism of $T$. According to Theorem 5, this automorphism is trivial iff $g \in T$. So in fact, it is the quotient group $N(T)/T$ which acts on $T$.

**Definition 4** The group $W = N(T)/T$ is called the "Weyl group" of $G$.

Since the Weyl group acts faithfully on $\mathfrak{t}$ and $\mathfrak{t}^*$, it is common to consider $W$ as a subgroup in $\mathrm{GL}(\mathfrak{t}^*)$. It is known that $W$ is finite.

The Weyl group can also be defined in terms of Lie algebra $\mathfrak{g}$ and its complexification $\mathfrak{g}_{\mathbb{C}}$.

**Theorem 8** *The Weyl group coincides with the subgroup in* $\mathrm{GL}(\mathrm{it}^*)$ *generated by reflections* $s_\alpha : x \mapsto x - (2(\alpha, x))/(\alpha, \alpha), \alpha \in R$, *where, as before*, $(\,,\,)$ *is a nondegenerate invariant bilinear form on* $\mathfrak{g}^*$.

**Theorem 9**

(i) *Two elements* $t_1, t_2 \in T$ *are conjugate in* $G$ *iff* $t_2 = w(t_1)$ *for some* $w \in W$.
(ii) *There exists a natural homeomorphism of quotient spaces* $G/\mathrm{Ad}G \simeq T/W$, *where* $\mathrm{Ad}G$ *stands for action of* $G$ *on itself by conjugation. (Note, however, that these quotient spaces are not manifolds: they have singularities.)*
(iii) *Let us call a function* $f$ *on* $G$ *central if* $f(hgh^{-1}) = f(g)$ *for any* $g, h \in G$. *Then the restriction map gives an isomorphism*

$$\{\textit{continuous central functions on } G\} \simeq \{W - \textit{invariant continuous functions on } T\}$$

**Example 6** Let $G = \mathrm{U}(n)$. The set of diagonal unitary matrices is a maximal torus, and the Weyl group is the symmetric group $S_n$ acting on diagonal matrices by permutations of entries. In this case, Theorem 9 shows that if $f(U)$ is a central function of a unitary matrix, then $f(U) = \tilde{f}(\lambda_1, \ldots, \lambda_n)$, where $\lambda_i$ are eigenvalues of $U$ and $\tilde{f}$ is a symmetric function in $n$ variables.

## Representations of Compact Groups

### Basic Notions

By a representation of $G$ we understand a pair $(\pi, V)$, where $V$ is a complex vector space and $\pi$ is a continuous homomorphism $G \to \mathrm{Aut}(V)$. This notation is often shortened to $\pi$ or $V$. In this article, we only consider finite-dimensional (f.d.) representations; in this case, the homomorphism $\pi$ is automatically smooth and even real-analytic.

We associate to any f.d. representation $(\pi, V)$ of $G$ the representation $(\pi_*, V)$ of the Lie algebra $\mathfrak{g} = \mathrm{Lie}(G)$ which is just the derivative of the map $\pi : G \to \mathrm{Aut}V$ at the unit point $e \in G$. In terms of the exponential map, we have the following commutative diagram:

$$\begin{array}{ccc} G & \xrightarrow{\pi} & \mathrm{Aut}V \\ {\scriptstyle\exp}\uparrow & & \uparrow{\scriptstyle\exp} \\ \mathfrak{g} & \xrightarrow{\pi_*} & \mathrm{End}V \end{array}$$

Choosing a basis in $V$, we can write the operators $\pi(g)$ and $\pi_*(X)$ in matrix form and consider $\pi$ and $\pi_*$ as matrix-valued functions on $G$ and $\mathfrak{g}$. The diagram above means that

$$\pi(\exp X) = e^{\pi_*(X)} \qquad [4]$$

Recall that if $G$ is connected, simply connected, then every representation of $\mathfrak{g}$ can be uniquely lifted to a representation of $G$. Thus, classification of representations of connected simply connected Lie groups is equivalent to the classification of representations of Lie algebras.

Let $(\pi_1, V_1)$ and $(\pi_2, V_2)$ be two representations of the same group $G$. An operator $A \in \mathrm{Hom}(V_1, V_2)$ is called an "intertwining operator," or simply an "intertwiner," if $A \circ \pi_1(g) = \pi_2(g) \circ A$ for all $g \in G$. Two representations are called "equivalent" if they admit an invertible intertwiner. In this case, using an appropriate choice of bases, we can write $\pi_1$ and $\pi_2$ by the same matrix-valued function.

Let $(\pi, V)$ be a representation of $G$. If all operators $\pi(g), g \in G$, preserve a subspace $V_1 \subset V$, then the restrictions $\pi_1(g) = \pi(g)|_{V_1}$ define a "subrepresentation" $(\pi_1, V_1)$ of $(\pi, V)$. In this case, the quotient space $V_2 = V/V_1$ also has a canonical structure of a representation, called the "quotient representation."

A representation $(\pi, V)$ is called "reducible" if it has a nontrivial (different from $V$ and $\{0\}$) subrepresentation. Otherwise it is called "irreducible."

We call representation $(\pi, V)$ "unitary" if $V$ is a Hilbert space and all operators $\pi(g), g \in G$, are unitary, that is, given by unitary matrices in any orthonormal basis. We use a short term "unirrep" for a "unitary irreducible representation."

### Main Theorems

The following simple but important result was one of the first discoveries in representation theory. It holds for representations of any group, not necessarily compact.

**Theorem 10** (Schur lemma). *Let $(\pi_i, V_i), i = 1, 2$, be any two irreducible finite-dimensional representations of the same group $G$. Then any intertwiner $A : V_1 \to V_2$ is either invertible or zero.*

**Corollary 1** *If $V$ is an irreducible f.d. representation, then any intertwiner $A : V \to V$ is scalar: $A = c \cdot \mathrm{id}, c \in \mathbb{C}$.*

**Corollary 2** *Every irreducible representation of a commutative group is one dimensional.*

The following theorem is one of the fundamental results of the representation theory of compact groups. Its proof is based on the technique of invariant integrals on a compact group, which will be discussed in the next section.

**Theorem 11**

(i) *Any f.d. representation of a compact group is equivalent to a unitary representation.*

(ii) *Any f.d. representation is completely reducible: it can be decomposed into direct sum*

$$V = \bigoplus n_i V_i$$

*where $V_i$ are pairwise nonequivalent unirreps. Numbers $n_i \in \mathbb{Z}_+$ are called "multiplicities."*

### Examples of Representations

The representation theory looks rather different for abelian (i.e., commutative) and nonabelian groups. Here we consider two simplest examples of both kinds.

Our first example is a one-dimensional compact connected Lie group. Topologically, it is a circle which we realize as a set $\mathbb{T} \simeq \mathrm{U}(1)$ of all complex numbers $t$ with absolute value 1.

Every unirrep of $\mathbb{T}$ is one dimensional; thus, it is just a continuous multiplicative map $\pi$ of $\mathbb{T}$ to itself. It is well known that every such map has the form

$$\pi_k(t) = t^k \quad \text{for some } k \in \mathbb{Z}$$

The collection of all unirreps of $\mathbb{T}$ is itself a group, called "Pontrjagin dual" of $\mathbb{T}$ and denoted by $\widehat{\mathbb{T}}$. This group is isomorphic to $\mathbb{Z}$.

By Theorem 11, any f.d. representation $\pi$ of $\mathbb{T}$ is equivalent to a direct sum of one-dimensional unirreps. So, an equivalence class of $\pi$ is defined by the multiplicity function $\mu$ on $\widehat{\mathbb{T}} = \mathbb{Z}$ taking nonnegative values:

$$\pi \simeq \sum_{k \in \mathbb{Z}} \mu(k) \cdot \pi_k$$

The many-dimensional case of compact connected abelian Lie group can be treated in a similar way. Let $T$ be a torus, that is, an abelian compact group, $\mathfrak{t} = \mathrm{Lie}(T)$. Then every irreducible representation of $T$ is one dimensional and thus is defined by a group homomorphism $\chi : T \to \mathbb{T}^1 = \mathrm{U}(1)$. Such homomorphisms are called "characters" of $T$. One easily sees that such characters themselves form a group (Pontrjagin dual of $T$). If we denote by $L$ the kernel of the exponential map $\mathfrak{t} \to T$ (see Lemma 1), one easily sees that every character has a form

$$\chi(\exp(t)) = \mathrm{e}^{\langle t, \lambda \rangle}, \quad t \in \mathfrak{t}, \; \lambda \in X(T)$$

where $X(T) \subset \mathrm{i}\mathfrak{t}^*$ is the lattice defined by [3]. Thus, we can identify the group of characters $\widehat{T}$ with $X(T)$. In particular, this shows that $\widehat{T} \simeq \mathbb{Z}^{\dim T}$.

The second example is the group $G = \mathrm{SU}(2)$, the simplest connected, simply connected nonabelian compact Lie group. Topologically, $G$ is a three-dimensional sphere since the general element of $G$ is a matrix of the form

$$g = \begin{pmatrix} a & b \\ -\bar{b} & \bar{a} \end{pmatrix}, \quad a, b \in \mathbb{C}, \; |a|^2 + |b|^2 = 1$$

Let $V$ be two-dimensional complex vector space, realized by column vectors $\binom{u}{v}$. The group $G$ acts naturally on $V$. This action induces the representation $\Pi$ of $G$ in the space $S(V)$ of all polynomials in $u$, $v$. It is infinite dimensional, but has many f.d. subrepresentations. In particular, let $S^k(V)$, or simply $S^k$, be the space of all homogeneous polynomials of degree $k$. Clearly, $\dim S^k = k + 1$.

It turns out that the corresponding f.d. representations $(\Pi_k, S^k), k \geq 0$, are irreducible, pairwise nonequivalent, and exhaust the set $\widehat{G}$ of all unirreps.

Some particular cases are of special interest:

1. $k = 0$. The space $V_0$ consists of constant functions and $\Pi_0$ is the trivial one-dimensional representation: $\Pi_0(g) \equiv 1$.
2. $k = 1$. The space $V_1$ is identical to $V$ and $\Pi_1$ is just the tautological representation $\pi(g) \equiv g$.
3. $k = 2$. The space $V_2$ is spanned by monomials $u^2, uv, v^2$. The remarkable fact is that this

representation is equivalent to a real one. Namely, in the new basis

$$x = \frac{u^2+v^2}{2}, \qquad y = \frac{u^2-v^2}{2\mathrm{i}}, \qquad z = \mathrm{i}uv$$

we have

$$\Pi_2\begin{pmatrix} a & b \\ -\overline{b} & \overline{a}\end{pmatrix} = \begin{pmatrix} \mathrm{Re}(a^2+b^2) & 2\mathrm{Im}(ab) & \mathrm{Im}(b^2-a^2) \\ 2\mathrm{Im}(a\overline{b}) & |a|^2-|b|^2 & 2\mathrm{Re}(a\overline{b}) \\ \mathrm{Im}(a^2+b^2) & 2\mathrm{Re}(ab) & \mathrm{Re}(a^2-b^2)\end{pmatrix}$$

This formula defines a homomorphism $\Pi_2 : \mathrm{SU}(2) \to \mathrm{SO}(3)$. It can be shown that this homomorphism is surjective, and its kernel is the subgroup $\{\pm 1\} \subset \mathrm{SU}(2)$:

$$1 \to \{\pm 1\} \hookrightarrow \mathrm{SU}(2) \xrightarrow{\Pi_2} \mathrm{SO}(3) \to 1$$

The simplest way to see it is to establish the equivalence of $\Pi_2$ with the adjoint representation of $G$ in $\mathfrak{g}$. The corresponding intertwiner is

$$S^2 \ni (\alpha+\mathrm{i}\gamma)u^2 + 2\mathrm{i}\beta uv + (\alpha-\mathrm{i}\gamma)v^2 \longleftrightarrow \begin{pmatrix} \mathrm{i}\beta & \alpha+\mathrm{i}\gamma \\ -\alpha+\mathrm{i}\gamma & -\mathrm{i}\beta\end{pmatrix} \in \mathfrak{g}$$

Note that SU(2) and SO(3) are the only compact groups associated with the Lie algebra $\mathfrak{sl}(2,\mathbb{C})$.

The group $G$ contains the subgroup $H$ of diagonal matrices, isomorphic to $\mathbb{T}^1$. Consider the restriction of $\Pi_n$ to $\mathbb{T}^1$. It splits into the sum of unirreps $\pi_k$ as follows:

$$\mathrm{Res}^G_{T^1}\Pi_n = \sum_{s=0}^{s=[n/2]} \pi_{n-2s}$$

The characters $\pi_k$ which enter this decomposition are called the weights of $\Pi_n$. The collection of all weights (together with multiplicities) forms a multiset in $\widehat{\mathbb{T}}$ denoted by $P(\Pi_n)$ or $P(S^n)$.

Note the following features of this multiset:

1. $P(\Pi_n)$ is invariant under reflection $k \mapsto -k$.
2. All weights of $\Pi_n$ are congruent modulo 2.
3. The nonequivalent unirreps have different multisets of weights.

Below we show how these features are generalized to all compact connected Lie groups.

## Fourier Transform

### Haar Measure and Invariant Integral

The important feature of compact groups is the existence of the so-called "invariant integral," or "average."

**Theorem 12** *For every compact Lie group $G$, there exists a unique measure $\mathrm{d}g$ on $G$, called "Haar measure," which is invariant under left shifts $L_g : h \mapsto gh$ and satisfies $\int_G \mathrm{d}g = 1$.*

*In addition, this measure is also invariant under right shifts $h \mapsto hg$ and under involution $h \mapsto h^{-1}$.*

Invariance of the Haar measure implies that for every integrable function $f(g)$, we have

$$\int_G f(g)\,\mathrm{d}g = \int_G f(hg)\,\mathrm{d}g = \int_G f(gh)\,\mathrm{d}g = \int_G f(g^{-1})\,\mathrm{d}g$$

For a finite group $G$, the integral with respect to the Haar measure is just averaging over the group:

$$\int_G f(g)\,\mathrm{d}g = \frac{1}{|G|}\sum_{g\in G} f(g)$$

For compact connected Lie groups, the Haar measure is given by a differential form of top degree which is invariant under right and left translations.

For a torus $T^n = \mathbb{R}^n/\mathbb{Z}^n$ with real coordinates $\theta_k \in \mathbb{R}/\mathbb{Z}$ or complex coordinates $t_k = \mathrm{e}^{2\pi\mathrm{i}\theta_k}$, the Haar measure is $\mathrm{d}^n\theta := \mathrm{d}\theta_1\mathrm{d}\theta_2\cdots\mathrm{d}\theta_n$ or

$$\mathrm{d}^n t := \prod_{k=1}^{n} \frac{\mathrm{d}t_k}{2\pi\mathrm{i}t_k}$$

In particular, consider a central function $f$ (see Theorem 9). Since every conjugacy class contains elements of the maximal torus $T$ (see Theorem 5), such a function is determined by its values on $T$, and the integral of a central function can be reduced to integration over $T$. The resulting formula is called "Weyl integration formula." For $G = \mathrm{U}(n)$ it looks as follows:

$$\int_{U(n)} f(g)\mathrm{d}g = \frac{1}{n!}\int_T f(t)\prod_{i<j}|t_i - t_j|^2\mathrm{d}^n t$$

where $T$ is the maximal torus consisting of diagonal matrices

$$t = \mathrm{diag}(t_1,\ldots,t_n), \qquad t_k = \mathrm{e}^{2\pi\mathrm{i}\theta_k}$$

and $\mathrm{d}^n t$ is defined above.

Weyl integration formula for arbitrary compact group $G$ can be found in Simon (1996) or Bump (2004, section 18).

The main applications of the Haar measure are the proof of complete reducibility theorem (Theorem 11) and orthogonality relations (see below).

### Orthogonality Relations and Peter–Weyl Theorem

Let $V_1, V_2$ be unirreps of a compact group $G$. Taking any linear operator $A : V_1 \to V_2$ and averaging the expression $A(g) := \pi_2(g^{-1}) \circ A \circ \pi_1(g)$ over

$G$, we get an intertwining operator $\langle A \rangle = \int_G A(g)\mathrm{d}g$. Comparing this fact with the Schur lemma, one obtains the following fundamental results.

Let $(\pi, V)$ be any unirrep of a compact group $G$. Choose any orthonormal basis $\{v_k, 1 \le k \le \dim V\}$ in $V$ and denote by $t^V_{kl}$, or $t^\pi_{kl}$, the function on $G$ defined by

$$t^V_{kl}(g) = (\pi(g)v_l, v_k)$$

The functions $t^V_{kl}$ are called "matrix elements" of the unirrep $(\pi, V)$.

**Theorem 13** (Orthogonality relations)

- (i) *The matrix elements $t^V_{kl}$ are pairwise orthogonal and have norm* $(\dim V)^{-1/2}$ *in* $L^2(G, \mathrm{d}g)$.
- (ii) *The matrix elements corresponding to equivalent unirreps span the same subspace in* $L^2(G, \mathrm{d}g)$.
- (iii) *The matrix elements of two nonequivalent unirreps are orthogonal.*
- (iv) *The linear span of all matrix elements of all unirreps is dense in* $\mathrm{C}(G), C^\infty(G)$, *and in* $L^2(G, \mathrm{d}g)$ (*generalized Peter–Weyl theorem*).

In particular, this theorem implies that the set $\widehat{G}$ of equivalence classes of unirreps is countable. For an f.d. representation $(\pi, V)$ we introduce the character of $\pi$ as a function

$$\chi_\pi(g) = \mathrm{tr}\pi(g) = \sum_{k=1}^{\dim V} t^\pi_{kk}(g) \qquad [5]$$

It is obviously a central function on $G$.

**Remark** Traditionally, in representation theory the word "character" has two different meanings: (1) a multiplicative map from a group to U(1), and (2) the trace of a representation operator $\pi(g)$. For one-dimensional representations both notions coincide.

From the orthogonality relations we get the following result.

**Corollary** *The characters of unirreps of $G$ form an orthonormal basis in the subspace of central functions in* $L^2(G, \mathrm{d}g)$.

### Noncommutative Fourier Transform

The noncommutative Fourier transform on a compact group $G$ is defined as follows. Let $\widehat{G}$ denote the set of equivalence classes of unirreps of $G$. Choose for any $\lambda \in \widehat{G}$ a representation $(\pi_\lambda, V_\lambda)$ of class $\lambda$ and an orthonormal basis in $V_\lambda$. Denote by $d(\lambda)$ the dimension of $V_\lambda$.

We introduce the Hilbert space $L^2(\widehat{G})$ as the space of matrix-valued functions on $\widehat{G}$ whose value at a point $\lambda \in \widehat{G}$ belongs to $\mathrm{Mat}_{d(\lambda)}(\mathbb{C})$. The norm is defined as

$$\|F\|^2_{L^2(\widehat{G})} = \sum_{\lambda \in \widehat{G}} d(\lambda) \cdot \mathrm{tr}(F(\lambda)F(\lambda)^*)$$

For a function $f$ on $G$ define its Fourier transform $\widetilde{f}$ as a matrix-valued function on $\widehat{G}$:

$$\widetilde{f}(\lambda) = \int_G f(g^{-1})\pi_\lambda(g)\mathrm{d}g$$

Note that in the case $G = \mathbb{T}^1$ this transform associates to a function $f$ the set of its Fourier coefficients. In general this transform keeps some important features of Fourier coefficients.

**Theorem 14**

- (i) *For a function $f \in L^1(G, \mathrm{d}g)$ the Fourier transform $\widetilde{f}$ is well defined and bounded* (*by matrix norm*) *function on* $\widehat{G}$.
- (ii) *For a function* $f \in L^1(G, \mathrm{d}g) \cap L^2(G, \mathrm{d}g)$ *the following analog of the Plancherel formula holds*:

$$\|f\|^2_{L^2(G,\mathrm{d}g)} := \int_G |f(g)|^2 \mathrm{d}g = \sum_{\lambda \in \widehat{G}} d(\lambda) \cdot \mathrm{tr}(\widetilde{f}(\lambda)\widetilde{f}(\lambda)^*) =: \|\widetilde{f}\|^2_{L^2(\widehat{G})}$$

- (iii) *The following inversion formula expresses $f$ in terms of $\widetilde{f}$*:

$$f(g) = \sum_{\lambda \in \widehat{G}} d(\lambda) \cdot \mathrm{tr}(\widetilde{f}(\lambda)\pi_\lambda(g))$$

- (iv) *The Fourier transform sends the convolution to the matrix multiplication*:

$$\widetilde{f_1 * f_2} = \widetilde{f}_1 \cdot \widetilde{f}_2$$

*where the convolution product $*$ is defined by*

$$(f_1 * f_2)(h) = \int_G f_1(hg) f_2(g^{-1})\,\mathrm{d}g$$

Note the special case of the inversion formula for $g = e$:

$$f(e) = \sum_{\lambda \in \widehat{G}} d(\lambda) \cdot \mathrm{tr}(\widetilde{f}(\lambda)),$$

or

$$\delta(g) = \sum_{\lambda \in \widehat{G}} d(\lambda) \cdot \chi_\lambda(g)$$

where $\delta(g)$ is Dirac's delta-function: $\int_G f(g)\delta(g)\,\mathrm{d}g = f(e)$. Thus, we get a presentation of Dirac's delta-function as a linear combination of characters.

## Classification of Finite-Dimensional Representations

In this section, we give a classification of unirreps of a connected compact Lie group $G$.

### Weight Decomposition

Let $G$ be a connected compact group with maximal torus $T$, and let $(\pi, V)$ be a f.d. representation of $G$. Restricting it to $T$ and using complete reducibility, we get the following result.

**Theorem 15** *The vector space $V$ can be written in the form*

$$V = \bigoplus_{\lambda \in X(T)} V_\lambda, \\ V_\lambda = \{v \in V | \pi_*(t)v = \langle \lambda, t \rangle v \ \forall t \in \mathfrak{t}\} \qquad [6]$$

*where $X(T)$ is the character group of $T$ defined by* [3].
*The spaces $V_\lambda$ are called* "weight subspaces," *vectors $v \in V_\lambda$* – "weight vectors" *of weight $\lambda$. The set*

$$P(V) = \{\lambda \in X(T) | V_\lambda \neq \{0\}\} \qquad [7]$$

*is called the* "set of weights" *of $\pi$, or the* "spectrum" *of $\mathrm{Res}_T^G \pi$, and*

$$\mathrm{mult}_{(\pi,V)}(\lambda) := \dim V_\lambda$$

*is called the* "multiplicity" *of $\lambda$ in $V$.*

The next theorem easily follows from the definition of the Weyl group.

**Theorem 16** *For any f.d. representation $V$ of $G$, the set of weights with multiplicities is invariant under the action of the Weyl group*:

$$w(P(V)) = P(V), \qquad \mathrm{mult}_{(\pi,V)}(\lambda) = \mathrm{mult}_{(\pi,V)}(w(\lambda))$$

*for any $w \in W$.*

### Classification of Unirreps

Recall that $R$ is the root system of $\mathfrak{g}_\mathbb{C}$. Assume that we have chosen a basis of simple roots $\alpha_1, \ldots, \alpha_r \subset R$. Then $R = R_+ \cup R_-$; roots $\alpha \in R_+$ can be written as a linear combination of simple roots with positive coefficients, and $R_- = -R_+$.

A (not necessarily f.d.) representation of $\mathfrak{g}_\mathbb{C}$ is called a "highest-weight representation" if it is generated by a single vector $v \in V_\lambda$ (the highest-weight vector) such that $\mathfrak{g}_\alpha v = 0$ for all positive roots $\alpha \in R_+$.

It can be shown that for every $\lambda \in X(T)$, there is a unique irreducible highest-weight representation of $\mathfrak{g}_\mathbb{C}$ with highest weight $\lambda$, which is denoted $L(\lambda)$. However, this representation can be infinite dimensional; moreover, it may not be possible to lift it to a representation of $G$.

**Definition 5** A weight $\lambda \in X(T)$ is called "dominant" if $\langle \lambda, \alpha_i^\vee \rangle \in \mathbb{Z}_+$ for any simple root $\alpha_i$. The set of all dominant weights is denoted by $X_+(T)$.

**Theorem 17**

(i) *All weights of $L(\lambda)$ are of the form $\mu = \lambda - \Sigma n_i \alpha_i$, $n_i \in \mathbb{Z}_+$.*
(ii) *Let $\lambda \in X_+$. Then the irreducible highest-weight representation $L(\lambda)$ is f.d. and lifts to a representation of $G$.*
(iii) *Every irreducible f.d. representation of $G$ is of the form $L(\lambda)$ for some $\lambda \in X_+$.*

Thus, we have a bijection {unirreps of $G$} $\leftrightarrow X_+$.

**Example 7** Let $G = \mathrm{SU}(2)$. There is a unique simple root $\alpha$ and the unique fundamental weight $\omega$, related by $\alpha = 2\omega$. Therefore, $X_+ = \mathbb{Z}_+ \cdot \omega$ and unirreps are indexed by non-negative integers. The representation with highest weight $k \cdot \omega$ is precisely the representation $\Pi_k$ constructed in the subsection "Examples of representations."

**Example 8** Let $G = \mathrm{U}(n)$. Then $X = \mathbb{Z}^n$, and $X_+ = \{(\lambda_1, \ldots, \lambda_n) \in \mathbb{Z}^n \,|\, \lambda_1 \geq \cdots \geq \lambda_n\}$. Such objects are well known in combinatorics: if we additionally assume that $\lambda_n \geq 0$, then such dominant weights are in bijection with partitions with $n$ parts. They can also be described by "Young diagrams" with $n$ rows (see Fulton and Harris (1991)).

### Explicit Construction of Representations

In addition to description of unirreps as highest-weight representations, they can also be constructed in other ways. In particular, they can be defined analytically as follows. Let $B = HN_+$ be the Borel subgroup in $G_\mathbb{C}$; here $H = \exp \mathfrak{h}$, $N_+ = \exp \sum_{\alpha \in R_+} (\mathfrak{g}_\mathbb{C})_\alpha$. For $\lambda \in \mathfrak{h}^*$, let $\chi_\lambda : B \to \mathbb{C}^\times$ be a multiplicative map defined by

$$\chi_\lambda(hn) = \mathrm{e}^{\langle h, \lambda \rangle} \qquad [8]$$

**Theorem 18** (Cartan–Borel–Weil). *Let $\lambda \in X(T)$. Denote by $V(\lambda)$ the space of complex-analytic functions on $G_\mathbb{C}$ which satisfy the following transformation property*:

$$f(gb) = \chi_\lambda^{-1}(b) f(g), \quad g \in G_\mathbb{C}, \ b \in B$$

*The group $G_\mathbb{C}$ acts on $V(\lambda)$ by left shifts*:

$$(\pi(g)f)(h) = f(g^{-1}h) \qquad [9]$$

*Then*

(i) $V(\lambda) \neq \{0\}$ *iff* $-\lambda \in X_+$.

(ii) *If* $-\lambda \in X_+$, *the representation of* $G$ *in* $V(\lambda)$ *is equivalent to* $L(w_0(\lambda))$, *where* $w_0 \in W$ *is the unique element of the Weyl group which sends* $R_+$ *to* $R_-$.

This theorem can also be reformulated in more geometric terms: the spaces $V(\lambda)$ are naturally interpreted as spaces of global sections of appropriate line bundles on the "flag variety" $\mathcal{B} = G_{\mathbb{C}}/B = G/T$.

For classical groups, irreducible representations can also be constructed explicitly as the subspaces in tensor powers $(\mathbb{C}^n)^{\otimes k}$, transforming in a certain way under the action of the symmetric group $S_k$.

## Characters and Multiplicities

### Characters

Let $(\pi, V)$ be a f.d. representation of $G$ and let $\chi_\pi$ be its character as defined by [5]. Since $\chi_\pi$ is central, and every element in $G$ is conjugate to an element of $T$, $\chi_\pi$ is completely determined by its restriction to $T$, which can be computed from the weight decomposition [6]:

$$\chi_\pi|_T = \sum_{\lambda \in X(T)} \dim V_\lambda \cdot e_\lambda = \sum_{\lambda \in X(T)} \mathrm{mult}_\pi \lambda \cdot e_\lambda \qquad [10]$$

where $e_\lambda$ is the function on $T$ defined by $e_\lambda(\exp(t)) = \mathrm{e}^{\langle t, \lambda \rangle}$, $t \in \mathfrak{t}$. Note that $e_{\lambda+\mu} = e_\lambda e_\mu$ and that $e_0 = 1$.

### Weyl Character Formula

**Theorem 19** (Weyl character formula). *Let* $\lambda \in X_+$. *Then*

$$\chi_{L(\lambda)} = \frac{A_{\lambda+\rho}}{A_\rho}, \qquad A_\mu = \sum_{w \in W} \varepsilon(w) e_{w(\mu)}$$

*where, for* $w \in W$, *we denote* $\varepsilon(w) = \det w$ *considered as a linear map* $\mathfrak{t}^* \to \mathfrak{t}^*$, *and* $\rho = (1/2) \sum_{R_+} \alpha$.

In particular, computing the value of the character at point $t = 0$ by L'Hopital's rule, it is possible to deduce the following formula for the dimension of irreducible representations:

$$\dim L(\lambda) = \prod_{\alpha \in R_+} \frac{\langle \alpha^\vee, \lambda + \rho \rangle}{\langle \alpha^\vee, \rho \rangle} \qquad [11]$$

**Example 9** Let $G = \mathrm{SU}(2)$. Then Weyl character formula gives, for irreducible representation $\Pi_k$ with highest weight $k \cdot \omega$,

$$\chi_{\Pi_k} = \frac{x^{k+1} - x^{-(k+1)}}{x - x^{-1}} = x^k + x^{k-2} + \cdots + x^{-k}, \quad x = e_\omega$$

which implies $\dim \Pi_k = k + 1$.

Weyl character formula is equivalent to the following formula for weight multiplicities, due to Kostant:

$$\mathrm{mult}_{L(\lambda)} \mu = \sum_{w \in W} \varepsilon(w) K(w(\lambda + \rho) - \rho - \mu)$$

where $K$ is Kostant's partition function: $K(\tau)$ is the number of ways of writing $\tau$ as a sum of positive roots (with repetitions).

For classical Lie groups such as $G = \mathrm{U}(n)$, there are more explicit combinatorial formulas for weight multiplicities; for $\mathrm{U}(n)$, the answer can be written in terms of the number of "Young tableaux" of a given shape. Details can be found in Fulton and Harris (1991).

### Tensor Product Multiplicities

Let $(\pi, V)$ be a f.d. representation of $G$. By complete reducibility, one can write $V = \Sigma n_\lambda L(\lambda)$. The coefficients $n_\lambda$ are called multiplicities; finding them is an important problem in many applications. In particular, a special case of this is finding the multiplicities in tensor product of two unirreps:

$$L(\lambda) \otimes L(\mu) = \sum N^\nu_{\lambda\mu} L(\nu)$$

Characters provide a practical tool for computing multiplicities: since characters of unirreps are linearly independent, multiplicities can be found from the condition that $\chi_V = \Sigma n_\lambda \chi_{L(\lambda)}$. In particular,

$$\chi_{L(\lambda)} \chi_{L(\mu)} = \sum N^\nu_{\lambda\mu} \chi_{L(\nu)}$$

**Example 10** For $G = \mathrm{SU}(2)$, tensor product multiplicities are given by

$$\Pi_n \otimes \Pi_m = \oplus \Pi_l$$

where the sum is taken over all $l$ such that $|m - n| \leq l \leq m + n$, $m + n + l$ is even.

For $G = \mathrm{U}(n)$, there is an algorithm for finding the tensor product multiplicities, formulated in the language of Young tableaux (Littlewood–Richardson rule). There are also tables and computer programs for computing these multiplicities; some of them are listed in the bibliography.

# Compactification of Superstring Theory

**M R Douglas**, Rutgers, The State University of New Jersey, Piscataway, NJ, USA

## Introduction

Superstring theories and M-theory, at present the best candidate quantum theories which unify gravity, Yang–Mills fields, and matter, are directly formulated in ten and eleven spacetime dimensions. To obtain a candidate theory of our four-dimensional universe, one must find a solution of one of these theories whose low-energy physics is well described by a four-dimensional effective field theory (EFT), containing the well-established standard model (SM) of particle physics coupled to Einstein's general relativity (GR). The standard paradigm for finding such solutions is compactification, along the lines originally proposed by Kaluza and Klein in the context of higher-dimensional general relativity. One postulates that the underlying $D$-dimensional spacetime is a product of four-dimensional Minkowski spacetime, with a $(D-4)$-dimensional compact and small Riemannian manifold $K$. One then finds that low-energy physics effectively averages over $K$, leading to a four-dimensional EFT whose field content and Lagrangian are determined in terms of the topology and geometry of $K$.

Of the huge body of prior work on this subject, the part most relevant for string/M-theory is supergravity compactification, as in the limit of low energies, small curvatures and weak coupling, the various string theories and M-theory reduce to ten- and eleven-dimensional supergravity theories. Many of the qualitative features of string/M-theory compactification, and a good deal of what is known quantitatively, can be understood simply in terms of compactification of these field theories, with the addition of a few crucial ingredients from string/M-theory. Thus, most of this article will restrict attention to this case, leaving many "stringy" topics to the articles on conformal field theory, topological string theory, and so on. We also largely restrict attention to compactifications based on Ricci-flat compact spaces. There is an equally important class in which $K$ has positive curvature; these lead to anti-de Sitter (AdS) spacetimes and are discussed in the article on AdS/CFT (*see* AdS/CFT Correspondence).

After a general review, we begin with compactification of the heterotic string on a three complex dimensional Calabi–Yau manifold. This was the first construction which led convincingly to the SM, and remains one of the most important examples. We then survey the various families of compactifications to higher dimensions, with an eye on the relations between these compactifications which follow from superstring duality. We then discuss some of the phenomena which arise in the regimes of large curvature and strong coupling. In the final section, we bring these ideas together in a survey of the various known four-dimensional constructions.

## General Framework

Let us assume we are given a $D$- $(=d+k)$ dimensional field theory $\mathcal{T}$. A compactification is then a $D$-dimensional spacetime which is topologically the product of a $d$-dimensional spacetime with an $k$-dimensional manifold $K$, the compactification or "internal" manifold, carrying a Riemannian metric and with definite expectation values for all other fields in $\mathcal{T}$. These must solve the equations of motion, and preserve $d$-dimensional Poincaré invariance (or, perhaps another $d$-dimensional symmetry group).

The most general metric ansatz for a Poincaré invariant compactification is

$$G_{IJ} = \begin{pmatrix} f & \eta_{\mu\nu} & 0 \\ & 0 & G_{ij} \end{pmatrix}$$

where the tangent space indices are $0 \le I < d + k = D, 0 \le \mu < d$, and $1 \le i \le k$. Here $\eta_{\mu\nu}$ is the Minkowski metric, $G_{ij}$ is a metric on $K$, and $f$ is a real-valued function on $K$ called the "warp factor."

As the simplest example, consider pure $D$-dimensional GR. in this case, Einstein's equations reduce to Ricci flatness of $G_{IJ}$. Given our metric ansatz, this requires $f$ to be constant, and the metric $G_{ij}$ on $K$ to be Ricci flat. Thus, any $K$ which admits such a metric, for example, the $k$-dimensional torus, will lead to a compactification.

Typically, if a manifold admits a Ricci-flat metric, it will not be unique; rather there will be a moduli space of such metrics. Physically, one then expects to find solutions in which the choice of Ricci-flat metric is slowly varying in $d$-dimensional spacetime. General arguments imply that such variations must be described by variations of $d$-dimensional fields, governed by an EFT. Given an explicit parametrization of the family of metrics, say $G_{ij}(\phi^\alpha)$ for some parameters $\phi^\alpha$, in principle the EFT could be computed explicitly by promoting the parameters to $d$-dimensional fields, substituting this parametrization into the $D$-dimensional action, and expanding in powers of the $d$-dimensional derivatives. In pure GR, we would find the four-dimensional effective Lagrangian

$$\mathcal{L}_{\mathrm{EFT}} = \int \mathrm{d}^k y \sqrt{\det G(\phi)} R^{(4)} + \sqrt{\det G(\phi)} G^{ik}(\phi) G^{jl}(\phi) \frac{\partial G_{ij}}{\partial \phi^\alpha} \frac{\partial G_{kl}}{\partial \phi^\beta} \partial_\mu \phi^\alpha \partial_\mu \phi^\beta + \cdots \qquad [1]$$

While this is easily evaluated for $K$ a symmetric space or torus, in general a direct computation of $\mathcal{L}_{\mathrm{EFT}}$ is impossible. This becomes especially clear when one learns that the Ricci-flat metrics $G_{ij}$ are not explicitly known for the examples of interest. Nevertheless, clever indirect methods have been found that give a great deal of information about $\mathcal{L}_{\mathrm{EFT}}$; this is much of the art of superstring compactification. However, in this section, let us ignore this point and continue as if we could do such computations explicitly.

Given a solution, one proceeds to consider its small perturbations, which satisfy the linearized equations of motion. If these include exponentially growing modes (often called "tachyons"), the solution is unstable. (Note that this criterion is modified for AdS compactifications). The remaining perturbations can be divided into massless fields, corresponding to zero modes of the linearized equations of motion on $K$, and massive fields, the others. General results on eigenvalues of Laplacians imply that the masses of massive fields depend on the diameter of $K$ as $m \sim 1/\mathrm{diam}(K)$, so at energies far smaller than $m$, they cannot be excited (this is not universal; given strong negative curvature on $K$, or a rapidly varying warp factor, one can have perturbations of small nonzero mass). Thus, the massive fields can be "integrated out," to leave an EFT with a finite number of fields. In the classical approximation, this simply means solving their equations of motion in terms of the massless fields, and using these solutions to eliminate them from the action. At leading order in an expansion around a solution, these fields are zero and this step is trivial; nevertheless, it is useful in making a systematic definition of the interaction terms in the EFT.

As we saw in pure GR, the configuration space parametrized by the massless fields in the EFT, is the moduli space of compactifications obtained by deforming the original solution. Thus, from a mathematical point of view, low-energy EFT can be thought of as a sort of enhancement of the concept of moduli space, and a dictionary set up between mathematical and physical languages. To give its next entry, there is a natural physical metric on moduli space, defined by restriction from the metric on the configuration space of the theory $\mathcal{T}$; this becomes the sigma-model metric for the scalars in the EFT. Because the theories $\mathcal{T}$ arising from string theory are geometrically natural, this metric is also natural from a mathematical point of view, and one often finds that much is already known about it. For example, the somewhat fearsome two derivative terms in eqn [1], are (perhaps) less so when one realizes that this is an explicit expression for the Weil–Petersson metric on the moduli space of Ricci-flat metrics. In any case, knowing this dictionary is essential for taking advantage of the literature.

Another important entry in this dictionary is that the automorphism group of a solution translates into the gauge group in the EFT. This can be either continuous, leading to the gauge symmetry of Maxwell and Yang–Mills theories, or discrete, leading to discrete gauge symmetry. For example, if the metric on $K$ has continuous isometry group $G$, the resulting EFT will have gauge symmetry $G$, as in the original example of Kaluza and Klein with $K \cong S^1$ and $G \cong \mathrm{U}(1)$. Mathematically, these phenomena of "enhanced symmetry" are often treated using the languages of equivariant theories (cohomology, K-theory, etc.), stacks, and so on.

To give another example, obstructed deformations (solutions of the linearized equations which do not correspond to elements of the tangent space of the true moduli space) correspond to scalar fields which, while massless, appear in the effective potential in a way which prevents giving them expectation values. Since the quadratic terms $V''$ are masses, this dependence must be at cubic or higher order.

While the preceding concepts are general and apply to compactification of all local field theories, string and M-theory add some particular ingredients to this general recipe. In the limits of small curvatures and weak coupling, string and M-theory are well described by the ten- and 11-dimensional supergravity theories, and thus the string/M-theory discussion usually starts with Kaluza–Klein compactification of these theories, which we denote I, IIa, IIb, HE, HO and M. Let us now discuss a particular example.

## Calabi–Yau Compactification of the Heterotic String

Contact with the SM requires finding compactifications to $d=4$ either without supersymmetry, or with at most $N=1$ supersymmetry, because the SM includes chiral fermions, which are incompatible with $N>1$. Let us start with the $E_8 \times E_8$ heterotic string or "HE" theory. This choice is made rather than HO because only in this case can we find the SM fermion representations as subrepresentations of the adjoint of the gauge group.

Besides the metric, the other bosonic fields of the HE supergravity theory are a scalar $\Phi$ called the dilaton, Yang–Mills gauge potentials for the group $G \equiv E_8 \times E_8$, and a 2-form gauge potential $B$ (often called the "Neveu–Schwarz" or "NS" 2-form) whose defining characteristic is that it minimally couples to the heterotic string world-sheet. We will need their gauge field strengths below: for Yang–Mills, this is a 2-form $F^a_{IJ}$ with $a$ indexing the adjoint of Lie $G$, and for the NS 2-form this is a 3-form $H_{IJK}$. Denoting the two Majorana–Weyl spinor representations of $SO(1,9)$ as $S$ and $C$, then the fermions are the gravitino $\psi_I \in S \otimes V$, a spin 1/2 "dilatino" $\lambda \in C$, and the adjoint gauginos $\chi^a \in S$. We use $\Gamma_I$ to denote Dirac matrices contracted with a "zehnbein," satisfying $\{\Gamma_I, \Gamma_J\} = 2G_{IJ}$, and $\Gamma_{IJ} = (1/2)[\Gamma_I, \Gamma_J]$, etc.

A local supersymmetry transformation with parameter $\epsilon$ is then

$$\delta\psi_I = D_I\epsilon + \tfrac{1}{8}H_{IJK}\Gamma^{JK}\epsilon \qquad [2]$$

$$\delta\lambda = \partial_I\Phi\Gamma^I\epsilon - \tfrac{1}{12}H_{IJK}\Gamma^{IJK}\epsilon \qquad [3]$$

$$\delta\chi^a = F^a_{IJ}\Gamma^{IJ}\epsilon \qquad [4]$$

We now assume $N=1$ supersymmetry. An unbroken supersymmetry is a spinor $\epsilon$ for which the left-hand side is zero, so we seek compactifications with a unique solution of these equations.

We first discuss the case $H=0$. Setting $\delta\psi_\mu$ in eqn [2] to zero, we find that the warp factor $f$ must be constant. The vanishing of $\delta\psi_i$ requires $\epsilon$ to be a covariantly constant spinor. For a six-dimensional $M$ to have a unique such spinor, it must have SU(3) holonomy; in other words, $M$ must be a Calabi–Yau manifold. In the following, we use basic facts about their geometry.

The vanishing of $\delta\lambda$ then requires constant dilaton $\Phi$, while the vanishing of $\delta\chi^a$ requires the gauge field strength $F$ to solve the hermitian Yang–Mills equations,

$$F^{2,0} = F^{0,2} = F^{1,1} = 0$$

By the theorem of Donaldson and Uhlenbeck–Yau, such solutions are in one-to-one correspondence with $\mu$-stable holomorphic vector bundles with structure group $H$ contained in the complexification of $G$. Choose such a bundle $E$; by the general discussion above, the commutant of $H$ in $G$ will be the automorphism group of the connection on $E$ and thus the low-energy gauge group of the resulting EFT. For example, since $E_8$ has a maximal $E_6 \times SU(3)$ subgroup, if $E$ has structure group $H = SL(3)$, there is an embedding such that the unbroken gauge symmetry is $E_6 \times E_8$, realizing one of the standard grand unified groups $E_6$ as a factor.

The choice of $E$ is constrained by anomaly cancellation. This discussion (Green *et al.* 1987) modifies the Bianchi identity for $H$ to

$$\mathrm{d}H = \mathrm{tr}\ R \wedge R - \frac{1}{30}\sum_a F^a \wedge F^a \qquad [5]$$

where $R$ is the matrix of curvature 2-forms. The normalization of the $F \wedge F$ term is such that if we take $E \cong TK$ the holomorphic tangent bundle of $K$, with isomorphic connection, then using the embedding we just discussed, we obtain a solution of eqn [5] with $H=0$.

Thus, we have a complete solution of the equations of motion. General arguments imply that supersymmetric Minkowski solutions are stable, so the small fluctuations consist of massless and massive fields. Let us now discuss a few of the massless fields. Since the EFT has $N=1$ supersymmetry, the massless scalars live in chiral multiplets, which are local coordinates on a complex Kähler manifold.

First, the moduli of Ricci-flat metrics on $K$ will lead to massless scalar fields: the complex structure

moduli, which are naturally complex, and Kähler moduli, which are not. However, in string compactification the latter are complexified to the periods of the 2-form $B + iJ$ integrated over a basis of $H_2(K, \mathbb{Z})$, where $J$ is the Kähler form and $B$ is the NS 2-form. In addition, there is a complex field pairing the dilaton (actually, $\exp(-\Phi)$) and the "model-independent axion," the scalar dual in $d=4$ to the 2-form $B_{\mu\nu}$. Finally, each complex modulus of the holomorphic bundle $E$ will lead to a chiral multiplet. Thus, the total number of massless uncharged chiral multiplets is $1 + h^{1,1}(K) + h^{2,1}(K) + \dim H^1(K, \text{End }(E))$.

Massless charged matter will arise from zero modes of the gauge field and its supersymmetric partner spinor $\chi^a$. It is slightly easier to discuss the spinor, and then appeal to supersymmetry to get the bosons. Decomposing the spinors of SO(6) under SU(3), one obtains $(0, p)$ forms, and the Dirac equation becomes the condition that these forms are harmonic. By the Hodge theorem, these are in one-to-one correspondence with classes in Dolbeault cohomology $H^{0,p}(K, V)$, for some bundle $V$. The bundle $V$ is obtained by decomposing the spinor into representations of the holonomy group of $E$. For $H = \text{SU}(3)$, the decomposition of the adjoint under the embedding of $\text{SU}(3) \times E_6$ in $E_8$,

$$248 = (8,1) + (1,78) + (3,27) + (\bar{3},\bar{27}) \qquad [6]$$

implies that charged matter will form "generations" in the 27, of number $\dim H^{0,1}(K, E)$, and "antigenerations" in the $\bar{27}$, of number $\dim H^{0,1}(K, \bar{E}) = \dim H^{0,2}(K, E)$. The difference in these numbers is determined by the Atiyah–Singer index theorem to be

$$N_{\text{gen}} \equiv N_{27} - N_{\bar{27}} = \tfrac{1}{2} c_3(E)$$

In the special case of $E \cong TK$, these numbers are separately determined to be $N_{27} = h^{1,1}$ and $N_{\bar{27}} = h^{2,1}$, so their difference is $\chi(K)/2$, half the Euler number of $K$. In the real world, this number is $N_{\text{gen}} = 3$, and matching this under our assumptions so far is very constraining.

Substituting these zero modes into the ten-dimensional Yang–Mills action and integrating, one can derive the $d=4$ EFT. For example, the cubic terms in the superpotential, usually called Yukawa couplings after the corresponding fermion–boson interactions in the component Lagrangian, are obtained from the cubic product of zero modes

$$\int_K \Omega \wedge \text{tr}(\phi_1 \wedge \phi_2 \wedge \phi_3)$$

where $\Omega$ is the holomorphic $\phi_i \in H^{0,1}(K, \text{Rep } E)$ are the zero modes, and tr arises from decomposing the $E_8$ cubic group invariant.

Note the very important fact that this expression only depends on the cohomology classes of the $\phi_i$ (and $\Omega$). This means the Yukawa couplings can be computed without finding the explicit harmonic representatives, which is not possible (we do not even know the explicit metric). More generally, one expects to be able to explicitly compute the superpotential and all other holomorphic quantities in the effective Lagrangian solely from "topological" information (the Dolbeault cohomology ring, and its generalizations within topological string theory). On the other hand, computing the Kähler metric in an $N=1$ EFT is usually out of reach as it would require having explicit normalized zero modes. Most results for this metric come from considering closely related compactifications with extended supersymmetry, and arguing that the breaking to $N=1$ supersymmetry makes small corrections to this.

There are several generalizations of this construction. First, the necessary condition to solve eqn [5] is that the left-hand side be exact, which requires

$$c_2(E) = c_2(TK) \qquad [7]$$

This allows for a wide variety of $E$'s to be used, so that $N_{\text{gen}} = 3$ can be attained with many more $K$'s. This class of models is often called "(0, 2) compactification" to denote the world-sheet supersymmetry of the heterotic string in these backgrounds. One can also use bundles with larger structure group; for example, $H = SL(4)$ leads to unbroken $\text{SO}(10) \times E_8$, and $H = \text{SL}(5)$ leads to unbroken $\text{SU}(5) \times E_8$.

The subsequent breaking of the grand unified group to the SM gauge group is typically done by choosing $K$ with nontrivial $\pi_1$, so that it admits a flat line bundle $W$ with nontrivial holonomy (usually called a "Wilson line"). One then uses the bundle $E \otimes W$ in the above discussion, to obtain the commutant of $H \otimes W$ as gauge group. For example, if $\pi_1(K) \cong \mathbb{Z}_5$, one can use $W$ whose holonomy is an element of order 5 in SU(5), to obtain as commutant the SM gauge group $\text{SU}(3) \times \text{SU}(2) \times \text{U}(1)$.

Another generalization is to take the 3-form $H \neq 0$. This discussion begins by noting that, for supersymmetry, we still require the existence of a unique spinor $\epsilon$; however, it will no longer be covariantly constant in the Levi-Civita connection. One way to structure the problem is to note that the right-hand side of eqn [2] takes the form of a connection with torsion; the resulting equations have been discussed mathematically in (Li and Yau 2004).

Another recent approach to these compactifications (Gauntlett 2004) starts out by arguing that $\epsilon$ cannot vanish on $K$, so it defines a weak SU(3) structure, a local reduction of the structure group of

$T\,K$ to SU(3) which need not be integrable. This structure must be present in all $N=1, d=4$ supersymmetric compactifications and there are hopes that it will lead to a useful classification of the possible local structures and corresponding partial differential equations (PDEs) on $K$.

## Higher-Dimensional and Extended Supersymmetric Compactifications

While there are similar quasirealistic constructions which start from the other string theories and M-theory, before we discuss these, let us give an overview of compactifications with $N \geq 2$ supersymmetry in four dimensions, and in higher dimensions. These are simpler analog models which can be understood in more depth; their study led to one of the most important discoveries in string/M-theory, the theory of superstring duality.

As before, we require a covariantly constant spinor. For Ricci-flat $K$ with other background fields zero, this requires the holonomy of $K$ to be one of trivial, SU($n$), Sp($n$), or the exceptional holonomies $G_2$ or Spin(7). In Table 1 we tabulate the possibilities with spacetime dimension $d$ greater or equal to 3, listing the supergravity theory, the holonomy type of $K$, and the type of the resulting EFT: dimension $d$, total number of real supersymmetry parameters $Ns$, and the number of spinor supercharges $N$ (in $d=6$, since left- and right-chirality Majorana spinors are inequivalent, there are two numbers).

The structure of the resulting supergravity EFTs is heavily constrained by $Ns$. We now discuss the various possibilities.

**Table 1** String/M-theories, holonomy groups and the resulting supersymmetry

| *Theory* | *Holonomy* | *d* | *Ns* | *N* |
|---|---|---|---|---|
| M, II | *Torus* | Any | 32 | Max |
| M | SU(2) | 7 | 16 | 1 |
| | SU(3) | 5 | 8 | 1 |
| | $G_2$ | 4 | 4 | 1 |
| | Sp(4) | 3 | 6 | 3 |
| | SU(4) | 3 | 4 | 2 |
| | Spin(7) | 3 | 2 | 1 |
| IIa | SU(2) | 6 | 16 | (1, 1) |
| | SU(3) | 4 | 8 | 2 |
| | $G_2$ | 3 | 4 | 2 |
| IIb | SU(2) | 6 | 16 | (0, 2) |
| | SU(3) | 4 | 8 | 2 |
| | $G_2$ | 3 | 4 | 2 |

### $Ns = 32$

Given the supersymmetry algebra, if such a supergravity exists, it is unique. Thus, toroidal compactifications of $d=11$ supergravity, IIa and IIb supergravity lead to the same series of maximally supersymmetric theories. Their structure is governed by the exceptional Lie algebra $E_{11-d}$; the gauge charges transform in a fundamental representation of this algebra, while the scalar fields parametrize a coset space $G/H$, where $G$ is the maximally split real form of the Lie group $E_{11-d}$, and $H$ is a maximal compact subgroup of $G$. Nonperturbative duality symmetries lead to a further identification by a maximal discrete subgroup of $G$.

### $Ns = 16$

This supergravity can be coupled to maximally supersymmetric super Yang–Mills theory, which given a choice of gauge group $G$ is unique. Thus, these theories (with zero cosmological constant and thus allowing super-Poincaré symmetry) are uniquely determined by the choice of $G$.

In $d=10$, the choices $E_8 \times E_8$ and $\mathrm{Spin}(32)/\mathbb{Z}_2$ which arise in string theory, are almost uniquely determined by the Green–Schwarz anomaly cancellation analysis. Compactification of these HE, HO and type I theories on $T^n$ produces a unique theory with moduli space

$$\mathbb{R}^+ \times \mathrm{SO}(n, n+16; \mathbb{Z})\backslash \mathrm{SO}(n, n+16; \mathbb{R})/\mathrm{SO}(n, \mathbb{R}) \times \mathrm{SO}(n+16, \mathbb{R}) \qquad [8]$$

In Kaluza–Klein (KK) reduction, this arises from the choice of metric $g_{ij}$, the antisymmetric tensor $B_{ij}$ and the choice of a flat $E_8 \times E_8$ or $\mathrm{Spin}(32)/\mathbb{Z}_2$ connection on $T^n$, while a more unified description follows from the heterotic string world-sheet analysis. Here the group $\mathrm{SO}(n, n+16)$ is defined to preserve an even self-dual quadratic form $\eta$ of signature $(n, n+16)$; for example, $\eta = (-E_8) \oplus (-E_8) \oplus I \oplus I \oplus I$, where $I$ is the form of signature (1,1) and $E_8$ is the Cartan matrix. In fact, all such forms are equivalent under orthogonal integer similarity transformation; so, the resulting EFT is unique. It has a rank $16+2n$ gauge group, which at generic points in moduli space is $\mathrm{U}(1)^{16+2n}$, but is enhanced to a nonabelian group $G$ at special points. To describe $G$, we first note that a point $p$ in moduli space determines an $n$-dimensional subspace $V_p$ of $\mathbb{R}^{16+2n}$, and an orthogonal subspace $V_p^\perp$ (of varying dimension). Lattice points of length squared –2 contained in $V_p^\perp$ then correspond to roots of the Lie algebra of $G_p$.

The other compactifications with $Ns=16$ is M-theory on K3 and its further toroidal reductions, and IIb on K3. M-theory compactification to $d=7$ is dual to heterotic on $T^3$, with the same moduli space and enhanced gauge symmetry. As we discuss at the end of the section "Stringy and quantum corrections," the extra massless gauge bosons of enhanced gauge symmetry are M2 branes wrapped on 2-cycles with topology $S^2$. For such a cycle to have zero volume, the integral of the Kähler form and holomorphic 2-form over the cycle must vanish; expressing this in a basis for $H^2(K3, \mathbb{R})$ leads to exactly the same condition we discussed for enhanced gauge symmetry above. The final result is that all such K3 degenerations lead to one- of the two-dimensional canonical singularities, of types A, D or E, and the corresponding EFT phenomenon is the enhanced gauge symmetry of corresponding Dynkin type A, D, or E.

IIb on K3 is similar, but reducing the self-dual Ramond–Ramond (RR) 4-form potential on the 2-cycles leads to self-dual tensor multiplets instead of Maxwell theory. The moduli space is eqn [8] but with $n=5$, not $n=4$, incorporating periods of RR potentials and the $SL(2, \mathbb{Z})$ duality symmetry of IIb theory.

One may ask if the $Ns=16$ I/HE/HO theories in $d=8$ and $d=9$ have similar duals. For $d=8$, these are obtained by a pretty construction known as "F-theory." Geometrically, the simplest definition of F-theory is to consider the special case of M-theory on an elliptically fibered Calabi–Yau, in the limit that the Kähler modulus of the fiber becomes small. One check of this claim for $d=8$ is that the moduli space of elliptically fibered K3s agrees with eqn [8] with $n=2$.

Another definition of F-theory is the particular case of IIb compactification using Dirichlet 7-branes, and orientifold 7-planes. This construction is $T$-dual to the type I theory on $T^2$, which provides its simplest string theory definition. As discussed in Polchinski (1999), one can think of the open strings giving rise to type I gauge symmetry as living on 32 Dirichlet 9-branes (or D9-branes) and an orientifold nineplane. $T$-duality converts Dirichlet and orientifold $p$-branes to $(p-1)$-branes; thus this relation follows by applying two $T$-dualities.

These compactifications can also be parametrized by elliptically fibered Calabi–Yaus, where $K$ is the base, and the branes correspond to singularities of the fibration. The relation between these two definitions follows fairly simply from the duality between M-theory on $T^2$, and IIb string on $S^1$. There is a partially understood generalization of this to $d=9$.

Finally, these constructions admit further discrete choices, which break some of the gauge symmetry. The simplest to explain is in the toroidal compactification of I/HE/HO. The moduli space of theories we discussed uses flat connections on the torus which are continuously connected to the trivial connection, but in general the moduli space of flat connections has other components. The simplest example is the moduli space of flat $E_8 \times E_8$ connections on $S^1$, which has a second component in which the holonomy exchanges the two $E_8$'s. On $T^3$, there are connections for which the holonomies cannot be simultaneously diagonalized. This structure and the M-theory dual of these choices is discussed in (de Boer *et al*. 2001).

### $Ns=8$, $d<6$

Again, the gravity multiplet is uniquely determined, so the most basic classification is by the gauge group $G$. The full low-energy EFT is determined by the matter content and action, and there are two types of matter multiplets. First, vector multiplets contain the Yang–Mills fields, fermions and $6-d$ scalars; their action is determined by a prepotential which is a $G$-invariant function of the fields. Since the vector multiplets contain massless adjoint scalars, a generic vacuum in which these take nonzero distinct vacuum expectation values (VEVs) will have $U(1)^r$ gauge symmetry, the commutant of $G$ with a generic matrix (for $d<5$, while there are several real scalars, the potential forces these to commute in a supersymmetric vacuum). Vacua with this type of gauge symmetry breaking, which does not reduce the rank of the gauge group, are usually referred to as on a "Coulomb branch" of the moduli space. To summarize, this sector can be specified by $n_V$, the number of vector multiplets, and the prepotential $\mathcal{F}$, a function of the $n_V$ VEVs which is cubic in $d=5$, and holomorphic in $d=4$.

Hypermultiplets contain scalars which parametrize a quaternionic Kähler manifold, and partner fermions. Thus, this sector is specified by a $4n_H$ real dimensional quaternionic Kähler manifold. The $G$ action comes with triholomorphic moment maps; if nontrivial, VEVs in this sector can break gauge symmetry and reduce it in rank. Such vacua are usually referred to as on a "Higgs branch."

The basic example of these compactifications is M-theory on a Calabi–Yau 3-fold ($CY_3$). Reduction of the 3-form leads to $h^{1,1}(K)$ vector multiplets, whose scalar components are the CY Kähler moduli. The CY complex structure moduli pair with periods of the 3-form to produce $h^{2,1}(K)$ hypermultiplets. Enhanced gauge symmetry then appears when the

$CY_3$ contains ADE singularities fibered over a curve, from the same mechanism involving wrapped M2 branes we discussed under $Ns = 16$. If degenerating curves lead to other singularities (e.g., the ODP or "conifold"), it is possible to obtain extremal transitions which translate physically into Coulomb–Higgs transitions. Finally, singularities in which surfaces degenerate lead to nontrivial fixed-point theories.

Reduction on $S^1$ leads to IIa on $CY_3$, with the spectrum above plus a "universal hypermultiplet" which includes the dilaton. Perhaps the most interesting new feature is the presence of world-sheet instantons, which correct the metric on vector multiplet moduli space. This metric satisfies the restrictions of special geometry and thus can be derived from a prepotential.

The same theory can be obtained by compactification of IIb theory on the mirror $CY_3$. Now vector multiplets are related to the complex structure moduli space, while hypermultiplets are related to Kähler moduli space. In this case, the prepotential derived from variation of complex structure receives no instanton corrections, as we discuss in the next section.

Finally, one can compactify the heterotic string on $K3 \times T^{6-d}$, but this theory follows from toroidal reduction of the $d = 6$ case we discuss next.

#### *Ns* = 8, *d* = 6

These supergravities are similar to $d < 6$, but there is a new type of matter multiplet, the self-dual tensor (in $d < 6$ this is dual to a vector multiplet). Since fermions in $d = 6$ are chiral, there is an anomaly cancellation condition relating the numbers of the three types of multiplets (Aspinwall 1996, section 6.6),

$$n_{\mathrm{H}} - n_{\mathrm{V}} + 29 n_{\mathrm{T}} = 273 \qquad [9]$$

One class of examples is the heterotic string compactified on K3. In the original perturbative constructions, to satisfy eqn [7], we need to choose a vector bundle with $c_2(V) = \chi(K3) = 24$. The resulting degrees of freedom are a single self-dual tensor multiplet and a rank-16 gauge group. More generally, one can introduce $N_{5B}$ heterotic 5-branes, which generalize eqn [7] to $c_2(E) + N_{5B} = c_2(TK)$. Since this brane carries a self-dual tensor multiplet, this series of models is parametrized by $n_{\mathrm{T}}$. They are connected by transitions in which an $E_8$ instanton shrinks to zero size and becomes a 5-brane; the resulting decrease in the dimension of the moduli space of $E_8$ bundles on K3 agrees with eqn [9].

Another class of examples is F-theory on an elliptically fibered $CY_3$. These are related to M-theory on an elliptically fibered $CY_3$ in the same general way we discussed under $Ns = 16$. The relation between F-theory and the heterotic string on K3 can be seen by lifting M-theory-heterotic duality; this suggests that the two constructions are dual only if the $CY_3$ is a K3 fibration as well. Since not all elliptically fibered $CY_3$s are K3 fibered, the F-theory construction is more general.

We return to $d = 4$ and $Ns = 4$ in the final section. The cases of $Ns < 4$ which exist in $d \leq 3$ are far less studied.

## Stringy and Quantum Corrections

The $D$-dimensional low-energy effective supergravity actions on which we based our discussion so far are only approximations to the general story of string/M-theory compactification. However, if Planck's constant is small, $K$ is sufficiently large, and its curvature is small, then they are controlled approximations.

In M-theory, as in any theory of quantum gravity, corrections are controlled by the Planck scale parameter $M_{\mathrm{P}}^{D-2}$, which sits in front of the Einstein term of the $D$-dimensional effective Lagrangian, and plays the role of $\hbar$. In general, this is different from the four-dimensional Planck scale, which satisfies $M_{\mathrm{P}4}^2 = \mathrm{Vol}(K) M_{\mathrm{P}}^{D-2}$. After taking the low-energy limit $E \ll M_{\mathrm{P}}$, the remaining corrections are controlled by the dimensionless parameters $l_{\mathrm{P}}/R$, where $R$ can any characteristic length scale of the solution: a curvature radius, the length of a nontrivial cycle, and so on.

In string theory, one usually thinks of the corrections as a double series expansion in $g_{\mathrm{s}}$, the dimensionless (closed) string coupling constant, and $\alpha'$, the inverse string tension parameter, of dimensions $(\text{length})^2$. The ten-dimensional Planck scale is related to these parameters as $M_{\mathrm{P}}^8 = 1/g_{\mathrm{s}}^2 (\alpha')^4$, up to a constant factor that depends on conventions.

Besides perturbative corrections, which have power-like dependence on these parameters, there can be world sheet and "brane" instanton corrections. For example, a string world sheet can wrap around a topologically nontrivial spacelike 2-cycle $\Sigma$ in $K$, leading to an instanton correction to the effective action which is suppressed as $\exp(-\mathrm{Vol}(\Sigma)/2\pi\alpha')$. More generally, any $p$-brane wrapping a $p$-cycle can produce a similar effect. As for which terms in the effective Lagrangian receive corrections, this depends largely on the number and symmetries of the fermion zero modes on the instanton world volumes.

Let us start by discussing some cases in which one can argue that these corrections are not present.

First, extended supersymmetry can serve to eliminate many corrections. This is analogous to the familiar result that the superpotential in $d = 4, N = 1$ supersymmetric field theory does not receive (or "is protected from") perturbative corrections, and in many cases follows from similar formal arguments. In particular, supersymmetry forbids corrections to the potential and two derivative terms in the $Ns = 32$ and $Ns = 16$ Lagrangians.

In $Ns = 8$, the superpotential is protected, but the two derivative terms can receive corrections. However, there is a simple argument which precludes many such corrections – since vector multiplet and hypermultiplet moduli spaces are decoupled, a correction whose control parameter sits in (say) a vector multiplet, cannot affect hypermultiplet moduli space. This fact allows for many exact computations in these theories.

As an example, in IIb on $CY_3$, the metric on vector multiplet moduli space is precisely eqn [1] as obtained from supergravity (in other words, the Weil–Petersson metric on complex structure moduli space). First, while in principle it could have been corrected by world-sheet instantons, since these depend on Kähler moduli which sit in hypermultiplets, it is not. The only other instantons with the requisite zero modes to modify this metric are wrapped Dirichlet branes. Since in IIb theory these wrap even-dimensional cycles, they also depend on Kähler moduli and thus leave vector moduli space unaffected.

As previously discussed, for K3-fibered $CY_3$, this theory is dual to the heterotic string on $K3 \times T^2$. There, the vector multiplets arise from Wilson lines on $T^2$, and reduce to an adjoint multiplet of $N = 2$ supersymmetric Yang–Mills theory. Of course, in the quantum theory, the metric on this moduli space receives instanton corrections. Thus, the duality allows deriving the exact moduli space metric, and many other results of the Seiberg–Witten theory of $N = 2$ gauge theory, as aspects of the geometry of Calabi–Yau moduli space.

In $Ns = 4$, only the superpotential is protected, and that only in perturbation theory; it can receive nonperturbative corrections. Indeed, it appears that this is fairly generic, suggesting that the effective potentials in these theories are often sufficiently complicated to exhibit the structure required for supersymmetry breaking and the other symmetry breakings of the SM. Understanding this is an active subject of research.

We now turn from corrections to novel physical phenomena which arise in these regimes. While this is too large a subject to survey here, one of the basic principles which governs this subject is the idea that string/M-theory compactification on a singular manifold $K$ is typically consistent, but has new light degrees of freedom in the EFT, not predicted by KK arguments. We implicitly touched on one example of this in the discussion of M-theory compactification on K3 above, as the space of Ricci-flat K3 metrics has degeneration limits in which curvatures grow without bound, while the volumes of 2-cycles vanish. On the other hand, the structure of $Ns = 16$ supersymmetry essentially forces the $d = 7$ EFT in these limits to be nonsingular. Its only noteworthy feature is that a nonabelian gauge symmetry is restored, and thus certain charged vector bosons and their superpartners become massless.

To see what is happening microscopically, we must consider an M-theory membrane (or 2-brane), wrapped on a degenerating 2-cycle. This appears as a particle in $d = 7$, charged under the vector potential obtained by reduction of the $D = 11$ 3-form potential. The mass of this particle is the volume of the 2-cycle multiplied by the membrane tension, so as this volume shrinks to zero, the particle becomes massless. Thus, the physics is also well defined in 11 dimensions, though not literally described by 11-dimensional supergravity.

This phenomenon has numerous generalizations. Their common point is that, since the essential physics involves new light degrees of freedom, they can be understood in terms of a lower-dimensional quantum theory associated with the region around the singularity. Depending on the geometry of the singularity, this is sometimes a weakly coupled field theory, and sometimes a nontrivial conformal field theory. Occasionally, as in IIb on K3, the lightest wrapped brane is a string, leading to a "little string theory" (Aharony 2000).

## $N = 1$ Supersymmetry in Four Dimensions

Having described the general framework, we conclude by discussing the various constructions which lead to $N = 1$ supersymmetry. Besides the heterotic string on a $CY_3$, these compactifications include type IIa and IIb on orientifolds of $CY_3$, the related F-theory on elliptically fibered Calabi–Yau 4-folds ($CY_4$), and M-theory on $G_2$ manifolds. Let us briefly spell out their ingredients, the known nonperturbative corrections to the superpotential, and the duality relations between these constructions.

To start, we recap the heterotic string construction. We must specify a $CY_3 K$, and a bundle $E$ over $K$ which admits a Hermitian Yang–Mills connection. The gauge group $G$ is the commutant of the structure group of $E$ in $E_8 \times E_8$ or $\mathrm{Spin}(32)/\mathbb{Z}_2$,

while the chiral matter consists of metric moduli of $K$, and fields corresponding to a basis for the Dolbeault cohomology group $H^{0,1}(K, \mathrm{Rep}\, E)$ where Rep $E$ is the bundle $E$ embedded into an $E_8$ bundle and decomposed into $G$-reps.

There is a general (though somewhat formal) expression for the superpotential,

$$W = \int \Omega \wedge + \mathrm{tr}\left(\bar{A}\bar{\partial}\bar{A} + \tfrac{2}{3}\bar{A}^3\right) + \int \Omega \wedge H^{(3)} + W_{\mathrm{NP}} \qquad [10]$$

The first term is the holomorphic Chern–Simons action, whose variation enforces the $F^{0,2} = 0$ condition. The second is the "flux superpotential," while the third term is the nonperturbative corrections. The best understood of these arise from supersymmetric gauge theory sectors. In some, but not all, cases, these can be understood as arising from gauge theoretic instantons, which can be shown to be dual to heterotic 5-branes wrapped on $K$. Heterotic world-sheet instantons can also contribute.

The HO theory is $S$-dual to the type I string, with the same gauge group, realized by open strings on Dirichlet 9-branes. This construction involves essentially the same data. The two classes of heterotic instantons are dual to D1- and D5-brane instantons, whose world-sheet theories are somewhat simpler.

If the $\mathrm{CY}_3\, K$ has a fibration by tori, by applying $T$-duality to the fibers along the lines discussed for tori under $Ns = 16$ above, one obtains various type II orientifold compactifications. On an elliptic fibration, double $T$-duality produces a IIb compactification with D7s and O7s. Using the relation between IIb theory on $T^2$ and F-theory on K3 fiberwise, one can also think of this as an F-theory compactification on a K3-fibered $\mathrm{CY}_4$. More generally, one can compactify F theory on any elliptically fibered 4-fold to obtain $N = 1$. These theories have D3-instantons, the $T$-duals of both the type I D1- and D5-brane instantons.

The theory of mirror symmetry predicts that all $\mathrm{CY}_3$s have $T^3$ fibration structures. Applying the corresponding triple $T$-duality, one obtains a IIa compactification on the mirror $\mathrm{CY}_3\, \tilde{K}$, with D6-branes and O6-planes. Supersymmetry requires these to wrap special Lagrangian cycles in $\tilde{K}$. As in all Dirichlet brane constructions, enhanced gauge symmetry arises from coincident branes wrapping the same cycle, and only the classical groups are visible in perturbation theory. Exceptional gauge symmetry arises as a strong coupling phenomenon of the sort described in the previous section. The superpotential can also be thought of as mirror to eqn [10], but now the first term is the sum of a real Chern–Simons action on the special Lagrangian cycles, with disk world-sheet instanton corrections, as studied in open string mirror symmetry. The gauge theory instantons are now D2-branes.

Using the duality relation between the IIa string and 11-dimensional M-theory, this construction can be lifted to a compactification of M-theory on a seven-dimensional manifold $L$, which is an $S^1$ fibration over $K$. The D6 and O6 planes arise from singularities in the $S^1$ fibration. Generically, $L$ can be smooth, and the only candidate in Table 1 for such an $N = 1$ compactification is a manifold with $G_2$ holonomy; therefore, $L$ must have such holonomy. Finally, both the IIa world-sheet instantons and the D2-brane instantons lift to membrane instantons in M-theory.

This construction implicitly demonstrates the existence of a large number of $G_2$ holonomy manifolds. Another way to arrive at these is to go back to the heterotic string on $K$, and apply the duality (again under $Ns = 16$) between heterotic on $T^3$ and M-theory on K3 to the $T^3$ fibration structure on $K$, to arrive at M-theory on a K3-fibered manifold of $G_2$ holonomy. Wrapping membranes on 2-cycles in these fibers, we can see enhanced gauge symmetry in this picture fairly directly. It is an illuminating exercise to work through its dual realizations in all of these constructions.

Our final construction uses the interpretation of the strong coupling limit of the HE theory as M-theory on a one-dimensional interval $I$, in which the two $E_8$ factors live on the two boundaries. Thus, our original starting point can also be interpreted as the heterotic string on $K \times I$. This construction is believed to be important physically as it allows generalizing a heterotic string tree-level relation between the gauge and gravitational couplings which is phenomenologically disfavored. One can relate it to a IIa orientifold as well, now with D8- and O8-branes.

These multiple relations are often referred to as the "web" of dualities. They lead to numerous relations between compactification manifolds, moduli spaces, superpotentials, and other properties of the EFTs, whose full power has only begun to be appreciated.

## Suggestions for further reading

Original references for all but the most recent of these topics can be found in the following textbooks and proceedings. We have also referenced a few research articles which are good starting points for the more recent literature. There are far more reviews than we could reference here, and a partial listing of these appears at http://www.slac.stanford.edu/spires/reviews/

# Compressible Flows: Mathematical Theory

**G-Q Chen**, Northwestern University, Evanston, IL, USA

## Introduction

The Euler equations for compressible fluids consist of the conservation laws of mass, momentum, and energy:

$$\partial_t \rho + \nabla_{\boldsymbol{x}} \cdot \boldsymbol{m} = 0, \quad \boldsymbol{x} \in \boldsymbol{R}^d \qquad [1]$$

$$\partial_t \boldsymbol{m} + \nabla_{\boldsymbol{x}} \cdot \left( \frac{\boldsymbol{m} \otimes \boldsymbol{m}}{\rho} \right) + \nabla_{\boldsymbol{x}} p = 0 \qquad [2]$$

$$\partial_t E + \nabla_{\boldsymbol{x}} \cdot \left( \frac{\boldsymbol{m}}{\rho}(E + p) \right) = 0 \qquad [3]$$

Equivalently, these correspond to the general form of nonlinear hyperbolic systems of conservation laws:

$$\partial_t \boldsymbol{u} + \nabla_{\boldsymbol{x}} \cdot \boldsymbol{f}(\boldsymbol{u}) = 0, \quad \boldsymbol{x} \in \boldsymbol{R}^d, \ \boldsymbol{u} \in \boldsymbol{R}^n \qquad [4]$$

System [1]–[3] is closed by the following constitutive relations:

$$p = p(\rho, e), \qquad E = \frac{1}{2}\frac{|\boldsymbol{m}|^2}{\rho} + \rho e \qquad [5]$$

In [1]–[3] and [5], $\tau = 1/\rho$ is the deformation gradient (specific volume for fluids, strain for solids), $\boldsymbol{v} = (v_1, \ldots, v_d)^\top$ is the fluid velocity with $\rho \boldsymbol{v} = \boldsymbol{m}$ the momentum vector, $p$ is the scalar pressure, and $E$ is the total energy with $e$ the internal energy which is a given function of $(\tau, p)$ or $(\rho, p)$ defined through thermodynamical relations. The other two thermodynamic variables are temperature $\theta$ and entropy $S$. If $(\rho, S)$ are chosen as independent variables, then the constitutive relations can be written as

$$(e, p, \theta) = (e(\rho, S), p(\rho, S), \theta(\rho, S)) \qquad [6]$$

governed by $\theta \, \mathrm{d}S = \mathrm{d}e + p\mathrm{d}\tau = \mathrm{d}e - p\mathrm{d}\rho/\rho^2$. For polytropic gases,

$$\begin{aligned} p &= p(\rho, S) = \kappa \rho^\gamma \mathrm{e}^{S/c_v} \\ e &= \frac{p}{(\gamma - 1)\rho} \\ \theta &= \frac{p}{R\rho} \end{aligned} \qquad [7]$$

where $R > 0$ may be taken to be the universal gas constant divided by the effective molecular weight of the particular gas, $c_v > 0$ is the specific heat at constant volume, $\gamma = 1 + R/c_v > 1$ is the adiabatic exponent, and $\kappa$ can be any positive constant under scaling.

The most important criterion of applicability of any mathematical model is its well-posedness: existence, uniqueness, and stability. The well-posedness theory for compressible fluid flows is far from being complete, and many further issues are still unexplored. In particular, the global existence and uniqueness of solutions in $\boldsymbol{R}^d$, $d \geq 2$, is still a major open problem, and only partial results shed some lights on the amazing complexity of the problem. Below, we will mainly focus on the well-posedness issues with emphasis on the Cauchy problem, the initial value problem:

$$\boldsymbol{u}|_{t=0} = \boldsymbol{u}_0 \qquad [8]$$

first for inviscid compressible fluid flows and then for viscous compressible fluid flows.

Throughout this article, where a cited reference is not shown in the "Further reading" section, it may usually be found by consulting Bressan (2000),

Chen (2005), Dafermos (2005), Feireisl (2004), Lions (1986, 1988) or Liv (2000).

## Inviscid Compressible Fluid Flows: Euler Equations

Solutions to the Euler equations [1]–[3] are generically discontinuous functions obeying the Clausius–Duhem inequality, the second law of thermodynamics:

$$\partial_t(\rho S) + \nabla_{\boldsymbol{x}} \cdot (\boldsymbol{m}S) \geq 0 \qquad [9]$$

in the sense of distributions. Such discontinuous solutions are called entropy solutions.

When a flow is isentropic, that is, entropy $S$ is a uniform constant $S_0$ in the flow, then the Euler equations for the flow take the simpler form:

$$\begin{aligned} \partial_t\rho + \nabla_{\boldsymbol{x}} \cdot \boldsymbol{m} = 0 \\ \partial_t\boldsymbol{m} + \nabla_{\boldsymbol{x}} \cdot (\boldsymbol{m} \otimes \boldsymbol{m}/\rho) + \nabla_{\boldsymbol{x}}p = 0 \end{aligned} \qquad [10]$$

where the pressure is a function of the density, $p = p(\rho, S_0)$, with constant $S_0$. For a polytropic gas,

$$p(\rho) = \kappa\rho^\gamma, \quad \gamma > 1 \qquad [11]$$

where $\kappa$ can be any positive constant by scaling. This system can be derived from [1] to [3] as follows: for smooth solutions of [1]–[3], entropy $S(\rho, \boldsymbol{m}, E)$ is conserved along fluid particle trajectories, that is,

$$\partial_t(\rho S) + \nabla_{\boldsymbol{x}} \cdot (\boldsymbol{m}S) = 0$$

If the entropy is initially a uniform constant and the solution remains smooth, then the energy equation can be eliminated and entropy $S$ keeps the same constant in later time. Thus, under constant initial entropy, a smooth solution of [1]–[3] satisfies the equations in [10]. Furthermore, solutions of system [10] are also a good approximation to solutions of system [1]–[3] even after shocks form, since the entropy increases across a shock to the third order in wave strength for solutions of [1]–[3], while in [10] the entropy is constant. Moreover, system [10] is an excellent model for the isothermal fluid flow with $\gamma = 1$ and for the shallow-water flow with $\gamma = 2$. For such barotropic flows (i.e., $p = p(\rho)$), the energy equation [3] serves as an entropy inequality (see Lax (1973)):

$$\partial_t E + \nabla_{\boldsymbol{x}} \cdot (\boldsymbol{m}(E + p(\rho))/\rho) \leq 0$$
in the sense of distributions

In the one-dimensional case, system [1]–[3] in Eulerian coordinates is

$$\begin{aligned} &\partial_t\rho + \partial_x m = 0, \qquad \partial_t m + \partial_x\left(m^2/\rho + p\right) = 0 \\ &\partial_t E + \partial_x(m(E + p)/\rho) = 0 \end{aligned} \qquad [12]$$

The system above can be rewritten in Lagrangian coordinates:

$$\begin{aligned} &\partial_t\tau - \partial_x v = 0, \qquad \partial_t v + \partial_x p = 0 \\ &\partial_t(e + v^2/2) + \partial_x(pv) = 0 \end{aligned} \qquad [13]$$

with $v = m/\rho$, where the coordinates $(t, x)$ are the Lagrangian coordinates, which are different from the Eulerian coordinates for [12]; for simplicity of notations, we do not distinguish them. For the barotropic case, systems [12] and [13] reduce to

$$\partial_t\rho + \partial_x m = 0, \qquad \partial_t m + \partial_x\left(m^2/\rho + p\right) = 0 \qquad [14]$$

and

$$\partial_t\tau - \partial_x v = 0, \qquad \partial_t v + \partial_x p = 0 \qquad [15]$$

respectively, where pressure $p = p(\rho) = \tilde{p}(\tau)$, $\tau = 1/\rho$. The solutions of [12] and [13], as well as [14] and [15], are equivalent even for entropy solutions with vacuum where $\rho = 0$.

The potential flow is well known in transonic aerodynamics, beyond the isentropic approximation [10] from [1] to [3]. Denote $D_t = \partial_t + \sum_{k=1}^d v_k\partial_{x_k}$ the convective derivative along fluid particle trajectories. From [1] to [3], we have

$$D_t S = 0 \qquad [16]$$

and, by taking the curl of the momentum equations,

$$D_t\left(\frac{\omega}{\rho}\right) = \frac{\omega}{\rho} \cdot \nabla_{\boldsymbol{x}}\boldsymbol{v} + \frac{p_S(\rho, S)}{\rho^3}\nabla_{\boldsymbol{x}}\rho \times \nabla_{\boldsymbol{x}}S \qquad [17]$$

The identities [16] and [17] imply that a smooth solution of [1]–[3] which is both isentropic and irrotational at time $t = 0$ remains isentropic and irrotational for all later times, as long as this solution stays smooth. Then, the conditions $S = S_0 = \text{const.}$ and $\omega = \text{curl}_{\boldsymbol{x}}\boldsymbol{v} = 0$ are reasonable for smooth solutions. For a smooth irrotational solution, we integrate the $d$-momentum equations in [10] through Bernoulli's law:

$$\partial_t\boldsymbol{v} + \nabla_{\boldsymbol{x}}(|\boldsymbol{v}|^2/2) + \nabla_{\boldsymbol{x}}h(\rho) = 0$$

where $h'(\rho) = p_\rho(\rho, S_0)/\rho$. On a simply connected space region, the condition $\text{curl}_{\boldsymbol{x}}\,\boldsymbol{v} = 0$ implies that there exists $\Phi$ such that $\boldsymbol{v} = \nabla_{\boldsymbol{x}}\Phi$. Then,

$$\begin{aligned} \partial_t\rho + \nabla_{\boldsymbol{x}} \cdot (\rho\nabla_{\boldsymbol{x}}\Phi) = 0 \\ \partial_t\Phi + \tfrac{1}{2}|\nabla_{\boldsymbol{x}}\Phi|^2 + h(\rho) = K \end{aligned} \qquad [18]$$

for some constant $K$. From the second equation in [18], we have

$$\rho(D\Phi) = h^{-1}(K - (\partial_t\Phi + \tfrac{1}{2}|\nabla_{\boldsymbol{x}}\Phi|^2))$$

Then, system [18] can be rewritten as the following time-dependent potential flow equation of second order:

$$\partial_t \rho(D\Phi) + \nabla_x \cdot (\rho(D\Phi)\nabla_x \Phi) = 0 \qquad [19]$$

For a steady solution $\Phi = \Phi(x)$, that is, $\partial_t \Phi = 0$, we obtain the celebrated steady potential flow equation of aerodynamics:

$$\nabla_x \cdot (\rho(\nabla_x \Phi)\nabla_x \Phi) = 0 \qquad [20]$$

In applications in aerodynamics, [18] or [19] is used for discontinuous solutions, and the empirical evidence is that entropy solutions of [18] or [19] are fairly good approximations to entropy solutions for [1]–[3] provided that (1) the shock strengths are small, (2) the curvature of shock fronts is not too large, and (3) there is a small amount of vorticity in the region of interest. Model [19] or [18] is an excellent model to capture multidimensional shock waves by ignoring vorticity waves, while the incompressible Euler equations are an excellent model to capture multidimensional vorticity waves by ignoring shock waves.

### Local Well-Posedness for Classical Solutions

Consider the Cauchy problem for the Euler equations [1]–[3] with Cauchy data [8]:

> Assume that $u_0 : \mathbf{R}^d \to \mathcal{D}$ is in $H^s \cap L^\infty$ with $s > d/2 + 1$. Then, for the Cauchy problem [1]–[3] and [8], there exists a finite time $T = T(\|u_0\|_s, \|u_0\|_{L^\infty}) \in (0, \infty)$ such that there is a unique, stable bounded classical solution $u \in C^1([0, T] \times \mathbf{R}^d)$ with $u(t, x) \in \mathcal{D}$ for $(t, x) \in [0, T] \times \mathbf{R}^d$ and $u \in C([0, T]; H^s) \cap C^1([0, T]; H^{s-1})$. Moreover, the interval $[0, T)$ with $T < \infty$ is the maximal interval of the classical $H^s$ existence for [1]–[3] if and only if either $\|(u_t, \nabla_x u)\|_{L^\infty} \to \infty$ or $u(t, x)$ escapes every compact subset $K \Subset \mathcal{D}$ as $t \to T$.

This local existence can be established by relying solely on the elementary linear existence theory for symmetric hyperbolic systems with smooth coefficients (cf. Majda (1984)), or by the abstract semigroup theory (Kato 1975).

### Formation of Singularities

For the one-dimensional case, singularities include the development of shock waves and formation of vacuum states. For the multidimensional case, the situation is much more complicated: besides shock waves and vacuum states, singularities can also be generated from vortex sheets, focusing and breaking of waves, among others.

Consider the Cauchy problem of the Euler equations [1]–[3] in $\mathbf{R}^3$ for polytropic gases with smooth initial data:

$$(\rho, v, S)|_{t=0} = (\rho_0, v_0, S_0)(x)$$
$$\rho_0(x) > 0, \ x \in \mathbf{R}^3 \qquad [21]$$

satisfying $(\rho_0, v_0, S_0)(x) = (\bar{\rho}, 0, \bar{S})$ for $|x| \ge L$, where $\bar{\rho} > 0$, $\bar{S}$, and $L$ are given constants. The equations possess a unique local $C^1$ solution $(\rho, v, S)(t, x)$ with $\rho(t, x) > 0$ provided that the initial data [21] is sufficiently regular. The support of the smooth disturbance $(\rho_0(x) - \bar{\rho}, v_0(x), S_0(x) - \bar{S})$ propagates with speed at most $\sigma = \sqrt{p_\rho(\bar{\rho}, \bar{S})}$ (the sound speed), that is,

$$(\rho, v, S)(t, x) = (\bar{\rho}, 0, \bar{S}) \quad \text{if } |x| \ge L + \sigma t \qquad [22]$$

Define

$$P(t) = \int_{\mathbf{R}^3} \left( p(\rho(t, x), S(t, x))^{1/\gamma} - p(\bar{\rho}, \bar{S})^{1/\gamma} \right) \mathrm{d}x$$
$$F(t) = \int_{\mathbf{R}^3} (\rho v)(t, x) \cdot x \, \mathrm{d}x$$

which, roughly speaking, measure the entropy and the radial component of momentum. Then, if $(\rho, v, S)(t, x)$ is a $C^1$ solution of [1]–[3] and [21] for $0 < t < T$, and

$$P(0) \ge 0, \qquad F(0) > \alpha\sigma R^4 \max_x \rho_0(x)$$
$$\text{with} \quad \alpha = 16\pi/3 \qquad [23]$$

then the lifespan $T$ of the $C^1$ solution is finite (Sideris 1985).

To illustrate a way in which the conditions in [23] may be satisfied, consider the initial data: $\rho_0 = \bar{\rho}$, $S_0 = \bar{S}$. Then $P(0) = 0$, and [23] holds if

$$\int_{|x|<R} v_0(x) \cdot x \, \mathrm{d}x > \alpha\sigma R^4$$

Comparing both sides, one finds that the initial velocity must be supersonic in some region relative to the sound speed at infinity. The formation of a singularity (presumably a shock wave) is detected as the disturbance overtakes the wave front forcing the front to propagate with supersonic speed.

Singularities are formed even without the condition of largeness, such as [23], being satisfied. For example, if $S_0(x) \ge \bar{S}$ and, for some $0 < R_0 < R$,

$$\int_{|x|>r} |x|^{-1}(|x| - r)^2(\rho_0(x) - \bar{\rho}) \, \mathrm{d}x > 0$$
$$\int_{|x|>r} |x|^{-3}(|x|^2 - r^2)\rho_0(x) v_0(x) \cdot x \, \mathrm{d}x \ge 0 \qquad [24]$$

for $R_0 < r < R$, then the lifespan $T$ of the $C^1$ solution of [1]–[3] and [21] is finite. The

assumptions in [24] mean that, in an average sense, the gas must be slightly compressed and outgoing directly behind the wave front.

### Local Well-Posedness for Shock-Front Solutions

For a general hyperbolic system of conservation laws [4], shock-front solutions are discontinuous, piecewise smooth entropy solutions with the following structure:

1. There exists a $C^2$ spacetime hypersurface $\mathcal{S}(t)$ defined in $(t, \boldsymbol{x})$ for $0 \le t \le T$ with spacetime normal $(\nu_t, \nu_{\boldsymbol{x}}) = (\nu_t, \nu_1, \ldots, \nu_d)$ as well as two $C^1$ vector-valued functions: $\boldsymbol{u}^+(t, \boldsymbol{x})$ and $\boldsymbol{u}^-(t, \boldsymbol{x})$, defined on respective domains $\mathcal{D}^+$ and $\mathcal{D}^-$ on either side of the hypersurface $\mathcal{S}(t)$ and satisfying $\partial_t \boldsymbol{u}^\pm + \nabla_{\boldsymbol{x}} \cdot \boldsymbol{f}(\boldsymbol{u}^\pm) = 0$ in $\mathcal{D}^\pm$;
2. The jump across the hypersurface $\mathcal{S}(t)$ satisfies the Rankine–Hugoniot condition:

$$\{\nu_t(\boldsymbol{u}^+ - \boldsymbol{u}^-) + \nu_{\boldsymbol{x}} \cdot (\boldsymbol{f}(\boldsymbol{u}^+) - \boldsymbol{f}(\boldsymbol{u}^-))\}|_{\mathcal{S}} = 0$$

For [4], the surface $\mathcal{S}$ is not known in advance and must be determined as part of the solution of the problem; thus, the two equations in (1)–(2) describe a multidimensional, highly nonlinear, free-boundary-value problem. The initial data yielding shock-front solutions is defined as follows. Let $\mathcal{S}_0$ be a smooth hypersurface parametrized by $\alpha$, and let $\nu(\alpha) = (\nu_1, \ldots, \nu_d)(\alpha)$ be a unit normal to $\mathcal{S}_0$. Define the piecewise smooth initial values for respective domains $\mathcal{D}_0^+$ and $\mathcal{D}_0^-$ on either side of the hypersurface $\mathcal{S}_0$ as

$$\boldsymbol{u}_0(\boldsymbol{x}) = \begin{cases} \boldsymbol{u}_0^+(\boldsymbol{x}), & \boldsymbol{x} \in \mathcal{D}_0^+ \\ \boldsymbol{u}_0^-(\boldsymbol{x}), & \boldsymbol{x} \in \mathcal{D}_0^- \end{cases} \qquad [25]$$

It is assumed that the initial jump in [25] satisfies the Rankine–Hugoniot condition, that is, there is a smooth scalar function $\sigma(\alpha)$ so that

$$\begin{aligned} &-\sigma(\alpha)\big(\boldsymbol{u}_0^+(\alpha) - \boldsymbol{u}_0^-(\alpha)\big) \\ &+ \nu(\alpha) \cdot \big(\boldsymbol{f}\big(\boldsymbol{u}_0^+(\alpha)\big) - \boldsymbol{f}\big(\boldsymbol{u}_0^-(\alpha)\big)\big) = 0 \end{aligned} \qquad [26]$$

and that $\sigma(\alpha)$ does not define a characteristic direction, that is,

$$\sigma(\alpha) \ne \lambda_i\big(\boldsymbol{u}_0^\pm\big), \quad \alpha \in \bar{\mathcal{S}}_0,\ 1 \le i \le n \qquad [27]$$

where $\lambda_i$, $i = 1, \ldots, n$, are the eigenvalues of [4]. It is natural to require that $\mathcal{S}(0) = \mathcal{S}_0$.

Consider the Euler equations [1]–[3] in $\boldsymbol{R}^3$ for polytropic gases with piecewise smooth initial data:

$$(\rho, \boldsymbol{v}, E)|_{t=0} = \begin{cases} \big(\rho_0^+, \boldsymbol{v}_0^+, E^+\big)(\boldsymbol{x}), & \boldsymbol{x} \in \mathcal{D}_0^+ \\ \big(\rho_0^-, \boldsymbol{v}_0^-, E^-\big)(\boldsymbol{x}), & \boldsymbol{x} \in \mathcal{D}_0^- \end{cases} \qquad [28]$$

Assume that $\mathcal{S}_0$ is a smooth compact surface in $\boldsymbol{R}^3$ and that $(\rho_0^+, \boldsymbol{v}_0^+, E_0^+)(\boldsymbol{x})$ belongs to the uniform local Sobolev space $H^s_{\mathrm{ul}}(\mathcal{D}_0^+)$, while $(\rho_0^-, \boldsymbol{v}_0^-, E_0^-)(\boldsymbol{x})$ belongs to the Sobolev space $H^s(\mathcal{D}_0^-)$, for some fixed $s \ge 10$. Assume also that there is a function $\sigma(\alpha) \in H^s(\mathcal{S}_0)$ so that [26] and [27] hold, and the compatibility conditions up to order $s - 1$ are satisfied on $\mathcal{S}_0$ by the initial data, together with the entropy condition:

$$\begin{aligned} &\boldsymbol{v}_0^+ \cdot \nu(\alpha) + \sqrt{p_\rho(\rho_0^+, S_0^+)} < \sigma(\alpha) \\ &< \boldsymbol{v}_0^- \cdot \nu(\alpha) + \sqrt{p_\rho(\rho_0^-, S_0^-)} \end{aligned} \qquad [29]$$

Then, there are a $C^2$ hypersurface $\mathcal{S}(t)$ and $C^1$ functions $(\rho^\pm, \boldsymbol{v}^\pm, E^\pm)(t, \boldsymbol{x})$ defined for $t \in [0, T]$, with $T$ sufficiently small, so that

$$(\rho, \boldsymbol{v}, E)(t, \boldsymbol{x}) = \begin{cases} (\rho^+, \boldsymbol{v}^+, E^+)(t, \boldsymbol{x}), & (t, \boldsymbol{x}) \in \mathcal{D}^+ \\ (\rho^-, \boldsymbol{v}^-, E^-)(t, \boldsymbol{x}), & (t, \boldsymbol{x}) \in \mathcal{D}^- \end{cases} \qquad [30]$$

is the discontinuous shock-front solution of the Cauchy problem [1]–[3] and [28]. Here a vector function $\boldsymbol{u}$ is in $H^s_{\mathrm{ul}}$, provided that there exists some $r > 0$ so that $\max_{\boldsymbol{y} \in \boldsymbol{R}^d} \|w_{r,\boldsymbol{y}} \boldsymbol{u}\|_{H^s} < \infty$ with $w_{r,\boldsymbol{y}}(\boldsymbol{x}) = w((\boldsymbol{x} - \boldsymbol{y})/r)$, where $w \in C_0^\infty(\boldsymbol{R}^d)$ is a function so that $w(\boldsymbol{x}) \ge 0$, $w(\boldsymbol{x}) = 1$ when $|\boldsymbol{x}| \le 1/2$, and $w(\boldsymbol{x}) = 0$ when $|\boldsymbol{x}| > 1$.

The compatibility conditions are needed in order to avoid the formation of discontinuities in higher derivatives along other characteristic surfaces emanating from $\mathcal{S}_0$: Once the main condition [26] is satisfied, the compatibility conditions are automatically guaranteed for a wide class of initial data. The idea of the proof is to use the existence of a strictly convex entropy and the symmetrization of [4]; the shock-front solutions are defined as the limit of a convergent classical iteration scheme based on a linearization by using the theory of linearized stability for shock fronts (Majda 1984). The uniform existence time of shock-front solutions in shock strength can be achieved (Métivier 1990).

### Global Theory in $L^\infty$ for the Isentropic Euler Equations for $x \in \boldsymbol{R}$

Consider the Cauchy problem for [14] with initial data:

$$(\rho, m)|_{t=0} = (\rho_0, m_0)(x) \qquad [31]$$

where $\rho_0$ and $m_0$ are in the physical region $\{(\rho, m) : \rho \ge 0, |m| \le C_0 \rho\}$ for some $C_0 > 0$. System [14] is strictly hyperbolic at the states with $\rho > 0$, and strict hyperbolicity fails at the vacuum states $V := \{(\rho, m/\rho) : \rho = 0, |m/\rho| < \infty\}$. Then, we have:

1. There exists a global solution $(\rho, m)(t, x)$ of the Cauchy problem [14] and [31] satisfying

$$0 \le \rho(t, x) \le C, \qquad |m(t, x)| \le C\rho(t, x) \qquad [32]$$

for some $C > 0$ depending only on $C_0$ and $\gamma$, and the entropy inequality

$$\partial_t \eta(\rho, m) + \partial_x q(\rho, m) \leq 0 \qquad [33]$$

in the sense of distributions for any convex weak entropy–entropy flux pair $(\eta, q)$, that is,

$$\nabla q(\rho, m) = \nabla \eta(\rho, m) \nabla f(\rho, m)$$

with

$$\nabla^2 \eta(\rho, m) \geq 0 \quad \text{and} \quad \eta|_V = 0$$

2. The solution operator $(\rho, m)(t, \cdot) = S_t(\rho_0, m_0)(\cdot)$, determined by (1), is compact in $L^1_{\text{loc}}(\boldsymbol{R})$ for $t > 0$;
3. Furthermore, if $(\rho_0, m_0)(x)$ is periodic with period $P$, then there exists a global periodic solution $(\rho, m)(t, x)$ with [32] such that $(\rho, m)(t, x)$ asymptotically decays to

$$\frac{1}{|P|} \int_P (\rho_0, m_0)(x) \mathrm{d}x$$

in $L^1$.

The convergence of the Lax–Friedrichs scheme, the Godunov scheme, and the vanishing viscosity method for system [14] have also been established.

The results are based on a compensated compactness framework to replace the BV compactness framework. For a gas obeying the $\gamma$-law, the case $\gamma = (N+2)/N$, $N \geq 5$ odd, was first studied by DiPerna (1983), and the case $1 < \gamma \leq 5/3$ for usual gases was first solved by Chen (1986) and Ding-Chen-Luo (1985). The cases $\gamma \geq 3$ and $5/3 < \gamma < 3$ were treated by Lions–Perthame–Tadmor (1994) and Lions–Perthame–Souganidis (1996), respectively. The case of general pressure laws was solved by Chen–LeFloch (2000, 2003). All the results for entropy solutions to [14] in Eulerian coordinates can equivalently be presented as the corresponding results for entropy solutions to [15] in Lagrangian coordinates. The isothermal case $\gamma = 1$ was treated by Huang–Wang (2002).

### Global Theory in BV for the Adiabatic Euler Equations for $x \in \boldsymbol{R}$

Consider the Euler equations [13] for polytropic gases with the Cauchy data:

$$(\tau, v, S)|_{t=0} = (\tau_0, v_0, S_0)(x) \qquad [34]$$

Then we have (Liu 1977, Temple 1981, Chen and Wagner 2003):

> Let $K \subset \{(\tau, v, S) : \tau > 0\}$ be a compact set in $\boldsymbol{R}_+ \times \boldsymbol{R}^2$, and let $N \geq 1$ be any constant. Then there exists a constant $C_0 = C_0(K, N)$, independent of $\gamma \in (1, 5/3]$, such that, for every initial data $(\tau_0, v_0, S_0) \in K$ with $TV_{\boldsymbol{R}}(\tau_0, v_0, S_0) \leq N$, when
>
> $$(\gamma - 1) TV_{\boldsymbol{R}}(\tau_0, v_0, S_0) \leq C_0 \quad \text{for any } \gamma \in (1, 5/3]$$
>
> the Cauchy problem [13] and [34] has a global entropy solution $(\tau, v, S)(t, x)$ which is bounded and satisfies
>
> $$TV_{\boldsymbol{R}}(\tau, v, S)(t, \cdot) \leq C\, TV_{\boldsymbol{R}}(\tau_0, v_0, S_0)$$
>
> for some constant $C > 0$ independent of $\gamma$.

This result specially includes that for the barotropic case (Nishida 1968, Nishida–Smoller 1973, DiPerna 1973). Some efforts in the direction of relaxing the requirement of small total variation have been made. Some extensions to the initial-boundary value problems have also been made. In addition, an entropy solution in BV with periodic data or compact support decays when $t \to 0$. Furthermore, even for a general hyperbolic system [4] for $x \in R$, we have:

> If the initial data functions $\boldsymbol{u}_0(x)$ and $\boldsymbol{v}_0(x)$ have sufficiently small total variation and $\boldsymbol{u}_0 - \boldsymbol{v}_0 \in L^1(\boldsymbol{R})$, then, for the corresponding exact Glimm, or wave-front tracking, or vanishing viscosity solutions $\boldsymbol{u}(t, x)$ and $\boldsymbol{v}(t, x)$ of the Cauchy problem [4] and [8], there exists a constant $C > 0$ such that
>
> $$\|\boldsymbol{u}(t, \cdot) - \boldsymbol{v}(t, \cdot)\|_{L^1(\boldsymbol{R})} \leq C \|\boldsymbol{u}_0 - \boldsymbol{v}_0\|_{L^1(\boldsymbol{R})} \quad \text{for all } t > 0 \qquad [35]$$

An immediate consequence is that the whole sequence of the approximate solutions constructed by the Glimm (1965) scheme, as well as the wave-front tracking method and the vanishing viscosity method, converges to a unique entropy solution of [4] and [8] when the mesh size or the viscosity coefficient tends to zero. More detailed discussions and extensive references about the $L^1$-stability of BV entropy solutions and related topics can be found in Bressan (2000) and Dafermos (2000); also see Chen and Wang (2002). Furthermore, the Riemann solution is unique and asymptotically stable in the class of entropy solutions to [13] with large variation satisfying only one physical entropy inequality (Chen-Frid-Li 2002).

### Multidimensional Steady Theory

The mathematical study of two-dimensional steady supersonic flows past wedges, whose vertex angles are less than the critical angle, can date back to the 1940s, since the stability of such flows is fundamental in applications (cf. Courant–Friedrichs (1948)). Local solutions around the wedge vertex were first constructed (Gu 1962, Schaeffer 1976, Li 1980).

Such global potential solutions were constructed when the wedge has some convexity, or is a small perturbation of the straight wedge with fast decay in the flow direction (Chen 2001, Chen-Xin-Yin 2002), or is piecewise smooth which is a small perturbation of straight wedge (Zhang 2003). For the two-dimensional steady supersonic flows governed by the full Euler equations past Lipschitz wedges, it indicates (Chen-Zhang-Zhu 2005a) that, when the wedge vertex angle is less than the critical angle, the strong shock front emanating from the wedge vertex is nonlinearly stable in structure globally, although there may be many weak shocks and vortex sheets between the wedge boundary and the strong shock front, under the BV perturbation of the wedge so that the total variation of the tangent function along the wedge boundary is suitably small. This asserts that any supersonic shock for the wedge problem is nonlinearly stable.

A self-similar gas flow past an infinite cone in $\boldsymbol{R}^3$ with small vertex angle is also nonlinearly stable upon the BV perturbation of the obstacle (Lien-Liu 1999). It is still open for the nonlinear stability when the infinite cone in $\boldsymbol{R}^3$ has arbitrary vertex angle. The stability issues of supersonic vertex sheets have been studied by classical linearized stability analysis, large-scale numerical simulations, and asymptotic analysis. In particular, the nonlinear development of instabilities of supersonic vortex sheets at high Mach number was predicted as time evolves (Woodward 1985, Artola-Majda 1989). In contrast with the prediction of evolution instability, steady supersonic vortex sheets, as time-asymptotics, are stable globally in structure, even under the BV perturbation of the Lipschitz walls, although there may be many weak shocks and supersonic vortex sheets away from the strong vortex sheet (Chen-Zhang-Zhu 2005b).

Transonic shock problems for steady fluid flows are important in applications (cf. Courant and Friedrichs (1948)). A program on the existence and stability of multidimensional transonic shocks has been initiated and three new analytical approaches have been developed (Chen-Feldman 2003, 2004). The transonic problems include the existence and stability of transonic shocks in the whole $\boldsymbol{R}^d$, the existence and stability of transonic flows past finite or infinite nozzles, the stability of transonic flows past infinite nonsmooth wedges, and the existence of regular shock reflection solutions. The first approach is an iteration scheme based on the nondegeneracy of the free boundary condition: the jump of the normal derivative of a solution across the free boundary has a strictly positive lower bound (Chen-Feldman 2003, 2004), which works for the nonlinear equations whose coefficients may depend on not only the solution itself but also the gradients of the solution. The second approach is a partial hodograph procedure, with which the existence and stability of multidimensional transonic shocks that are not nearly orthogonal to the flow direction can be handled (Chen-Feldman 2004): one of the main ingredients in this approach is to employ a partial hodograph transform to reduce the free boundary problem into a conormal boundary value problem for the corresponding nonlinear equations of divergence form and then develop techniques to solve the conormal boundary value problem. When the regularity of the steady perturbation is $C^{3,\alpha}$ or higher, the third approach is to employ the implicit function theorem to deal with the existence and stability problem. Another iteration approach, which works well for the two-dimensional equations whose coefficients depend only on the solution itself, has also been developed (Canic-Keyfitz-Lieberman 2000).

Further longstanding open problems include the existence of global transonic flows past an airfoil or a smooth obstacle (Morawetz 1956–58, 1985).

#### Multidimensional Unsteady Problems

Now we present some multidimensional time-dependent problems with a simplifying feature that the data (domain and/or the initial data) coupled with the structure of the underlying equations obey certain geometric structure so that the multidimensional problems can be reduced to lower-dimensional problems with more complicated couplings. Different types of geometric structure call for different techniques.

The Euler equations for compressible fluids with geometric structure describe many important fluid flows, including spherically symmetric flows and self-similar flows. Such geometric flows are motivated by many physical problems such as shock diffractions, supernovas formation in stellar dynamics, inertial confinement fusion, and underwater explosions. For the initial data with large amplitude having geometric structure, the required physical insight is: (1) whether the solution has the same geometric structure globally and (2) whether the solution blows up to infinity in a finite time. These questions are not easily understood in physical experiments and numerical simulations, especially for the blow-up, because of the limited capacity of available instruments and computers.

The first type of geometric structure is spherical symmetry. A criterion for $L^\infty$ Cauchy data functions of arbitrarily large amplitude was observed to guarantee the existence of spherically symmetric solutions in $L^\infty$ in the large for the isentropic flows, which model outgoing blast waves and large-time asymptotic solutions (Chen 1997). On the other hand, it is evident that the density blows up as $|\boldsymbol{x}| \to 0$ in general, especially for the focusing case; the singularity at the origin makes the problem truly multidimensional due to the reflection of waves from infinity and their strengthening as they move radially inwards. One of the important open questions is to understand the order of singularity, $\rho(t, |\boldsymbol{x}|) \sim |\boldsymbol{x}|^{-\alpha}$, at the origin for bounded Cauchy data.

The second type of geometric structure is self-similarity, that is, the solutions with initial data functions that give rise to self-similar solutions, especially including Riemann solutions. Compressible flow equations in $\boldsymbol{R}^d$, $d \geq 2$, with one or more linearly degenerate modes of wave propagation have additional difficulties. In that case, the global flow is governed by a reduced (self-similar) system which is of composite (hyperbolic–elliptic) type in the subsonic region. The linearly degenerate waves give rise to one or more families of degenerate characteristics which remain real in the subsonic region. In some cases, the reduced equations couple an elliptic (degenerate elliptic) problem for the density with a hyperbolic (transport) equation for the vorticity.

An important prototype for both practical applications and the theory of multidimensional complex wave patterns is the problem of diffraction of a shock wave which is incident along an inclined ramp (see Glimm and Majda (1991)). When a plane shock hits a wedge head-on, a self-similar reflected shock moves outward as the original shock moves forward. The computational and asymptotic analysis shows that various patterns of reflected shocks may occur, including regular reflection and (simple, double, and complex) Mach reflections. The main part or whole reflected shock is a transonic shock in the self-similar coordinates, for which the corresponding equation changes the type from hyperbolic to elliptic across the shock. There are few rigorous mathematical results on the global existence and stability of shock reflection solutions and the transition among regular, simple Mach, double Mach, and complex Mach reflections for the potential flow equation [19] and the full Euler equations [1]–[3]. Some results were recently obtained for simplified models including the transonic small-disturbance equation near the reflection point and the pressure gradient equation when the wedge is close to a flat wall.

For the potential flow equation [19], a self-similar solution is a solution of the form: $\Psi = t\phi(\boldsymbol{y})$, $\boldsymbol{y} = \boldsymbol{x}/t$. Letting $\varphi(\boldsymbol{y}) = -\boldsymbol{y}^2/2 + \phi(\boldsymbol{y})$, then the system can be rewritten in the form of a second-order equation of mixed hyperbolic–elliptic type in $\boldsymbol{y} \in \boldsymbol{R}^d$ by scaling:

$$\nabla_{\boldsymbol{y}} \cdot (\rho(|\nabla_{\boldsymbol{y}}\varphi|^2, \varphi)\nabla_{\boldsymbol{y}}\varphi) + d\rho(|\nabla_{\boldsymbol{y}}\varphi|^2, \varphi) = 0 \qquad [36]$$

with $\rho(q^2, z) = (1 - (q^2 + 2z)/2)^{1/(\gamma-1)}$. Equation [36] at $|\nabla_{\boldsymbol{y}}\varphi| = q$ is hyperbolic (pseudosupersonic) if $\rho(q^2, z) + q\rho_q(q^2, z) < 0$ and elliptic (pseudosubsonic) if $\rho(q^2, z) + q\rho_q(q^2, z) > 0$. Under this framework, the nature of the shock reflection pattern has been explored for weak incident shocks (strength $b$) and small wedge angles $2\theta_{\mathrm{w}}$ by a number of different scalings, a study of mixed equations, and matching asymptotics for the different scalings, where the parameter $\beta = c_1\theta_{\mathrm{w}}^2/b(\gamma + 1)$ ranges from 0 to $\infty$ and $c_1$ is the speed of sound behind the incident shock (Morawetz 1994). For $\beta > 2$, a regular reflection of both strong and weak kinds is possible as well as a Mach reflection; for $\beta < 1/2$, a Mach reflection occurs and the flow behind the reflection is subsonic and can be constructed in principle (with an elliptic problem) and matched; and for $1/2 < \beta < 2$, the flow behind a Mach reflection may be transonic which is a solution of a nonlinear boundary-value problem of mixed type. The basic pattern of reflection has been shown to be an almost semicircular shock issuing, for a regular reflection, from the reflection point on the wedge and, for a Mach reflection, matched with a local interaction flow. Some related observations were also made (Keller-Blank 1951, Hunter-Keller 1984, Hunter 1988). It is important to establish rigorous proofs. Recently, a rigorous existence proof was established for global solutions to shock reflection by large-angle wedges in Chen and Feldman (2005).

### Analytical Frameworks for Entropy Solutions

The recent great progress for entropy solutions for one-dimensional time-dependent Euler equations and two-dimensional steady Euler equations, based on BV, $L^1$, or even $L^\infty$ estimates, naturally arises the expectation that a similar approach may also be effective for the multidimensional Euler equations, or more generally, hyperbolic systems of conservation laws, especially,

$$\|\boldsymbol{u}(t, \cdot)\|_{\mathrm{BV}} \leq \mathrm{C}\|\boldsymbol{u}_0\|_{\mathrm{BV}} \qquad [37]$$

Unfortunately, this is not the case. The necessary condition for [37] to be held for $p \neq 2$ (Rauch 1986) is

$$\nabla f_k(\boldsymbol{u})\nabla f_l(\boldsymbol{u}) = \nabla f_l(\boldsymbol{u})\nabla f_k(\boldsymbol{u}) \quad \text{for all } k, l = 1, 2, \ldots, d \qquad [38]$$

The analysis suggests that only systems in which the commutativity relation [38] holds offer any hope for treatment in the framework of BV. This special case includes the scalar case $n = 1$ and the case of one space dimension $d = 1$. Beyond that, it contains very few systems of physical interest.

In this regard, it is important to identify effective analytical frameworks for studying entropy solutions of the multidimensional Euler equations [1]–[3], which are not in BV. Naturally, we want to approach the questions of existence, stability, uniqueness, and long-time behavior of entropy solutions with as much generality as possible. For this purpose, a theory of divergence-measure fields to construct such a global framework has been developed for studying entropy solutions (Chen-Frid 1999, 2000, Chen-Torres 2005, Chen-Torres-Ziemer 2005). For more details, see Chen (2005).

## Viscous Compressible Fluid Flows: Navier–Stokes Equations

Compressible fluid flows that are viscous and conduct heat are governed by the following Navier–Stokes equations:

$$\partial_t \rho + \nabla_{\boldsymbol{x}} \cdot \boldsymbol{m} = 0, \quad \boldsymbol{x} \in \boldsymbol{R}^d \qquad [39]$$

$$\partial_t \boldsymbol{m} + \nabla_{\boldsymbol{x}} \cdot \left(\frac{\boldsymbol{m} \otimes \boldsymbol{m}}{\rho}\right) + \nabla_{\boldsymbol{x}} p = \nabla_{\boldsymbol{x}} \cdot \boldsymbol{\Sigma} \qquad [40]$$

$$\partial_t E + \nabla_{\boldsymbol{x}} \cdot \left(\frac{\boldsymbol{m}}{\rho}(E + p)\right) = \nabla_{\boldsymbol{x}} \cdot \left(\frac{\boldsymbol{m}}{\rho} \cdot \boldsymbol{\Sigma}\right) - \nabla_{\boldsymbol{x}} \cdot \boldsymbol{q} \qquad [41]$$

Here, $\boldsymbol{\Sigma} = \boldsymbol{\Sigma}(\nabla_{\boldsymbol{x}}\boldsymbol{v}, \rho, \theta)$ is the viscous stress tensor which is symmetric from the conservation of angular momentum and $\boldsymbol{q}$ is the heat flux. If the fluid is isotropic and the viscous tensor $\boldsymbol{\Sigma}$ is a linear function of $\nabla_{\boldsymbol{x}}\boldsymbol{v}$ and invariant under a change of reference frame (translation and rotation), then we deduce from elementary algebraic manipulations that necessarily

$$\boldsymbol{\Sigma} = \lambda(\rho, \theta)\nabla_{\boldsymbol{x}} \cdot \boldsymbol{v} + 2\mu(\rho, \theta)D \qquad [42]$$

which corresponds to the Newtonian fluids, where $D = (\nabla_{\boldsymbol{x}}\boldsymbol{v} + (\nabla_{\boldsymbol{x}}\boldsymbol{v})^{\top})/2$ is the deformation tensor and $\lambda$ and $\mu$ are the Lamé viscosity coefficients. Furthermore, since the fluid is isotropic, we are led to the Fourier law:

$$\boldsymbol{q} = -k(\rho, \theta, |\nabla_{\boldsymbol{x}}\theta|)\nabla_{\boldsymbol{x}}\theta$$

for scalar function $k$ which, in most cases, is taken to be simply a function of $\rho$ and $\theta$, or even a constant called the thermal conduction coefficient. Again, system [39]–[41] is closed by the constitutive relations in [5]. The equation for entropy $S$ is

$$\partial_t(\rho S) + \nabla_{\boldsymbol{x}} \cdot \left(\boldsymbol{m}S + \frac{\boldsymbol{q}}{\theta}\right) = \frac{\boldsymbol{\Sigma}(\nabla_{\boldsymbol{x}}\boldsymbol{v}) : \nabla_{\boldsymbol{x}}\boldsymbol{v}}{\theta} - \frac{\boldsymbol{q} \cdot \nabla_{\boldsymbol{x}}\theta}{\theta^2} \qquad [43]$$

The second law of thermodynamics indicates that the right-hand side of [43] should be non-negative which yields the restriction:

$$k(\rho, \theta, |\nabla_{\boldsymbol{x}}\theta|) \geq 0, \quad \mu \geq 0, \quad \lambda + 2\mu/d \geq 0$$

The case $\mu > 0$ and $\lambda + \mu > 0$ is the viscous case with heat conductivity $k > 0$. In particular, the kinetic theory indicates that the Stokes relationship should hold, namely $\lambda = -2\mu/d$ and the adiabatic component $\gamma = 5/3$ for monatomic gases.

In mathematical viscous fluid dynamics, an important model is the barotropic model for viscous fluids, that is, $p = p(\rho)$. Then, the specific energy $E$ can be taken in the form of $E = (1/2)\rho|\boldsymbol{v}|^2 + \rho e(\rho)$ with $e'(\rho) = p(\rho)/\rho^2$. For classical solutions, the energy of a barotropic flow satisfies the equality:

$$\partial_t E + \nabla_{\boldsymbol{x}} \cdot ((E + p)\boldsymbol{v}) = \nabla_{\boldsymbol{x}} \cdot (\boldsymbol{\Sigma}\boldsymbol{v}) - \boldsymbol{\Sigma} : \nabla_{\boldsymbol{x}}\boldsymbol{v}$$

which is now a direct consequence of [39] and [40].

The question of local existence of classical solutions to [39]–[41] for regular initial data was addressed by Nash (1962), where there is no indication whether or not these solutions exist for all times.

In the case of one space dimension, the well-posedness is largely settled. The basic result for the existence of classical solutions is that of Kazhikhov (1976); see Lions (1998) and Feireisl (2004) for extensive references. The discontinuous solutions have been constructed (Shelukhin 1979, Serre 1986, Hoff 1987, Chen-Hoff-Trivisa 2000).

For the Navier–Stokes equations in $\boldsymbol{R}^3$ with general equation of state, the global classical solutions for the Cauchy problem and various initial-boundary value problems whose initial data is small around a constant state have been

constructed (Matsumura-Nishida 1980, 1983). The approach is to obtain *a priori* estimates via energy methods for extending the local solution or for a difference method globally. These results have been extended to the Cauchy problem or the initial-boundary value problems with small discontinuous initial data (Hoff 1997).

For the Navier–Stokes equations in $\boldsymbol{R}^d$ for barotropic flows with [11] and large initial data, the global existence of solutions containing vacuum for the Cauchy problem or various initial-boundary value problems was first established by Lions (1998) for $\gamma \geq 3/2$ if $d=2$, $\gamma \geq 9/5$ if $d=3$, and $\gamma > d/2$ if $d \geq 4$. The gap was closed by Feireisl–Novotný–Petzeltová (2001) for the full range $\gamma > d/2$. These results have been extended to the full Navier–Stokes equations describing the motion of a general compressible, viscous, and heat conducting fluid (see Feireisl (2004)). The physically relevant isothermal case, $\gamma = 1$, is completely open even if $d=2$. The only large data existence result is that for radially symmetric data (Hoff 1992). The general case $\gamma \geq 1$ and $d=3$ for radially symmetric data was solved only recently (Jiang-Zhang 2001).

The lower-bound estimate on the density is a delicate issue. Weak solutions containing vacuum for the isentropic viscous flows with constant viscosity are unstable in general (Hoff-Serre 1991). Hence, it is important to see whether vacuum will never develop if the initial data is away from vacuum; this has been shown for the one-dimensional case for large initial data and for the multidimensional case with small data. On the other hand, from the kinetic theory, if solutions contain vacuum, then the viscosity coefficients in the Navier–Stokes equations should depend on the density near vacuum; this indeed stabilizes the solutions for the one-dimensional case.

The stability of viscous shock waves has been studied for the one-dimensional case (see Liu (2000) and the references therein). The compressible–incompressible limits from the isentropic compressible to incompressible Navier–Stokes equations when the Mach number tends to zero have been established for arbitrarily weak solutions (Lions-Masmoudi 1998) and for smooth solutions and a class of initial data functions (Hoff 1998).

The inviscid limits from the Navier–Stokes equations to the Euler equations have been established as long as the solutions of the Euler equations are smooth, when the viscosity and heat conductivity coefficients tend to zero (Klainerman-Majda 1982). It is completely open for general entropy solutions, even in the one-dimensional case.

# Computational Methods in General Relativity: The Theory

**M W Choptuik**, University of British Columbia, Vancouver, Canada

## Conventions and Units

This article adopts many of the conventions and notations of Misner, Thorne, and Wheeler (1973) – hereafter denoted MTW – including metric signature $(-+++)$; definitions of Christoffel symbols and curvature tensors (up to index permutations permitted by standard symmetries of the tensors in a coordinate basis); the use of Greek indices $\alpha, \beta, \gamma, \ldots$, ranging over the spacetime coordinate values $(0,1,2,3) \rightarrow (t, x^1, x^2, x^3)$, to denote the components of spacetime tensors such as $g_{\mu\nu}$; the similar use of Latin indices $i, j, k, \ldots$, ranging over the spatial coordinate values $(1,2,3) \rightarrow (x^1, x^2, x^3)$, for spatial tensors such as $\gamma_{ij}$; the use of the Einstein summation convention for both types of indices; the use of standard Kronecker delta symbols (tensors), $\delta^{\mu}{}_{\nu}$ and $\delta^{i}{}_{j}$; the choice of geometric units, $G = c = 1$; and, finally, the normalization of the matter fields implicit in the choice of the constant $8\pi$ in [1].

The majority of the equations that appear in this article are tensor equations, or specific components of tensor equations, written in traditional index (not abstract index) form. Thus, these equations are generally valid in any coordinate system, $(t, x^i)$, but, of course do require the introduction of a coordinate basis and its dual. This approach is also largely a matter of convention, since all of what follows can be derived in a variety of fashions, some of them purely geometrical, and there are also approaches to numerical relativity based, for example, on frames rather than coordinate bases.

This article departs from MTW in its use of $\alpha, \beta^i$, and $\gamma_{ij}$ to denote the lapse, shift, and spatial metric, respectively, rather than MTW's $N$, $N^i$, and ${}^{(3)}g_{ij}$.

Finally, the operations of partial differentiation with respect to coordinates $x^{\mu}$, $t$, and $x^i$ are denoted $\partial_{\mu}$, $\partial_t$, and $\partial_i$, respectively.

## Introduction

The numerical analysis of general relativity, or numerical relativity, is concerned with the use of computational methods to derive approximate solutions to the Einstein field equations

$$G_{\mu\nu} = 8\pi T_{\mu\nu} \qquad [1]$$

Here, $G_{\mu\nu}$ is the Einstein tensor – that contracted piece of the Riemann curvature tensor that has vanishing divergence – and $T_{\mu\nu}$ is the stress tensor of the matter content of the spacetime. $T_{\mu\nu}$ likewise has vanishing divergence, an expression of the principle of local conservation of stress–energy that general relativity embodies.

The elegant tensor formulation [1] belies the fact that, ultimately, the field equations are generically a complicated and nonlinear set of partial differential equations (PDEs) for the components of the spacetime metric tensor, $g_{\mu\nu}(x^{\alpha})$, in some coordinate system $x^{\alpha}$. Moreover, implicit in a numerical solution of [1] is the numerical solution of the equations of motion for any matter fields that couple to the gravitational field – that is, that contribute to $T_{\mu\nu}$. The reader is reminded that it is a hallmark of general relativity that, in principle, all matter fields – including massless ones such as the electromagnetic field – contribute to $T_{\mu\nu}$.

Now, in the $3+1$ approach to general relativity that is described below, the task of solving the field equations [1] is formulated as an initial-value or Cauchy problem. Specifically, the spacetime metric, $g_{\mu\nu}(x^{\alpha}) = g_{\mu\nu}(t, x^k)$, which encodes all geometric information concerning the spacetime, $\mathcal{M}$, is viewed as the time history, or dynamical evolution, of the spatial metric, $\gamma_{ij}(0, x^k)$, of an initial spacelike hypersurface, $\Sigma(0)$. In any practical calculation, the degree to which the matter fields "back-react" on the gravitational field, that is, contribute to $T_{\mu\nu}$ substantially enough to cause perturbations in $g_{\mu\nu}$ at or above the desired accuracy threshold, will thus depend on the specifics of the initial configuration.

In astrophysics, there are relatively few well-identified environments in which it is generally thought to be crucial to the faithful emulation of the physics that the matter fields be fully coupled to the gravitational field. However, both observationally and theoretically, the existence of gravitationally compact objects is quite clear. Gravitationally compact means that a star with mass, $M$, has a radius, $R$, comparable to its Schwarzschild radius, $R_M$, which is defined by

$$R_M = \frac{2G}{c^2} M \approx 10^{-27}\,\mathrm{kg\,m^{-1}} \qquad [2]$$

Here, and only here, $G$ and $c$ – Newton's gravitational constant and the speed of light, respectively – have been explicitly reintroduced. The fact that $R_M/R$ is about $10^{-6}$ and $10^{-9}$ at the surfaces of the sun and earth, respectively, is a reminder of just how

weak gravity is in the locality of Earth. However, as befits anything of Einsteinian nature, the weakness of gravity is relative, so that at the surface of a neutron star, one would find

$$\frac{R_M}{R} \sim 0.4 \qquad [3]$$

while for black holes, one has

$$\frac{R_M}{R} = 1 \qquad [4]$$

In such circumstances, gravity is anything but weak! Furthermore, in situations where the matter–energy distribution has a highly time-dependent quadrupole moment – such as occurs naturally with a compact-binary system (i.e., a gravitationally bound two-body system, in which each of the bodies is either a black hole or a neutron star) – the dynamics of the gravitational field, including, crucially, the dynamics of the radiative components of the gravitational field, can be expected to dominate the dynamics of the overall system, matter included. For scenarios such as these, it should come as no surprise that the solution of the combined gravitohydrodynamical system begs for numerical analysis.

In addition, both from the physical and mathematical perspectives, it is also natural to study the strong, field dynamic regimes ($R \to R_M$ and/or $v \to c$, where $v$ is the typical speed characterizing internal bulk motion of the matter) of general relativity within the context of a variety of matter models. Typical processes addressed by these theoretical studies include the process of black hole formation, end-of-life events for various types of model stars, and, again, the interaction, including collisions, of gravitationally compact objects. Note that it is another hallmark of general relativity that highly dynamical spacetimes need not contain any matter; indeed, the interaction of two black holes – the natural analog of the Kepler problem in relativity – is a vacuum problem; that is, it is described by a solution of [1] with $T_{\mu\nu} = 0$.

Motivated in significant part by the large-scale efforts currently underway to directly detect gravitational radiation (gravitational waves), much of the contemporary work in numerical relativity is focused on precisely the problem of the late phases of compact-binary inspiral and merger. Such binaries are expected to be the most likely candidates for early detection by existing instruments such as TAMA, GEO, VIRGO, LIGO, and, more likely, by planned detectors including LIGO II and LISA (see, e.g., Hough and Rowan (2000)). Detailed and accurate predictions of expected waveforms from these events – using the techniques of numerical relativity – have the potential to substantially hasten the discovery process, on the basis of the general principle that if one knows what signal to look for, it is much easier to extract that signal from the experimental noise.

The computational task facing numerical relativists who study problems such as binary inspiral is formidable. In particular, such problems are intrinsically "3D," to use the CFD (computational fluid dynamics) nomenclature in which time dependence is always assumed. That is, the PDEs that must be solved govern functions, $F(t, x^k)$, that depend on all three spatial coordinates, $x^k$, as well as on time, $t$. Unfortunately, even a cursory description of 3D work in numerical relativity as it stands at this time is far beyond the scope of this article.

What follows, then, is an outline of a traditional approach to numerical relativity that underpins many of the calculations from the early years of the field (1970s and 1980s), most of which were carried out with simplifying restrictions to either spherical symmetry or axisymmetry. The mathematical development, which will hereafter be called the $3+1$ approach to general relativity, has the advantage of using tensors and an associated tensor calculus that are reasonably intuitive for the physicist. This "standard" $3+1$ approach is also sufficient in many instances (particularly those with symmetry) in the sense that it leads to well-posed sets of PDEs that can be discretized and then solved computationally in a convergent (stable) fashion. In addition, a thorough understanding of the $3+1$ approach will be of significant help to the reader wishing to study any of the current literature in numerical relativity, including the 3D work.

However, the reader is strongly cautioned that the blind application of any of the equations that follow, especially in a 3D context, may well lead to "ill-posed systems," numerical analysis of which is useless. Anyone specifically interested in using the methods of numerical relativity to generate discrete, approximate solutions to [1], particularly in the generic 3D case, is thus urged to first consult one of the comprehensive reviews of numerical relativity that continue to appear at fairly regular intervals (see, e.g., Lehner (2001), or Baumgarte and Shapiro (2003)). Most such references will also provide a useful overview of many of the most popular numerical techniques that are currently being used to discretize (convert to algebraic form) the Einstein equations, as well as the main algorithms that are used to solve the resulting discrete equations. These subjects are not

described below, not least since discussion of the available discretization techniques only makes sense in the context of PDEs of specific systems with specific boundary conditions, while there is only space here to describe the general mathematical setting for $3+1$ numerical relativity.

## The $3+1$ Spacetime Split

At least at the current time, computations in numerical relativity are restricted to the case of globally hyperbolic spacetimes. A spacetime (four-dimensional pseudo-Riemannian manifold), $\mathcal{M}_\Sigma$, endowed with a metric, $g_{\mu\nu}$, is globally hyperbolic if there is at least one edgeless, spacelike hypersurface, $\Sigma(0)$, that serves as a Cauchy surface. That is, provided that the initial data for the gravitational field are set consistently on $\Sigma(0)$ – so that the four constraint equations are satisfied (see below) – the entire metric $g_{\mu\nu}(t, x^i)$ can be determined from the field equations [1] (with appropriate boundary conditions), and thus, so can the complete geometric structure of the spacetime manifold.

To be sure, global hyperbolicity is restrictive. It excludes, for example, the highly interesting Gödel universe. However, particularly from the point of view of studying asymptotically flat solutions (or solutions asymptotic to any of the currently popular cosmologies), as is usually the case in astrophysics, the requirement of global hyperbolicity is natural.

The $3+1$ split is based on the complete foliation of $\mathcal{M}_\Sigma$ based on level surfaces of a scalar function, $t$ – the time function. That is, the $t=\text{const.}$ slices, are three-dimensional spacelike (Riemannian) hypersurfaces, and, as $t$ ranges from $-\infty$ to $+\infty$, completely fill the spacetime manifold, $\mathcal{M}_\Sigma$. In order for the $\Sigma(t)$ to be everywhere spacelike, $t$ must be everywhere timelike:

$$g_{\mu\nu}\nabla^\mu t \nabla^\nu t < 0 \qquad [5]$$

Here $\nabla_\mu$ is the spacetime covariant derivative operator compatible with the four metric, $g_{\mu\nu}$, thus satisfying $\nabla_\alpha g_{\mu\nu}=0$, and $g^{\mu\nu}$ is the inverse metric tensor, which satisfies $g^{\mu\alpha}g_{\alpha\nu}=\delta^\mu{}_\nu$. The reader is reminded that $\delta^\mu{}_\nu$ is a Kronecker delta symbol; that is, $\delta^\mu{}_\nu$ has the value 1 if $\mu=\nu$, and the value 0 otherwise.

Furthermore, the scalar function $t$ is now adopted as the temporal coordinate, so that $x^\mu=(t, x^i)$, where the $x^i$ are the three spatial coordinates. As noted implicitly above, since the problem under consideration is a pure Cauchy evolution, the range of $t$ should nominally be infinite, both to the future as well as to the past; that is, the solution domain is

$$-\infty < t < \infty \qquad [6]$$

$$|X| \equiv \left(\gamma_{ij}x^i x^j\right)^{1/2} < \infty \qquad [7]$$

However, this assumes that one has global existence for arbitrarily strong initial data, which is decidedly not always the case in general relativity. Indeed, "continued" or "catastrophic" gravitational collapse – that is, the process of black hole formation – signaled, in modern language, by the appearance of a trapped surface, inexorably leads to a physical singularity, which – the somewhat vague nature of the singularity theorems of Penrose, Hawking, and others notwithstanding – in actual numerical computations invariably turns out to be "catastrophic" in terms of Cauchy evolution.

Such behavior in time-dependent nonlinear PDEs is quite familiar in the mathematical community at large, where it is frequently known as finite-time blow-up (or finite-time singularity). However, despite the fact that such behavior is one of the most fascinating aspects of solutions of the Einstein equations, the following discussion will be, implicitly at least, restricted to the case of weak initial data, that is, to initial data for which there is global existence.

With the manifold $\mathcal{M}_\Sigma$ sliced into an infinite stack of spacelike hypersurfaces, $\Sigma(t)$, attention shifts to any single surface, as well as to the manner in which such a generic surface is embedded in the spacetime.

First, each spacelike hypersurface, $\Sigma(t)$, is itself a three-dimensional Riemannian differential manifold with a metric $\gamma_{ij}(t, x^k)$. (Note that in this discussion, the symbol $t$ is to be understood to represent any specific value of coordinate time.) From this metric, one can construct an inverse metric, $\gamma^{ij}(t, x^k)$, defined, as usual, so that

$$\gamma^{ik}\gamma_{kj} = \delta^i{}_j \qquad [8]$$

Associated with the spatial metric, $\gamma_{ij}$, is a natural spatial covariant derivative operator, $D_i$, that is compatible with $\gamma_{ij}$:

$$D_k\gamma_{ij} = 0 \qquad [9]$$

With the spatial metric, $\gamma_{ij}$, and its inverse, $\gamma^{ij}$, in hand, the standard formulas of tensor analysis can be applied to compute the usual suite of geometrical tensors. All tensors thus computed, and indeed, all tensors defined intrinsically to the

hypersurfaces $\Sigma(t)$ are called "spatial" tensors, and have their indices (if any) raised and lowered with $\gamma^{ij}$ and $\gamma_{ij}$, respectively.

Thus, the Christoffel symbols of the second kind, $\Gamma^i{}_{jk}$, are given by

$$\Gamma^i{}_{jk} = \frac{1}{2}\gamma^{il}\left(\partial_k\gamma_{lj} + \partial_j\gamma_{lk} - \partial_l\gamma_{jk}\right) \qquad [10]$$

Note that these quantities are symmetric in their last two indices

$$\Gamma^i{}_{jk} = \Gamma^i{}_{kj} \qquad [11]$$

and that they can be used, as usual, in explicit calculation of the action of the spatial covariant derivative operator on an arbitrary tensor. In particular, for the special cases of a spatial vector, $V^i$, and a covector (1-form), $W_i$, one has

$$D_i V^j = \partial_i V^j + \Gamma^j{}_{ik} V^k \qquad [12]$$

and

$$D_i W_j = \partial_i W_j - \Gamma^k{}_{ij} W_k \qquad [13]$$

respectively.

Given the Christoffel symbols, the components of the spatial Riemann tensor, denoted here $\mathcal{R}_{ijk}{}^l$, are computed using

$$\mathcal{R}_{ijk}{}^l = \partial_j\Gamma^l{}_{ik} - \partial_i\Gamma^l{}_{jk} + \Gamma^m{}_{ik}\Gamma^l{}_{mj} - \Gamma^m{}_{jk}\Gamma^l{}_{mi} \qquad [14]$$

Finally, the Ricci tensor, $\mathcal{R}^i{}_j$, and Ricci scalar, $\mathcal{R}$, are defined in the usual fashion

$$\mathcal{R}^i{}_j = \gamma^{ik}\mathcal{R}_{kj} = \gamma^{ik}\mathcal{R}_{klj}{}^l \qquad [15]$$

$$\mathcal{R} = \gamma^{ij}\mathcal{R}_{ij} \qquad [16]$$

The reader should again note that all of the tensors just defined "live" on each and every single spacelike hypersurface, $\Sigma(t)$, and are thus known as hypersurface-intrinsic quantities. In particular, the spatial Riemann tensor, $\mathcal{R}_{ijk}{}^l$, which encodes all intrinsic geometric information about $\Sigma(t)$, in no way depends on how the slice is embedded in the spacetime $\mathcal{M}_\Sigma$.

The next step in the 3 + 1 approach involves rewriting the fundamental spacetime line element for the squared proper distance, $ds^2$, between two spacetime events, $\mathcal{P}$ and $\mathcal{Q}$, having coordinates $x^\mu$ and $x^\mu + dx^\mu$, respectively,

$$ds^2 = g_{\mu\nu}dx^\mu dx^\nu \qquad [17]$$

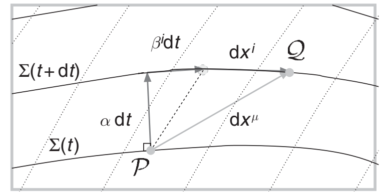

**Figure 1** Spacetime displacement in the $3+1$ approach, following Misner, Thorne, and Wheeler (1973). Solid lines represent surfaces of constant time, $t$; that is, each solid line represents a single spacelike hypersurface, $\Sigma(t)$. Dotted lines denote trajectories of constant spatial coordinate, that is, trajectories with $x^k = \text{const}$. The lapse function, $\alpha(t, x^k)$, encodes the (local) ratio between elapsed coordinate time, $dt$, and elapsed proper time, $d\tau = \alpha\, dt$, for an observer moving normal to the slices (i.e., for an observer with a 4-velocity, $u^\mu$, identical to the hypersurface normal, $n^\mu$). Similarly, the shift vector, $\beta^i(t, x^k)$, describes the shift, $\beta^i(t, x^i)\, dt$, in trajectories of constant spatial coordinate – the dotted lines in the figure – relative to motion perpendicular to the slices. The $3+1$ form of the line element [18] then follows immediately from an application of the spacetime version of the Pythagorean theorem.

As Figure 1 illustrates, a quick route to the 3 + 1 decomposition of the above expression, and thus of the tensor $g_{\mu\nu}$ itself, is based on an application of the "four-dimensional Pythagorean theorem." In setting up the calculation, one naturally identifies four functions, the scalar lapse, $\alpha(t, x^k)$, and the vector shift, $\beta^i(t, x^k)$, that encode the full coordinate (gauge) freedom of the theory. That is, complete specification of the lapse and shift is equivalent to completely fixing the spacetime coordinate system.

In light of the above discussion, and again referring to Figure 1, one readily deduces the 3 + 1 decomposition of the spacetime line element:

$$ds^2 = -\alpha^2 dt^2 + \gamma_{ij}\left(dx^i + \beta^i dt\right)\left(dx^j + \beta^j dt\right) \qquad [18]$$

A rearranged form of this last expression is also often seen in the literature:

$$ds^2 = \left(-\alpha^2 + \beta_k\beta^k\right)dt^2 + 2\beta_k dx^k dt + \gamma_{ij}dx^i dx^j \qquad [19]$$

The following useful identifications of the "time–time," "time–space," and "space–space" pieces of the spacetime metric, $g_{\mu\nu}$, follow immediately from [19]:

$$g_{00} = -\alpha^2 + \beta^i\beta_i \qquad [20]$$

$$g_{0i} = g_{i0} = \beta_i = \gamma_{ik}\beta^k \qquad [21]$$

$$g_{ij} = \gamma_{ij} \qquad [22]$$

This last relation is an example of a useful general result; the purely spatial components, $Q_{ijk\cdots}$, of a

completely covariant, but otherwise arbitrary, spacetime tensor, $Q_{\alpha\beta\gamma\cdots}$, constitute the components of a completely covariant spatial tensor.

A straightforward calculation, which provides a good exercise in the use of the $3+1$ calculus, yields the following equally useful identifications for various pieces of the inverse spacetime metric: $g^{\alpha\beta}$

$$g^{00} = -\alpha^{-2} \quad [23]$$

$$g^{0i} = g^{i0} = \alpha^{-2}\beta^i \quad [24]$$

$$g^{ij} = \gamma^{ij} - \alpha^{-2}\beta^i\beta^j \quad [25]$$

Since the Einstein field equations are equations with, loosely speaking, geometry on one side and matter on the other, tensors built from matter fields must also be decomposed. In particular, it is conventional to define tensors, $\rho$, $j_i$, and $S_{ij}$ that result from various projections of the spacetime stress energy tensor, $T_{\mu\nu}$, onto the hypersurface:

$$\rho \equiv n_\mu n_\nu T^{\mu\nu} \quad [26]$$

$$j_i \equiv -n_\mu T^\mu{}_i \quad [27]$$

$$S_{ij} \equiv T_{ij} \quad [28]$$

For observers with 4-velocities $u^\mu$ equal to $n^\mu$, and only for those observers with $u^\mu = n^\mu$, the above quantities have the interpretation of the locally and instantaneously measured energy density, momentum density, and spatial stresses, respectively. As with the geometric quantities, all of the matter variables, $\rho$, $j_i$, and $S_{ij}$ defined in [26]–[28] are spatial tensors and thus have their indices (if any) raised and lowered with the 3-metric. Note that the identification $S_{ij} = T_{ij}$ is another illustration of the general result mentioned in the context of the previous identification of $\gamma_{ij}$ and $g_{ij}$.

Finally, observing that time parameters are naturally defined in terms of level surfaces (equipotential surfaces), it should be no surprise that the covariant components, $n_\mu$, of the hypersurface normal field,

$$n_\mu = (-\alpha, 0, 0, 0) \quad [29]$$

are simpler than the components, $n^\mu$, of the normal itself,

$$n^\mu = \left(\alpha^{-1}, \alpha^{-1}\beta^i\right) \quad [30]$$

and, in fact, eqn [29] can also be deduced from a quick study of **Figure 1**.

In the $3+1$ approach, in addition to the 3-metric, $\gamma_{ij}(t, x^k)$, and coordinate functions, $\alpha(t, x^i)$ and $\beta(t, x^i)$, it is convenient to introduce an additional rank-2 symmetric spatial tensor, $K_{ij}(t, x^k)$, known as the extrinsic curvature (or second fundamental form). This additional tensor is analogous to a time derivative of $\gamma_{ij}(t, x^k)$, or, from a Hamiltonian perspective, to a variable that is dynamically conjugate to $\gamma_{ij}(t, x^k)$.

As the name suggests, the extrinsic curvature describes the manner in which the slice $\Sigma(t)$ is embedded in the manifold (to be contrasted with $\mathcal{R}_{ijk}{}^l$ defined by [14] which is, as mentioned previously, completely insensitive to the manner in which the hypersurface is embedded in $\mathcal{M}_\Sigma$).

Geometrically, $K_{ij}$ is computed by calculating the spacetime gradient of the normal covector field, $n_\mu$, and projecting the result on to the hypersurface,

$$K_{ij} = -\tfrac{1}{2}\nabla_i n_j \quad [31]$$

where it must be stressed that $\nabla_\mu$ is the spacetime covariant derivative operator compatible with the 4-metric, $g_{\alpha\beta}$; that is, $\nabla_\mu g_{\alpha\beta} = 0$. A straightforward tensor calculus calculation then yields the following, which can be viewed as a definition of the $K_{ij}$:

$$K_{ij} = \frac{1}{2\alpha}\left(\partial_t \gamma_{ij} + D_i\beta_j + D_j\beta_i\right) \quad [32]$$

Here, $D_i$ is the spatial covariant metric, compatible with $\gamma_{ij}(D_k\gamma_{ij} = 0)$, that was defined previously. Observe that this equation can be easily solved for $\partial_t\gamma_{ij}$ (this will be done below), and thus, in the $3+1$ approach it is [32] that is the origin of the evolution equations for the 3-metric components, $\gamma_{ij}$.

## Einstein's Equations in $3+1$ Form

### The Constraint Equations

As is well known, as a result of the coordinate (gauge) invariance of the theory, general relativity is overdetermined in a sense completely analogous to the situation in electrodynamics with the Maxwell equations. One of the ways that this situation is manifested is via the existence of the constraint equations of general relativity. Briefly, starting from the naive view that the ten metric functions, $g_{\mu\nu}(t, x^i)$, that completely determine the spacetime geometry are all dynamical – that is, that they satisfy second-order-in-time equations of motion – one finds that the Einstein equations do not provide dynamical equations of motion for the lapse, $\alpha$, or the shift, $\beta^i$. Rather, four of the field equations [1] are equations of constraint for the "true" dynamical variables of the theory, $\{\gamma_{ij}, \partial_t\gamma_{ij}\}$, or, equivalently, $\{\gamma_{ij}, K^i{}_j\}$. Note that in the following, the mixed form, $K^i{}_j$, is at times used – again by convention – as the principal representation of the extrinsic curvature tensor (instead of $K_{ij}$ as previously, or $K^{ij}$).

Thus, four of the components of [1] can be written in the form

$$C^{\mu}\left(\gamma_{ij}, K^{i}{}_{j}, \partial_k \gamma_{ij}, \partial_l \partial_k \gamma_{ij}, \partial_k K^{i}{}_{j}\right) = T^{\mu} \qquad [33]$$

where $T^{\mu}$ depends only on the matter content in the spacetime. Note that in addition to having no dependence on $\partial_t^2 \gamma_{ij}$, the constraints are also independent of $\alpha$ and $\beta^i$.

If the Einstein equations [1] are to hold throughout the spacetime, then the constraints [33] must hold on each and every spacelike hypersurface, $\Sigma(t)$, including, crucially, the initial hypersurface, $\Sigma(0)$. From the point of view of Cauchy evolution, this means that the 12 functions, $\{\gamma_{ij}(0, x^k), K^i{}_j(0, x^k)\}$, constituting the gravitational part of the initial data, are not completely freely specifiable, but must satisfy the four constraints

$$C^{\mu}\left(\gamma_{ij}(0, x^k), K^i{}_j(0, x^k), \ldots\right) = T^{\mu}(0, x^k) \qquad [34]$$

However, provided initial data that do satisfy the equations is chosen, then – as consistency of the theory demands – the dynamical equations of motion for the $\{\gamma_{ij}, K^i{}_j\}$ (eqns [37] and [38] below) guarantee that the constraints will be satisfied on all future (or past) hypersurfaces, $\Sigma(t)$. In this internal self-consistency, the geometrical Bianchi identities, $\nabla_{\mu} G^{\mu\nu} = 0$, and the local conservation of stress energy, $\nabla_{\mu} T^{\mu\nu} = 0$, play crucial roles.

In the $3+1$ approach, as one would expect, the constraint equations further naturally subdivide into a scalar equation

$$\mathcal{R} - K_{ij}K^{ij} + K^2 = 16\pi\rho \qquad [35]$$

and a (spatial) vector equation

$$D_j K^{ij} - D^i K = 8\pi j^i \qquad [36]$$

where the energy and momentum densities, $\rho$ and $j^i = \gamma^{ik} j_k$, are given by [26]–[28]. Equations [35] and [36] are often known as the Hamiltonian and momentum constraint, respectively, not least since the behavior of their solutions as $X \equiv \sqrt{\gamma_{ij} x^i x^j} \to \infty$ encodes the conserved mass and linear momentum (four numbers) that can be defined in asymptotically flat spacetimes.

In a general $3+1$ coordinate system, and with an appropriate choice of variables, the constraints can be written as a set of quasilinear elliptic equations for four of the $\{\gamma_{ij}, K^i{}_j\}$ (or, more properly, for certain algebraic combinations of the $\{\gamma_{ij}, K^i{}_j\}$). Thus, especially for 2D and 3D calculations, the setting of initial data for the Cauchy problem in general relativity is itself a highly nontrivial mathematical and computational exercise. Readers wishing more details on this subject are directed to the comprehensive review by Cook (2000).

### The Evolution Equations

As discussed above, in the $3+1$ form of the Einstein equations [1], the spatial metric, $\gamma_{ij}$, and the extrinsic curvature, $K^i{}_j$, are viewed as the dynamical variables for the gravitational field. The remainder of the $3+1$ equations are thus two sets of six first-order-in-time evolution equations; one set for $\gamma_{ij}$,

$$\begin{aligned}\partial_t \gamma_{ij} = &- 2\alpha\gamma_{ik}K^k{}_j + \beta^k \partial_k \gamma_{ij} \\ &+ \gamma_{ik}\partial_j \beta^k + \gamma_{kj}\partial_i \beta^k\end{aligned} \qquad [37]$$

and the other set for $K^i{}_j$,

$$\begin{aligned}\partial_t K^i{}_j = &\beta^k \partial_k K^i{}_j - \partial_k \beta^i K^k{}_j + \partial_j \beta^k K^i{}_k - D^i D_j \alpha \\ &+ \alpha\left(\mathcal{R}^i{}_j + K K^i{}_j + 8\pi\left(\tfrac{1}{2}\delta^i{}_j(S-\rho) - S^i{}_j\right)\right)\end{aligned} \qquad [38]$$

As also noted previously, the evolution equations [37] for the spatial metric components, $\gamma_{ij}$, follow from the definition of the extrinsic curvature [31]. The derivation of the equations for the extrinsic curvature, on the other hand, require lengthy, but well-documented, manipulations of the spatial components of the field equations [1].

### The (Naive) Cauchy Problem

A naive statement of the Cauchy problem for $3+1$ numerical relativity is thus as follows: fix a specified number, $N$, of matter fields $\xi^A(t, x^k)$, $A = 1, 2, \ldots, N$, all minimally coupled to the gravitational field, with a total stress tensor, $T_{\mu\nu}$, given by

$$T_{\mu\nu} = \sum_{A=1}^{N} T^A_{\mu\nu} \qquad [39]$$

where $T^A_{\mu\nu}$ is the stress tensor corresponding to the matter field $\xi^A$. Choose a topology for $\Sigma(0)$ (e.g., $\mathcal{R}^3$ with asymptotically flat boundary conditions; $T^3$, with no boundaries, etc.) This also fixes the topology of $\mathcal{M}_\Sigma$ to be $\mathbb{R}\times$the topology of $\Sigma(0)$.

Next, freely specify eight of the 12 $\{\gamma_{ij}(0, x^k), K^i{}_j(0, x^k)\}$, as well as initial values, $\xi^A(0, x^k)$, for the matter fields. Then determine the remaining four dynamical gravitational fields from the constraints [35] and [36]. This completes the initial data specification.

One must now choose a prescription for the kinematical (coordinate) functions, $\alpha$ and $\beta^i$, so that either explicitly or implicitly, they are completely fixed; for the case of implicit specification, this may well mean that the coordinate functions themselves will satisfy PDEs, which, furthermore, can be of essentially any type in practice (i.e., elliptic, hyperbolic, parabolic, ...). Finally, with consistent initial data, $\{\gamma_{ij}(0, x^k), K^i{}_j(0, x^k); \xi_A(0, x^k)\}$, in hand, and with a prescription for the coordinate functions, the evolution

equations [37] and [38] can be used to advance the dynamical variables forward or backward in time.

The above description is naive since, apart from a consistent mathematical specification, the most crucial issue in the solution of a time-dependent PDE as a Cauchy problem is that the problem be "well posed." Roughly speaking, this means that solutions do not grow without bound ("blow-up") without physical cause, and that small, smooth changes to initial data yield correspondingly small, smooth changes to the evolved data. In short, the Cauchy problem must be stable, and whether or not a particular subset of the equations displayed in this section yields a well-posed problem is a complicated and delicate issue, especially in the generic 3D case. The reader is thus again cautioned against blind application of any of the equations displayed in this article.

### Boundary Conditions

In principle, because all spacelike hypersurfaces, $\Sigma(t)$, in a pure Cauchy evolution are edgeless – and provided that the initial data $\{\gamma_{ij}(0,x^k), K^i{}_j(0,x^k);\ \xi_A(0,x^k)\}$ is consistent with asymptotic flatness, or whatever other condition is appropriate given the topology of the $\Sigma(t)$ – there are essentially no boundary conditions to be imposed on the dynamical variables, $\{\gamma_{ij}(t,x^k), K^i{}_j(t,x^k)\}$, during Cauchy evolution. Note that asymptotic flatness generally requires that

$$\lim_{X\to\infty} \gamma_{ij} = f_{ij} + O\left(\frac{1}{X}\right) \qquad [40]$$

and

$$\lim_{X\to\infty} K^i{}_j = O\left(\frac{1}{X^2}\right) \qquad [41]$$

where $X$ is defined by

$$X \equiv \sqrt{\gamma_{ij}x^i x^j} \qquad [42]$$

as previously, and $f_{ij}$ is the flat 3-metric. Similarly, should the lapse, $\alpha$, and shift, $\beta$, be constrained by elliptic PDEs – as is frequently the case in practice – then the only natural place to set boundary conditions is at spatial infinity, and then, provided that the frame at spatial infinity is inertial, with coordinate time $t$ measuring proper time, one should have

$$\lim_{X\to\infty} \alpha = 1 + O\left(\frac{1}{X}\right) \qquad [43]$$

and

$$\lim_{X\to\infty} \beta^i = O\left(\frac{1}{X}\right) \qquad [44]$$

It is critical to note at this point, however, that in the vast bulk of past and current work in numerical relativity, including most of the ongoing work in 3D, the Einstein equations [1] have been solved, not as a pure Cauchy problem, but as a mixed initial-value/boundary-value (IBVP) problem. That is, in the discretization process in which the continuum equations [1] are replaced with algebraic equations, the continuum domain [6]–[7] is typically replaced with a truncated spatial domain

$$|x^i| \le X^i_{\max} \qquad [45]$$

where the $X^i_{\max}$ are *a priori* specified constants (parameters of the computational solution) that define the extremities of the "computational box." As one might expect, the theory underlying stability and well-posedness of IBVP problems – especially for differential systems as complicated as [1] – is even more involved than for the pure initial-value case, and is another very active area of research in both mathematical and numerical relativity (see, e.g., Friedrich and Nagy (1999)).

## Introduction

Consider a dynamical system with coordinates $q^i$ $(i = 1, \ldots, n)$ and Lagrangian $L(q^i, \dot{q}^i)$ (field theory is formally covered by regarding the spatial coordinates as a continuous index). When going to the Hamiltonian formulation, it is usually assumed that the Legendre transformation between the velocities $\dot{q}^i$ and the momenta

$$p_i = \frac{\partial L}{\partial \dot{q}^i} \qquad [1]$$

can be inverted to yield the velocities as functions of the $q$'s and the $p$'s. This "regular" situation occurs for most systems appearing in standard classical mechanics and enables one to proceed to the Hamiltonian formulation of the theory without difficulty.

In field theory, however, the regular case is the exception rather than the rule. This is due to gauge invariance and first-order Lagrangians.

- *Gauge invariance* A system possesses gauge symmetries if it is invariant under transformations that involve arbitrary functions of time (gauge transformations). In that case, the solution of the equations of motion with given initial data is not unique, since it is always possible to perform a gauge transformation in the course of the evolution without changing the initial data. It is then clear that the Legendre transformation cannot be invertible, for if it were, one could rewrite the equations of motion in the standard canonical form $\dot{q}^i = \partial H/\partial p_i, \dot{p}_i = -\partial H/\partial q^i$. These canonical equations are in normal form and have a unique solution for given initial data, which would contradict the presence of a gauge symmetry.

  A simple example that illustrates this phenomenon is given by the following model for three variables $q^1$, $q^2$, and $\lambda$, the Lagrangian of which reads

  $$L = \tfrac{1}{2}\left((\dot{q}^1 - \lambda)^2 + (\dot{q}^2 - \lambda)^2\right) \qquad [2]$$

  This model is inspired by electromagnetism: the variables $q^1$ and $q^2$ play a role somewhat similar to that of the spatial components of the vector potential, while $\lambda$ corresponds to the temporal component. The Lagrangian is invariant under the gauge transformations

  $$q^1 \to q^1 + \varepsilon, \qquad q^2 \to q^2 + \varepsilon, \qquad \lambda \to \lambda + \dot{\varepsilon} \qquad [3]$$

  where $\varepsilon$ is an arbitrary function of time. The conjugate momenta are

  $$p_1 = \dot{q}^1 - \lambda, \qquad p_2 = \dot{q}^2 - \lambda, \qquad \pi_\lambda = 0$$

  One cannot invert the Legendre transformation since one cannot express the velocity $\dot{\lambda}$ in terms of the momenta.
- *First-order Lagrangians* Fermionic fields obey first-order equations. Their Lagrangian is linear in the derivatives, so that the conjugate momenta $p_i$ depend on the coordinates $q^i$ only. It is then clearly impossible to express the velocities in terms of the momenta through the Legendre transformation. More generally, any first-order Lagrangian with or without gauge symmetry leads to a noninvertible Legendre transformation.

A simple system that exhibits this feature is described by the Lagrangian

$$L = z^2\dot{z}^1 - \frac{1}{2}(z^2)^2 \qquad [4]$$

for two bosonic degrees of freedom ($z^1$, $z^2$). This is in fact the canonical form of the Lagrangian for a free particle in one dimension ($z^2$ is the momentum conjugate to the position $z^1$): the system is already in Hamiltonian form. There is no gauge invariance, but because the Lagrangian is first order, the Legendre transformation with [4] as starting point,

$$p_1 = z^2, \qquad p_2 = 0 \qquad [5]$$

is non invertible for the velocities (which do not even appear in the formulas for the momenta).

Dirac showed how to develop the Hamiltonian formalism in the case when the Legendre transformation is not invertible. One can still reformulate the equations in phase space and write them in terms of brackets with the Hamiltonian, but a new major feature emerges, namely the canonical variables are no longer free. Rather, the permissible phase-space points are constrained to be on the so-called "constrained surface." For this reason, systems for which the Legendre transformation is not invertible are also called "constrained Hamiltonian systems." We shall adopt this terminology here.

The purpose of this article is to explain the main ideas underlying the Dirac method. To simplify the discussions and to focus on the features peculiar to the Dirac construction, we shall assume as a rule that all necessary smoothness conditions are fulfilled by the functions, surfaces, etc., appearing in the formalism. How to develop the analysis when some of the smoothness conditions are not fulfilled is of definite interest but goes beyond the scope of this review. We shall also assume, for definiteness, that all the variables are bosonic in order to avoid straightforward but somewhat cumbersome sign factors in the formulas.

## General Theory

### Dirac Algorithm

**Primary constraints** When the Legendre transformation [1] cannot be inverted, the momenta $p_i$'s do not span an $n$-dimensional space but are constrained by relations

$$\phi_m(q,p) = 0, \quad m = 1, \ldots, M \qquad [6]$$

which follow from their definition. These equations reduce to identities when the momenta are replaced by their expression [1] in terms of the coordinates and the velocities. They are called primary constraints. We shall assume that the matrix

$$\frac{\partial(\phi_m)}{\partial(p_i, q^i)}$$

is everywhere of constant (maximum) rank $M$ on the phase-space surface defined by eqns [6] which is assumed to be smooth. This surface is of dimension $2n - M$.

**Canonical Hamiltonian** The next step in the Dirac procedure is to define the canonical Hamiltonian $H$ through

$$H = \dot{q}^i p_i - L \qquad [7]$$

As shown by Dirac, $H$ can be re-expressed as a function $H(q, p)$ of the momenta and the coordinates, even when the Legendre transformation is not invertible: the canonical Hamiltonian $H$ depends on the velocities only through the $p_i$'s. Furthermore, the original equations of motion in Lagrangian form are equivalent to the Hamiltonian equations

$$\dot{q}^i = \frac{\partial H}{\partial p_i} + u^m \frac{\partial \phi_m}{\partial p_i} \qquad [8]$$

$$\dot{p}_i = -\frac{\partial H}{\partial q^i} - u^m \frac{\partial \phi_m}{\partial q^i} \qquad [9]$$

$$\phi_m(q, p) = 0 \qquad [10]$$

where the $u^m$'s are parameters, some of which will be determined through the consistency algorithm to be discussed shortly. (In [7]–[9] and everywhere below, there is a summation over the repeated indices.)

**Secondary constraints** The equations of motion [8] and [9] can be rewritten as

$$\dot{F} = [F, H] + u^m[F, \phi_m] \qquad [11]$$

where $F = F(q,p)$ is any function of the canonical variables. Here, the Poisson bracket is defined as usual by

$$[G, F] = \frac{\partial G}{\partial q^i}\frac{\partial F}{\partial p_i} - \frac{\partial G}{\partial p_i}\frac{\partial F}{\partial q^i} \qquad [12]$$

If one takes for $F$ one of the primary constraints $\phi_m$, one should get zero, $\dot{\phi}_m = 0$. This yields the consistency conditions

$$[\phi_m, H] + u^{m'}[\phi_m, \phi_{m'}] = 0 \qquad [13]$$

These conditions can imply further restrictions on the canonical variables and/or impose conditions on the

variables $u^m$. Any new relation $X(q,p)=0$ on the canonical variables leads, in turn, to a further consistency condition $\dot{X}=[X,H]+u^{m'}[X,\phi_{m'}]=0$, which can bring in either further restriction on the constraint surface or fix more variables $u^m$. Constraints that follow from the consistency algorithm are called "secondary constraints." Finally, one is left with a certain number of secondary constraints, which are denoted by $\phi_k=0$, $k=M+1,\ldots,M+K$. We assume again that all the constraints (primary and secondary) define a smooth surface, called the "constraint surface," and fulfill the condition that $\partial(\phi_k)/\partial(q^i,p_i)$ is of maximum rank $J\equiv M+K$ on the constraint surface. (We also assume for simplicity that there is no branching in the consistency algorithm.)

**Restrictions on the $u$'s** Having a complete set of constraints

$$\phi_j=0, \quad j=1,\ldots,M+K\equiv J \qquad [14]$$

we can now investigate more precisely the restrictions on the variables $u^m$. These read

$$[\phi_j,H]+u^m[\phi_j,\phi_m]\approx 0, \quad j=1,\ldots,J \qquad [15]$$

where the notation $\approx$ means "equal modulo the constraints." In [15], $m$ is summed from 1 to $M$. Equations [15] are a set of $J$ linear, inhomogeneous equations for the $u$'s, with coefficients that are functions of the canonical variables $q^i$, $p_i$. The general solution of this system is of the form

$$u^m=U^m+u^aV_a^m \qquad [16]$$

where $U^m$ is a particular solution and where the $V_a^m$ $(a=1,\ldots,A)$ provide a complete set of independent solutions of the homogeneous system

$$V_a^m[\phi_j,\phi_m]\approx 0 \qquad [17]$$

The coefficients $u^a (a=1,\ldots,A)$ are completely arbitrary.

We thus see the emergence of another new feature in the theory, in addition to the appearance of constraints. It is that the general solution of the equations of motion may contain arbitrary functions of time (when $A\neq 0$), in agreement with the possible presence of a gauge symmetry.

## First- and Second-Class Constraints

**First- and second-class functions** A function $F(q,p)$ is called a first-class function if it generates a canonical transformation that maps the constraint surface on itself. Thus, $F(q,p)$ is first class if its Poisson brackets with all the constraints vanish weakly (i.e., are zero on the constraint surface),

$$[F,\phi_j]\approx 0, \quad j=1,\ldots,J \qquad [18]$$

A function is second class otherwise, that is, if there is at least one constraint $\phi_j$ such that $[F,\phi_j]\neq 0$ (not even weakly). Second-class functions generate canonical transformations that do not leave the constraint surface invariant. Since canonical transformations that map the constraint surface on itself form a group, the Poisson bracket of two first-class functions is itself a first-class function.

Because the system is constrained to lie on the constraint surface, the only allowed canonical transformations are those that are generated by first-class functions. The importance of the distinction between first-class and second-class functions stems from this elementary fact. Note, in particular, that the time evolution is generated – as it should – by a first-class generator since the equations of motion [11] can be rewritten as

$$\dot{F}\approx[F,H']+u^a[F,V_a^m\phi_m] \qquad [19]$$

with

$$H'=H+U^m\phi_m \qquad [20]$$

One has both $[H',\phi_m]\approx 0$ and $[V_a^m\phi_m,\ \phi_j]\approx 0$.

**Splitting of the constraints** One can separate the constraints between first-class and second-class constraints. This can be achieved by considering the matrix $C_{jj'}$ of the Poisson bracket of the constraints,

$$C_{jj'}=[\phi_j,\phi_{j'}], \quad j,j'=1,\ldots,J \qquad [21]$$

One has the following theorem due to Dirac.

**Theorem 1** *If* $\det C_{jj'}\approx 0$, *there exists at least one first-class constraint among the* $\phi_j$*'s.*

**Proof** Straightforward: if $\det C_{jj'}\approx 0$, one can find a nontrivial solution $\lambda^j$ of $\lambda^jC_{jj'}\approx 0$. The corresponding constraint $\lambda^j\phi_j$ is easily verified to be first class.

By redefining the constraints as $\phi_j\rightarrow\bar{\phi}_j=a_j^{j'}\phi_{j'}$ with $a_j^{j'}(q,p)$ invertible, one can bring the Poisson brackets of the constraints to the form

$$[\gamma_a,\gamma_b]=0, \qquad [\gamma_a,\chi_\alpha]=0, \qquad [\chi_\alpha,\chi_\beta]=C_{\alpha\beta} \qquad [22]$$

with $(\bar{\phi}_j)\equiv(\gamma_a,\chi_\alpha)$ and where the matrix $C_{\alpha\beta}$ is invertible. (We assume, for simplicity, throughout that the rank of the matrix $C_{jj'}$ is constant on the constraint surface ("regular case").) In this representation, the constraints are completely split into first-class constraints $(\gamma_a)$ and second-class

constraints ($\chi_\alpha$): there is no first-class constraint left among the $\chi_\alpha$'s, and the set $\{\gamma_a\}$ exhausts all the first-class constraints. Note that now the index $a = 1, \ldots, A, A+1, \ldots, \bar{A}$ runs over all (primary and secondary) first-class constraints.

This separation of the constraints into first-class and second-class constraints is quite important because, as already seen above, the first-class constraints generate admissible canonical transformations, while the second-class constraints do not.

For a bosonic system, the matrix $C_{\alpha\beta}$ is antisymmetric. As $C_{\alpha\beta}$ is invertible, this implies that the number of second-class constraints is even. In the fermionic case, $C_{\alpha\beta}$ is symmetric (in the fermionic sector) and, therefore, the number of second-class constraints can be even or odd.

**First-class constraints and gauge symmetries** The first-class constraints not only map the constraint surface on itself, but generate, in fact, transformations that do not change the physical state of the system, that is, gauge transformations. Indeed, the presence of arbitrary functions in the solutions of the equations of motion indicates that the $q$'s and the $p$'s involve some redundancy and are not all physically distinct. Only those phase-space functions whose time evolution does not depend on the arbitrary functions $u^a$ are observables.

That the first-class constraints generate gauge transformations is rather clear in the case of the first-class primary constraints, since these appear explicitly in the generator of the time evolution multiplied by arbitrary functions. That it also holds for the first-class secondary constraints is known as the "Dirac conjecture." This conjecture can be proved under reasonable assumptions (see, e.g., Henneaux *et al.* 1990). The reason that the secondary first-class constraints also correspond to gauge transformations is that they appear in the brackets of the Hamiltonian with the primary first-class constraints. Thus, different choices of arbitrary functions $u^a$ in the dynamical equations of motion will lead to phase-space points that differ by a canonical transformation whose generator involves the secondary first-class constraints as well.

In any case, as noted below, one must identify the phase-space points in the same orbit generated by all the first-class constraints (primary and secondary) in order to get a reduced space with a symplectic structure ("reduced phase space"). For this reason, one postulates that the first-class constraints always generate gauge transformations, even for systems which are counterexamples to the Dirac conjecture (i.e., in that case, one defines the gauge transformations as being the transformations generated by the first-class constraints).

The extended Hamiltonian $H_E$ is defined to be the sum of the first-class Hamiltonian [20] and of all the first-class constraints $\gamma_a$ multiplied by an arbitrary Lagrange multiplier,

$$H_E = H' + v^a \gamma_a \qquad [23]$$

(with $a$ summed from 1 to $\bar{A}$). It is the generator of the time evolution in which the complete gauge symmetry is fully displayed.

**Elimination of second-class constraints – Dirac brackets** Second-class constraints do not generate permissible canonical transformations, since they do not map the constraint surface on itself. For this reason, it is convenient to eliminate them. This can consistently be done by using the Dirac brackets instead of the Poisson brackets. By definition, the Dirac bracket $[F, G]_D$ of two phase-space functions $F$ and $G$ is given by

$$[F, D]_D = [F, G] - [F, \chi_\alpha] C^{\alpha\beta} [\chi_\beta, G] \qquad [24]$$

where $C^{\alpha\beta}$ is the inverse to $C_{\alpha\beta}$,

$$C^{\alpha\beta} C_{\beta\gamma} = \delta^\alpha_\gamma$$

(which exists since the $\chi_\alpha$'s are second class). As shown by Dirac, the bracket [24] is indeed a bracket (antisymmetry, derivation property, and Jacobi identity). Furthermore, it fulfills the crucial property that the Dirac bracket of anything with any second-class constraint is zero,

$$[F, \chi_\alpha]_D = 0 \quad (F \text{ arbitrary}) \qquad [25]$$

Thus, one can consistently eliminate the second-class constraints and replace the Poisson bracket by the Dirac bracket. Once this is done, one has fewer canonical variables and only first-class constraints remain (if any). It also follows from the definition that the Dirac bracket of two first-class functions is equal to their Poisson bracket.

**Gauge conditions** One can push the reduction procedure further and eliminate the first-class constraints by means of gauge conditions. Gauge conditions $C_a = 0$ are conditions on the phase-space variables which do not follow from the Lagrangian and which have the property that they cut each gauge orbit once and only once. Since the gauge transformations are generated by the first-class constraints, this requirement is (locally) equivalent to

$$[C_a, \gamma_b] \varepsilon^b \approx 0 \Rightarrow \varepsilon^b \approx 0 \qquad [26]$$

That is, the constraints $(\gamma_a, C_b)$ form together a second-class system: there is no first-class constraint left once the conditions $C_a = 0$ are included. One can then eliminate all the constraints and gauge conditions and introduce the corresponding Dirac bracket. For gauge-invariant functions, this Dirac bracket coincides with the original Poisson bracket.

The reduced phase space is the unconstrained space obtained after this reduction, equipped with the Dirac bracket. It has dimension $2n - s - 2\bar{A}$, where $2n$ is the dimension of the original phase space, $s$ is the number of second-class constraints, and $\bar{A}$ is the number of first-class constraints. In the bosonic case, this number is even (as it should) because $s$ is even. One sees that "first-class constraints strike twice" since they need gauge conditions.

The observables of the theory are the reduced phase-space functions. They form a Poisson algebra, the relevant reduced phase-space bracket being the Dirac bracket associated with all the constraints and gauge conditions. The symplectic structure defined in the reduced phase space is nondegenerate because one has removed all the first-class constraints.

The definition of reduced phase space given above is useful in practice but has the conceptual drawback of relying on gauge conditions. This approach does not display clearly its intrinsic significance and, furthermore, in the case of the so-called Gribov problems (global obstructions to cutting each gauge orbit once and only once), may yield the incorrect expectation that the reduced phase space does not exist. We shall provide a more intrinsic definition below, which does not involve gauge conditions.

**Examples**

*First example* (see eqn [2]). There is here one primary constraint, namely $\pi_\lambda = 0$. The canonical Hamiltonian is $(1/2)((p_1)^2 + (p_2)^2) + \lambda(p_1 + p_2)$. The consistency algorithm yields the secondary constraint $p_1 + p_2 = 0$ and no condition on the $u$'s. The constraints are first class. They generate the gauge transformations $q^1 \to q^1 + \varepsilon$, $q^2 \to q^2 + \varepsilon$, and $\lambda \to \lambda + \eta$, which coincide with the Lagrangian gauge transformations if one identifies $\eta$ with $\dot{\varepsilon}$ ($\varepsilon$ and $\dot{\varepsilon}$ are, of course, independent at any given time). One can fix the gauge by means of the gauge conditions $\lambda = 0$, $q^1 + q^2 = 0$. The reduced phase space is two-dimensional and the observables can be identified with the functions of the gauge-invariant variables $(1/2)(q^1 - q^2)$ and $p_1 - p_2$, which are conjugate. Any other gauge condition leads to the same reduced phase space.

*Second example* (see eqn [4]). The primary constraints are $p_1 - z^2 = 0$ and $p_2 = 0$ and define a two-dimensional plane in the four-dimensional phase space $(z^1, z^2, p_1, p_2)$. The consistency algorithm forces $u^1 = z^2$ and $u^2 = 0$ and does not bring any further constraint. The constraints are second class since $[p_2, p_1 - z^2] = 1$. One can eliminate $p_1$ and $p_2$ through the constraints. The Dirac brackets of the remaining variables vanish, except $[z^1, z^2] = 1$. The reduced phase is the space of the $z$'s, with $z^2$ conjugate to $z^1$. The Hamiltonian is the free-particle Hamiltonian , $H = (1/2)(z^2)^2$. Thus, one recovers the original description which was already in Hamiltonian form. (The recognition that a system is already in first-order form often enables one to shortcut some aspects of the Dirac procedure by not introducing the unnecessary momenta which would in any case be eliminated in the end.)

## Quantization

The phase space of physical interest is the reduced phase space and the physical algebra is the algebra of the observables. The quantization of the theory then amounts to quantizing the algebra of the observables. This can be achieved along two different lines:

1. *Reduce then quantize*: In this direct approach, one represents as quantum operators only the reduced phase-space functions. There is no operator associated with non-gauge-invariant functions.
2. *Quantize then reduce*: In this approach, one represents as quantum operators the bigger algebra of functions of all the phase-space variables. One must then take into account the constraints. The second-class constraints are enforced as operator equations, which is consistent with the correspondence rule that the commutator in the quantum theory is $i\hbar$ times the Dirac bracket,

$$AB - BA = i\hbar [A, B]_{\mathrm{D}} \qquad [27]$$

(plus higher-order terms in $\hbar$). The first-class constraints are implemented in a more subtle way. It would be inconsistent to impose them as operator equations since in general $[\gamma_a, F]_{\mathrm{D}} \neq 0$ (even in the Dirac bracket). What one does is to impose them as conditions on the physical states: these are defined as the states annihilated by the first-class constraints,

$$\gamma_a |\psi\rangle = 0 \qquad [28]$$

For simple systems, it is easy to verify that the two procedures are equivalent. There is yet another

approach, in which one extends the system rather than reduce it. This is the Becchi–Rouet–Stora–Tyutin (BRST) approach, in which the new variables are called ghosts.

## Geometric Description

We defined above first-class and second-class constraints through algebraic means. It turns out that these definitions also have a geometrical interpretation, which sheds considerable insight into their nature.

The phase-space symplectic 2-form $\sigma$ induces, by pullback, a 2-form $\sigma_\Sigma$ on the constraint surface $\Sigma$. While $\sigma$ is of maximal rank, this may not be the case for the induced $\sigma_\Sigma$, which may be degenerate. In fact, the rank of $\sigma_\Sigma$ fails to be equal to the maximum rank $2n - J$ (where $J$ is the total number of constraints) by precisely the number $\bar{A}$ of first-class constraints.

Indeed, the Hamiltonian vector fields $X_{\gamma a}$ associated with the first-class constraints are tangent to the constraint surface $\Sigma$ and are null eigenvectors of $\sigma_\Sigma$,

$$\sigma_\Sigma(X_{\gamma a}, Y) = 0 \quad \forall Y \text{ tangent to } \Sigma \qquad [29]$$

as an immediate consequence of the first-class property. Here, all first-class constraints (primary and secondary) yield a null eigenvector. The integral surfaces of the vector fields $X_{\gamma a}$ are the gauge orbits. The reduced phase space is nothing else but the quotient space of the constraint surface by the gauge orbits. The 2-form induced in the quotient space is invertible because one has removed all degeneracy directions (including the ones associated with secondary first-class constraints). Reaching the reduced phase space falls under the scope of Hamiltonian reduction. The observables are the functions on the reduced phase space.

Thus, the reduced phase space is obtained through a two-step procedure. First, one restricts the functions to functions on the constraint surface $\Sigma$. One may view the algebra $C^\infty(\Sigma)$ of smooth functions on $\Sigma$ as the quotient algebra $C^\infty(P)/\mathcal{N}$ of the algebra $C^\infty(P)$ of smooth phase-space functions by the ideal $\mathcal{N}$ of phase-space functions that vanish on the constraint surface $\sigma$. The second step in the reduction procedure is to impose the gauge-invariant condition on the functions in $C^\infty(\Sigma)$, that is, to impose that they are constant along the gauge orbits $\mathcal{O}$. Assuming all necessary smoothness and regularity conditions to be fulfilled (i.e., that the orbits fiber which is, for instance, the case if the gauge orbits are the orbits of a free and proper group action), one may denote the algebra of observables as $C^\infty(\Sigma/\mathcal{O})$. This algebra is a Poisson algebra because the induced 2-form on the quotient space $\Sigma/\mathcal{O}$ is nondegenerate. The algebraic description of the observables underlies the BRST construction.

It is interesting to note that in the covariant approach to phase space, a similar two-step reduction procedure occurs. What plays the role of the constraint surface is the stationary surface in the space of all histories $q^i(t)$ of the dynamical variables. The gauge symmetry acts on this space and the reduced phase space is just the quotient space. One can establish the equivalence of the two descriptions (Barnich *et al.* 1991).

# Constructive Quantum Field Theory

**G Gallavotti**, Università di Roma "La Sapienza," Rome, Italy

## Euclidean Quantum Fields

The construction of a relativistic quantum field is still an open problem for fields in spacetime dimension $d \geq 4$. The conceptual difficulty that sometimes led to fear an incompatibility between nontrivial quantum systems and special relativity has however been solved in the case of dimension $d = 2, 3$ although, so far, has not influenced the corresponding debate on the foundations of quantum mechanics, still much alive.

It began in the early 1960s with Wightman's work on the axioms and the attempts at understanding the mathematical aspects of renormalization theory and with Hepps' renormalization theory for scalar fields. The breakthrough idea was, perhaps, Nelson's realization that the problem could really be studied in Euclidean form. A solution in dimensions $d = 2, 3$ has been obtained in the 1960s and 1970s through a remarkable series of papers by Nelson, Glimm, Jaffe, and Guerra. While the works of Nelson and Guerra relied on the "Euclidean approach" (see below) and on $d = 2$, the early works of Glimm and Jaffe dealt with $d = 3$ making use of the "Minkowskian approach" (based on second quantization) but making already use of a "multiscale analysis" technique. The latter received great impulsion and systematization by the adoption of Wilson's views and methods on renormalization: in physics terminology, renormalization group methods; a point of view taken here following the Euclidean approach. The solution dealt initially with scalar fields but it has been subsequently considerably extended.

The Euclidean approach studies quantum fields through the following problems:

1. existence of the functional integrals defining the generating functions (see below) of the probability distribution of the interacting fields in finite volume: the "ultraviolet stability problem,"
2. existence of the infinite-volume limit of the generating functions: the "infrared problem," and
3. check that the infinite volume generating functions satisfy the axioms needed to pass from the Euclidean, probabilistic, formulation to a Minkowskian formulation guaranteeing the existence of the Hamiltonian operator, relativistic covariance, Ruelle–Haag scattering theory: the "reconstruction problem."

The characteristic problem for the construction of quantum fields is (1) and here attention will be confined to it with the further restriction to the paradigmatic massive scalar fields cases. The dimension $d$ of the spacetime will be $d = 2, 3$ unless specified otherwise.

Given a cube $\Lambda$ of side $L$, $\Lambda \subset \mathbb{R}^d$, consider the following functional integral on the space of the fields on $\Lambda$, that is, on functions $\varphi_{\boldsymbol{\xi}}^{(\leq N)}$ defined for $\boldsymbol{\xi} \in \Lambda$,

$$Z_N(\Lambda, f) = \int \exp\left(-\int_\Lambda \left(\lambda_N \varphi_{\boldsymbol{\xi}}^{(\leq N)^4} + \mu_N \varphi_{\boldsymbol{\xi}}^{(\leq N)^2} + \nu_N + f_{\boldsymbol{\xi}} \varphi_{\boldsymbol{\xi}}^{(\leq N)}\right) \mathrm{d}\boldsymbol{\xi}\right) P_N(\mathrm{d}\varphi^{(\leq N)}) \qquad [1]$$

The fields $\varphi_{\boldsymbol{\xi}}^{(\leq N)}$ are called "Euclidean" fields with ultraviolet cutoff $N > 0$, $f_{\boldsymbol{\xi}}$ is a smooth function with compact support bounded by $|f_{\boldsymbol{\xi}}| \leq 1$ (for definiteness), the constants $\lambda_N > 0, \mu_N, \nu_N$ are called "bare couplings," and $P_N$ is a Gaussian probability distribution defining the free-field distribution with mass $m$ and ultraviolet cutoff $N$; the probability distribution $P_N$ is determined by its "covariance" $C_{\boldsymbol{\xi},\boldsymbol{\eta}}^{(\leq N)} \stackrel{\text{def}}{=} \int \varphi_{\boldsymbol{\xi}}^{(\leq N)} \varphi_{\boldsymbol{\eta}}^{(\leq N)} \, \mathrm{d}P_N$, which in the physics literature is called a "propagator," given by

$$C_{\boldsymbol{\xi},\boldsymbol{\eta}}^{(\leq N)} = \frac{1}{(2\pi)^d} \sum_{\boldsymbol{n} \in \mathbb{Z}^d} \int \frac{e^{i\boldsymbol{p}\cdot(\boldsymbol{\xi}-\boldsymbol{\eta}+\boldsymbol{n}L)}}{\boldsymbol{p}^2 + m^2} \chi_N(|\boldsymbol{p}|) \mathrm{d}^d \boldsymbol{p} \qquad [2]$$

The sum over the integers $\boldsymbol{n} \in \mathbb{Z}^d$ is introduced so that the field $\varphi_{\boldsymbol{\xi}}^{(\leq N)}$ is periodic over the box $\Lambda$: this is not really necessary as in the limit $L \to \infty$ either translation invariance would be recovered or lack of it properly understood, but it makes the problem more symmetric and generates a few technical simplifications; here $\chi_N(z)$ is a "regularizer" and a standard choice is

$$\chi_N(|\boldsymbol{p}|) = \frac{m^2(\gamma^{2N} - 1)}{\boldsymbol{p}^2 + \gamma^{2N} m^2}$$

with $\gamma > 1$, which is such that

$$\frac{\chi_N(|\boldsymbol{p}|)}{\boldsymbol{p}^2 + m^2} \equiv \frac{1}{\boldsymbol{p}^2 + m^2} - \frac{1}{\boldsymbol{p}^2 + \gamma^{2N} m^2} \equiv \sum_{h=1}^{N} \left(\frac{1}{\boldsymbol{p}^2 + \gamma^{2(h-1)} m^2} - \frac{1}{\boldsymbol{p}^2 + \gamma^{2h} m^2}\right) \qquad [3]$$

here $\gamma > 1$ can be chosen arbitrarily: so $\gamma = 2$. If $d > 3$, the above regularization will not be sufficient and a $\chi_N$ decaying faster than $\boldsymbol{p}^{-2}$ would be needed.

A simple estimate yields, if $\varepsilon \in (0,1)$ is fixed and $c$ is suitably chosen,

$$\left|C^{(\leq N)}_{\xi,\eta}\right| \leq c\gamma^{(d-2)N} e^{-m|\xi-\eta|}$$
$$\left|C^{(\leq N)}_{\xi,\eta} - C^{(\leq N)}_{\xi,\eta'}\right| \leq c\gamma^{(d-2)N}(\gamma^N m|\eta-\eta'|)^{\varepsilon} \quad [4]$$

with $\gamma^{(d-2)N}$ interpreted as $N$ if $d=2$.

The

$$\zeta(f) = \log\frac{Z_N(\Lambda,f)}{Z_N(\Lambda,0)}$$

defines a "generating function" of a probability distribution $P_{\text{int}}$ over the fields on $\Lambda$ which will be called the "distribution with $\varphi^4$-interaction" regularized on $\Lambda$ and at length scale $m^{-1}\gamma^{-N}$: the integral, in [1],

$$V_N\left(\varphi^{(\leq N)}\right) \overset{\text{def}}{=} -\int_\Lambda \left(\lambda_N \varphi_\xi^{(\leq N)^4} + \mu_N \varphi_\xi^{(\leq N)^2} + \nu_N + f_\xi \varphi_\xi^{(\leq N)}\right) d^d\xi \quad [5]$$

will be called the "interaction potential" with external field $f$. The regularization is introduced to guarantee that the integral [1], $\int e^{V_N}\, dP_N$, is well defined if $\lambda_N > 0$. The momenta of $P_{\text{int}}$ are the functional derivatives of $\zeta(f)$: they are called "Schwinger functions."

The problem (1) can now be made precise: it is to show the existence of $\lambda_N, \mu_N, \nu_N$ so that the limit

$$\lim_{N\to\infty} \frac{Z_N(\Lambda,f)}{Z_N(\Lambda,0)}$$

exists for all $f$ and is not Gaussian, that is, it is not the exponential of a quadratic form in $f$: which would be the case if $\lambda_N, \mu_N \to 0$ fast enough: the last requirement is of course essential because the Gaussian case describes, in the physical interpretation, free fields and noninteracting particles, that is, it is trivial. Note that $\nu_N$ does not play a role: its introduction is useful to be able to study separately the numerator and the denominator of the fraction

$$\frac{Z_N(\Lambda,f)}{Z_N(\Lambda,0)}$$

For more details, the reader is referred to Wightman and Gärding (1965), Streater and Wightman (1964), Nelson (1966), Guerra (1972), Osterwalder and Schrader (1973), and Simon (1974).

## The Regularized Free Field

Since the propagator, see [4], decays exponentially over a scale $m^{-1}$ and is smooth over a scale $m^{-1}\gamma^{-N}$, the fields $\varphi_\xi^{(\leq N)}$ sampled with distribution $P_N$ are rather singular objects. Their properties cannot be described by a single length scale: they are extremely large for large $N$, take independent values only beyond distances of order $m^{-1}$ but, at the same time, they look smooth only on the much smaller scale $m^{-1}\gamma^{-N}$. Their essential feature is that fixed $\varepsilon < 1$, for example, $\varepsilon = 1/2$, with $P_N$-probability 1 there is $B > 0$ such that (interpreting $\gamma^{(d-2)/2N}$ as $N$ if $d=2$)

$$\left|\varphi_\xi^{(\leq N)}\right| \leq B\gamma^{N(d-2)/2}$$
$$\left|\varphi_\xi^{(\leq N)} - \varphi_\eta^{(\leq N)}\right| < B\gamma^{N(d-2)/2}\left(\gamma^N m|\xi-\eta|\right)^{\varepsilon/2} \quad [6]$$

and furthermore the probability of the relations in [6] will be $N$-independent, that is, $\varphi_\xi^{(\leq N)}$ are bounded and roughly of size $\gamma^{N(d-2)/2}$ as $N \to \infty$ and, on a very small length scale $m^{-1}\gamma^{-N}$, almost constant.

Substantial control on the field $\varphi_\xi^{(\leq N)}$ statistically sampled with distribution $P_N$ can be obtained by decomposing it, through [3], into "components of various scales": that is, as a sum of statistically mutually independent fields whose properties are entirely characterized by a single scale of length. This means that they have size of order 1 and are independent and smooth on the same length scale.

Assuming the side of $\Lambda$ to be an integer multiple of $m^{-1}$, let $\mathcal{Q}_h$ be a pavement of $\Lambda$ into boxes of side $m^{-1}\gamma^{-h}$, imagined hierarchically arranged so that the boxes of $\mathcal{Q}_h$ are exactly paved by those of $\mathcal{Q}_{h+1}$.

Define $z_\xi^{(h)}$ to be the random field with propagator $C_{\xi,\eta}^{(h)}$ with Fourier transform

$$\sum_{n\in\mathbb{Z}^d}\left(\frac{1}{p^2+\gamma^{-2}m^2} - \frac{1}{p^2+m^2}\right) e^{in\cdot p L\gamma^h}$$

so that $\varphi_\xi^{(\leq N)}$ and its propagator $C_{\xi,\eta}^{(\leq N)}$ can be represented, see [2], [3], as

$$\varphi_\xi^{(\leq N)} \equiv \sum_{h=1}^N \gamma^{h(d-2)/2} z^{(h)}_{\gamma^h\xi}$$
$$C_{\xi,\eta}^{(\leq N)} = \sum_{h=1}^N \gamma^{h(d-2)} C^{(h)}_{\gamma^h\xi,\gamma^h\eta} \quad [7]$$

where the fields $z^{(h)}$ are independently distributed Gaussian fields. Note that the fields $z^{(h)}$ are also almost identically distributed because their propagator is obtained by periodizing over the period $\gamma^h L$ the same function

$$\overline{C}^{(0)}_{\xi,\eta} \overset{\text{def}}{=} \int \frac{e^{ip\cdot(\xi-\eta)}dp}{(2\pi)^d}\left(\frac{1}{p^2+\gamma^{-2}m^2} - \frac{1}{p^2+m^2}\right)$$

that is, their propagator is

$$C^{(h)}_{\xi,\eta} = \sum_{n\in\mathbb{Z}^d} \overline{C}^{(0)}_{\xi,\eta+\gamma^h nL}$$

The reason why they are not exactly equally distributed is that the field $z^{(h)}_{\xi}$ is periodic with period $\gamma^h L$ rather than $L$. But proceeding with care the sum over $n$ in the above expressions can be essentially ignored: this is a little price to pay if one wants translation invariance built in the analysis since the beginning.

The representation [7] defines a "multiscale representation" of the field $\varphi^{(\leq N)}_{\xi}$. Smoothness properties for the field $\varphi^{(\leq N)}_{\xi}$ can be read from those of its "components" $z^{(h)}$. Define, for $\Delta\in\mathcal{Q}_0$,

$$\left\|z^{(h)}\right\|_{\Delta} = \max_{\substack{\xi\in\Delta,\eta\in\Lambda\\ |\xi-\eta|\leq m^{-1}}} \left( \left|z^{(h)}_{\xi}\right| + \tau \frac{\left|z^{(h)}_{\xi} - z^{(h)}_{\eta}\right|}{|\xi-\eta|^{1/4}} \right) \qquad [8]$$

and $\tau$ will be chosen $\tau=0$ or $\tau=1$ as needed (in practice $\tau=0$ if $d=2$ and $\tau=1$ if $d=3$): $\tau=1$ will allow us to discuss some smoothness properties of the fields which will be necessary (e.g., if $d=3$). Then the size $\|z\|_{\Delta}$ of any field $z^{(h)}$, for all $h\geq 1$, is estimated by

$$P\left(\max_{\Delta\subset\mathcal{Q}_0} \|z\|_{\Delta} \leq B\right) \geq \mathrm{e}^{-c\mathrm{e}^{-c'B^2}|\Lambda|}$$
$$P(\|z\|_{\Delta} \geq B_{\Delta}, \forall\Delta\in\mathcal{D}) \leq \prod_{\Delta\in\mathcal{D}} c\mathrm{e}^{-c'B^2_{\Delta}} \qquad [9]$$

where $P$ is the Gaussian probability distribution of $z$, $\mathcal{D}$ is any collection of boxes $\Delta\in\mathcal{Q}_0$ and $c, c'>0$ are suitable constants. The [9] imply in particular [6]. The estimates [9] follow from the Markovian nature of the Gaussian field $z^{(h)}$, that is, from the fact that the propagator is the Green's function of an elliptic operator (of fourth order, see the first of [3]), with constant coefficients which implies also the inequalities (fixing $\varepsilon\in(0,1)$)

$$\left|C^{(h)}_{\xi,\eta}\right| \equiv \left|\int z_{\xi} z_{\eta} P(\mathrm{d}z)\right| \leq c\mathrm{e}^{-mc'|\xi-\eta|}$$
$$\left|C^{(h)}_{\xi,\eta} - C^{(h)}_{\xi,\eta'}\right| \leq c(m|\eta-\eta'|)^{\varepsilon} \qquad [10]$$

where $|\xi-\eta|$ is reinterpreted as the distance between $\xi,\eta$ measured over the periodic box $\gamma^h\Lambda$ (hence $|\xi-\eta|$ differs from the ordinary distance only if the latter is of the order of $\gamma^h L$). The interpretation of [10] is that $z^{(h)}_{\xi}$ are essentially bounded variables which, on scale $\sim m^{-1}$, are essentially constant and furthermore beyond length $\sim m^{-1}$ are essentially independently distributed.

For more details, the reader is referred to Wilson (1970, 1972) and Gallavotti (1981, 1985).

## Perturbation Theory

The naive approach to the problem is to fix $\lambda_N\equiv\lambda>0$ and to develop $Z_N(\Lambda,f)$ or, more conveniently and equivalently, $(1/|\Lambda|)\log Z_N(\Lambda,f)$ in powers of $\lambda$. If one fixes *a priori* $\mu_N,\nu_N$ independent of $N$, however, even a formal power series is not possible: this is trivially due to the divergence of the coefficients of the power series, already to second order, for generic $f$ in the limit $N\to\infty$. Nevertheless it is possible to determine $\mu_N(\lambda),\nu_N(\lambda)$ as functions of $N$ and $\lambda$ so that a formal power series exists (to all orders in $\lambda$): this is the key result of renormalization theory.

To find the perturbative expansion, the simplest is to use a graphical representation of the coefficients of the power expansion in $\lambda,\mu_N,\nu_N,f$ and the Gaussian integration rules which yield (after a classical computation) that the coefficient of $\lambda^n\mu^p_N f_{\xi_1}\ldots f_{\xi_r}$ is obtained by considering the graph elements shown in **Figure 1**, where the segments will be called half-lines and the graph elements will be called, respectively, "coupling" or "$\varphi^4$-vertex," "mass vertex," "vacuum vertex," and "external vertex."

The half-lines of the graph elements are considered distinct (i.e., imagine a label attached to distinguish them). Then consider all possible *connected* graphs $G$ obtained by first drawing, respectively, $n,p,r$ graph elements in **Figure 1**, which are not vacuum vertices, with their nodes marked by points in $\Lambda$ named $\xi_1,\ldots,\xi_n$, $\xi_{n+1},\ldots,\xi_{n+p+r}$; and form all possible graphs obtained by attaching pairs of half-lines emerging from the vertices of the graph elements. These are the "nontrivial graphs." Furthermore, consider also the single "trivial" graph formed just by the third graph element and consisting of a single point. All graphs obtained in this way are particular Feynman graphs.

Given a nontrivial graph $G$ (there are many of them) we define its value to be the product

$$W_G(\xi_1,\ldots,\xi_n,\xi_{n+1},\ldots,\xi_{n+p+r})$$
$$= (-1)^{n+p+r}\frac{\lambda^n\mu^p_N\prod f_{\xi_{n+p+j}}}{n!p!r!}\prod_{\ell} C^{(\leq N)}_{\xi_\ell,\eta_\ell} \qquad [11]$$

where the last product runs over all pairs $\ell=(\xi_\ell,\eta_\ell)$ of half-lines of $G$ that are joined and connect two vertices labeled by points $\xi_\ell,\eta_\ell$: "call line of $G$" any such pair. If the graph consists of the single vacuum

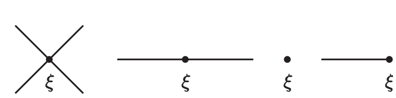

**Figure 1** The graph elements to representing $\varphi^{(\leq N)4}_{\xi}$, $\varphi^{(\leq N)2}$, a constant $\varphi^{(\leq N)}$.

vertex its value will be $\nu_N$. The series for $(1/|\Lambda|)\log Z_N(\Lambda, f)$ is then

$$-\nu_N + \frac{1}{|\Lambda|}\sum_G \int W_G(\boldsymbol{\xi}_1, \ldots, \boldsymbol{\xi}_{n+p+r}) \prod_{j=1}^{n+p+r} \mathrm{d}\boldsymbol{\xi}_j \qquad [12]$$

and the integral will be called the integrated graph value.

Suppose first that $\mu_N = \nu_N = 0$. Then if a graph $G$ contains subgraphs like in Figure 2, the corresponding respective contribution to the integral in [12] (considering only the integrals over $\boldsymbol{\eta}$ and suitably taking care of the combinatorial factors) is a factor obtained by integrating over $\boldsymbol{\xi}$ the quantities

$$-6\lambda C^{(\leq N)}_{\alpha\xi} C^{(\leq N)}_{\xi\xi} C^{(\leq N)}_{\xi\beta}$$

$$\text{or} \quad \frac{4^2 \cdot 3!}{2!}\lambda^2 C^{(\leq N)}_{\alpha\xi} \int C^{(\leq N)3}_{\xi\eta} C^{(\leq N)}_{\eta\beta} \mathrm{d}\boldsymbol{\eta} \qquad [13]$$

which if $d = 3$ diverge as $N \to \infty$ as $\gamma^N$ or, respectively, as $N$; the second factor does not diverge in dimension $d = 2$ while the first still diverges as $N$. The divergences arise from the fact that as $\boldsymbol{\xi} - \boldsymbol{\eta} \to 0$ the propagator behaves as $|\boldsymbol{\xi} - \boldsymbol{\eta}|^{-N}$ if $d = 3$ or as $-\log|\boldsymbol{\xi} - \boldsymbol{\eta}|$ if $d = 2$, all the way until saturation occurs at distance $|\boldsymbol{\xi} - \boldsymbol{\eta}| \simeq m^{-1}\gamma^{-N}$: for this reason the latter divergences are called "ultraviolet divergences."

However, if we set $\mu_N \neq 0$, then for every graph containing a subgraph like those in Figure 2 there is another one identical except that the points $\boldsymbol{\alpha}, \boldsymbol{\beta}$ are connected via a mass vertex, see Figure 1, with the vertex in $\boldsymbol{\xi}$, by a line $\boldsymbol{\alpha\xi}$ and a line $\boldsymbol{\xi\beta}$; the new graph value receives a contribution from the mass vertex inserted in $\boldsymbol{\xi}$ between $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ simply given by a factor $-\mu_N$. Therefore if we fix, for $d = 3$,

$$\mu_N = -6\lambda C^{(\leq N)}_{\xi\xi} + \frac{4^2 \cdot 3!}{2}\lambda^2 \times \int_\Lambda C^{(\leq N)3}_{\xi\eta} \mathrm{d}\boldsymbol{\eta} \stackrel{\text{def}}{=} -6\lambda C^{(\leq N)}_{\xi\xi} + \delta\mu_N \qquad [14]$$

we can simply consider graphs which do not contain any mass graph element and in which there are no subgraphs like the first in Figure 2 while the subgraphs like the second in Figure 2 do not contribute a factor $\int C^{(\leq N)}_{\alpha\xi} C^{(\leq N)3}_{\xi\eta} C^{(\leq N)}_{\eta\beta} \mathrm{d}\boldsymbol{\eta}$ but a renormalized factor $\int C^{(\leq N)}_{\alpha\xi} C^{(\leq N)3}_{\xi\eta} (C^{(\leq N)}_{\eta\beta} - C^{(\leq N)}_{\xi\beta}) \mathrm{d}\boldsymbol{\eta}$. If $d = 2$, we only need to define $\mu_N$ as the first term on the right-hand side (RHS) of [14] and we can leave the subgraphs like the second in Figure 2 as they are (without any renormalization).

Graphs without external lines are called vacuum graphs and there are a few such graphs which are divergent. Namely, if $d = 3$, they are the first three drawn in Figure 3; furthermore, if $\mu_N$ is set to the above nonzero value a new vacuum graph, the fourth in Figure 3, can be formed. Such graphs contribute to the graph value, respectively, the terms in the sum

$$-3\lambda C^{(\leq N)2}_{\xi_1,\xi_1} + \frac{4!}{2}\lambda^2 \int C^{(\leq N)4}_{\xi_1\xi_2} \mathrm{d}\boldsymbol{\xi}_2 - \frac{2^3 \cdot 3!^3}{3!}\lambda^3 \times \int C^{(\leq N)2}_{\xi_1\xi_2} C^{(\leq N)2}_{\xi_2\xi_3} C^{(\leq N)2}_{\xi_3\xi_1} \mathrm{d}\boldsymbol{\xi}_2 \mathrm{d}\boldsymbol{\xi}_3 - \mu_N C^{(\leq N)}_{\xi_1\xi_1} \qquad [15]$$

and diverge, respectively, as $\gamma^{2N}, \gamma^N, N, \gamma^{2N}$ if $d = 3$ while, if $d = 2$, only the first and the last (see [14]) diverge, like $N^2$.

Therefore, if we fix $\nu_N$ as minus the quantity in [15] we can disregard graphs like those in Figure 3; if $d = 2$ $\nu_N$ can be defined to be the sum of the first and last terms in [15].

The formal series in $\lambda$ and $f$ thus obtained is called the "renormalized series" for the field $\varphi^4$ in dimension $d = 2$ or, respectively, $d = 3$. Note that with the given definitions and choices of $\mu_N, \nu_N$ the only graphs $G$ that need to be considered to construct the expansion in $\lambda$ and $f$ are formed by the first and last graph elements in Figure 1, paying attention that the graphs in Figure 3 do not contribute and, if $d = 3$, the graphs with subgraphs like the second in Figure 2 have to be computed with the modification described.

In the next section, it will be shown that the above are the only sources of divergences as $N \to \infty$ and therefore the problem of studying [1] is solved at the level of formal power series by the subtraction in [14]. This also shows that giving a meaning to the series thus obtained is likely to be much easier if $d = 2$ than if $d = 3$.

The coefficients of order $k$ of the expansion in $\lambda$ of $(1/|\Lambda|)\log Z_N(\Lambda, f)$ can be ordered by the number $2n$ of vertices representing external fields: and have the form $\int S^{(k)}_{2n}(\boldsymbol{\xi}_1, \ldots, \boldsymbol{\xi}_{2n}) \prod_{i=1}^{2n} (f_{\xi_i} \mathrm{d}\boldsymbol{\xi}_i)$: the kernels $S^{(k)}_{2n}$ are the Schwinger functions of order $2n$, see the section "Euclidean quantum fields."

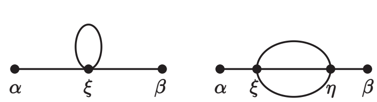

**Figure 2** Divergent subgraphs, if $d = 3$. If $d = 2$ only the first diverges.

**Figure 3** Divergent vacuum graphs.

**Remark** If $d=4$, the regularization at cutoff $N$ in [2] is not sufficient as in the subtraction procedure smoothness of the first derivatives of the field $\varphi^{(\leq N)}$ is necessary, while the regularization [2] does not even imply [6], that is, not even Hölder continuity. A higher regularization (i.e., using a $\chi_N$ like the square of the $\chi_N$ in [3]). Furthermore, the subtractions discussed in the case $d=3$ are not sufficient to generate a formal power series and many more subtractions are needed: for instance, graphs with a subgraph like the one in Figure 4 would give a contribution to the graph value which is a factor

$$\lambda^2 \ell_N \stackrel{\text{def}}{=} \frac{2\cdot 6^2}{2!}\lambda^2 \int_\Lambda C_{\xi\eta}^{(\leq N)2} \mathrm{d}\eta$$

also divergent as $N\to\infty$ proportionally to $N$. Although this divergence could be canceled by changing $\lambda$ into $\lambda_N = \lambda + \lambda^2 \ell_N$ the previously discussed cancelations would be affected and a change in the value of $\mu_N$ would become necessary; furthermore, the subtraction in [14] will not be sufficient to make finite the graphs, not even to second order in $\lambda$, unless a new term $-\alpha_N \int (\partial_\xi \varphi_\xi^{(\leq N)})^2 \,\mathrm{d}\boldsymbol{\xi}$ with $\alpha_N = (1/2)\lambda^2 \int \partial_\eta C_{\xi\eta}^{(\leq N)3} (\boldsymbol{\xi}-\boldsymbol{\eta})^2$ is added in the exponential in [1].

But all this will not be enough and still new divergences, proportional to $\lambda^3$, will appear.

And so on indefinitely, the consequence being that it will be necessary to define $\lambda_N, \mu_N, \alpha_N, \nu_N$ as formal power series in $\lambda$ (with coefficients diverging as $N\to\infty$) in order to obtain a formal power series in $\lambda$ for [1] in which all coefficients have a finite limit as $N\to\infty$. Thus, the interpretation of the formal renormalized series in the case $d=4$ is substantially different and naturally harder than the cases $d=2,3$. Beyond formal perturbation expansions, the case $d=4$ is still an open problem: the most widespread conjecture is that the series cannot be given a meaning other than setting to 0 all coefficients of $\lambda^j, j>0$. In other words, the conjecture claims, there should be no nontrivial solution to the ultraviolet problem for scalar $\varphi^4$ fields in $d=4$. But this is far from being proved, even at a heuristic level. The situation is simpler if $d\geq 5$: in such cases, it is impossible to find formal power series in $\lambda$ for $(1/|\Lambda|)\log Z_N(\Lambda, f)$, even allowing $\lambda_N, \mu_N, \alpha_N, \nu_N$ to be formal power series in $\lambda$ with divergent coefficients.

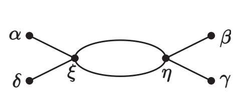

**Figure 4** The simplest new divergent subgraph on $d=4$.

The distinctions between the cases $d=2,3,4,>4$ explain the terminology given to the $\varphi^4$-scalar field theories calling them super-renormalizable if $d=2,3$, renormalizable if $d=4$ and nonrenormalizable if $d>4$. Since the (divergent) coefficients in the formal power series defining $\lambda_N, \mu_N, \alpha_N, \nu_N$ are called counter-terms, the $\varphi^4$-scalar fields require finitely many counter-terms (see [14]) in the super-renormalizable cases and infinitely many in the renormalizable case. The nonrenormalizable cases ($d>4$) cannot be treated in a way analogous to the renormalizable ones.

For more details, the reader is referred to Gallavotti (1985), Aizenman (1982), and Fröhlich (1982).

## Finiteness of the Renormalized Series, $d=2,3$: "Power Counting"

Checking that the renormalized series is well defined to all orders is a simple dimensional estimate characteristic of many multiscale arguments that in physics have become familiar with the name of "renormalization group arguments."

Consider a graph $G$ with $n+r$ vertices built over $n$ graph elements with vertices $\boldsymbol{\xi}_1, \ldots, \boldsymbol{\xi}_n$ each with four half-lines and $r$ graph elements with vertices $\boldsymbol{\xi}_{n+1}, \ldots, \boldsymbol{\xi}_{n+r}$ representing the external fields: as remarked in the previous section, these are the only graphs to be considered to form the renormalized series.

Develop each propagator into a sum of propagators as in [7]. The graph $G$ value will, as a consequence, be represented as a sum of values of new graphs obtained from $G$ by adding scale labels on its lines and the value of the graph will be computed as a product of factors in which a line joining $\boldsymbol{\xi\eta}$ and bearing a scale label $h$ will contribute with $C_{\xi\eta}^{(h)}$ replacing $C_{\xi\eta}^{(\leq N)}$. To avoid proliferation of symbols, we shall call the graphs obtained in this way, i.e., with the scale labels attached to each line, still $G$: no confusion should arise as we shall, henceforth, only consider graphs $G$ with each line carrying also a scale label.

The scale labels added on the lines of the graph $G$ allow us to organize the vertices of $G$ into "clusters": a cluster of scale $h$ consists in a maximal set of vertices (of the graph elements in the graph) connected by lines of scale $h'\geq h$ among which one at least has scale $h$.

It is convenient to consider the vertices of the graph elements as "trivial" clusters of highest scale: conventionally call them clusters of scale $N+1$.

The clusters can be of "first generation" if they contain only trivial clusters, of "second generation"

if they contain only clusters which are trivial or of the first generation, and so on.

Imagine to enclose in a box the vertices of graph elements inside a cluster of the first generation and then into a larger box the vertices of the clusters of the second generation and so on: the set of boxes ordered by inclusion can then be represented by a rooted tree graph whose nodes correspond to the clusters and whose "top points" are nodes representing the trivial clusters (i.e., the vertices of the graph).

If the maximum number of nodes that have to be crossed to reach a top point of the tree starting from a node $v$ is $n_v$ ($v$ included and the top nodes included), then the node $v$ represents a cluster of the $n_v$th generation. The first node before the root is a cluster containing all vertices of $G$ and the root of the tree will not be considered a node and it can conventionally bear the scale label 0: it represents symbolically the value of the graph.

For instance, in Figure 5 a tree $\theta$ is drawn: its nodes correspond to clusters whose scale is indicated next to them; in the second part of the drawing, the trivial clusters as well as the clusters of the first generation are enclosed into boxes.

Then consider the next generation clusters, that is, the clusters which only contain clusters of the first generation or trivial ones, and draw boxes enclosing all the graph vertices that can be reached from each of them by descending the tree, etc. Figure 6 represents all boxes (of any generation) corresponding to the nodes of the tree in Figure 5. The representations of the clusters of a graph $G$ by a tree or by hierarchically ordered boxes (see Figures 5 and 6) are completely equivalent provided inside each box not representing a top point of the tree the scale $h_v$ of the corresponding cluster $v$ is marked. For

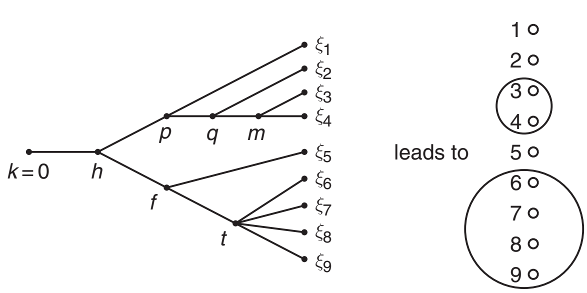

**Figure 5** A tree and its clusters of generation 1 and 2.

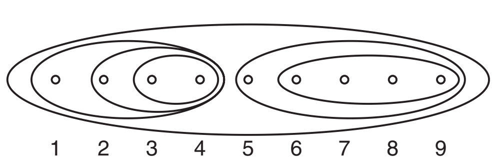

**Figure 6** All clusters of any generation for the tree in Figure 5.

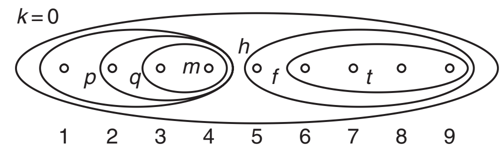

**Figure 7** The clusters in Figure 6 after affixing the scale labels.

instance, in the case of Figure 6 one gets Figure 7. By construction, if two top points $\xi$ and $\eta$ are inside the same box $b_v$ of scale $h_v$ but not in inner boxes, then there is a path of graph lines joining $\xi$ and $\eta$ all of which have scales $\geq h_v$ and one at least has scale $h_v$.

Given a graph $G$, fix one of its points $\xi_1$ (say) and integrate the absolute value of the graph over the positions of the remaining points. The exponential decay of the propagators implies that if a point $\eta$ is linked to a point $\eta'$ by a line of scale $h$ the integration over the position of $\eta'$ is essentially constrained to extend only over a distance $\gamma^{-h}m^{-1}$. Furthermore, the maximum size of the propagator associated with a line of scale $h$ is bounded proportionally to $\gamma^{(d-2)h}$. Therefore, recalling that $|f_\xi|$ is suppose bounded by 1, the mentioned integral can be immediately bounded by

$$\frac{\lambda^n}{n!r!}C^{n+r}I \stackrel{\text{def}}{=} \frac{\lambda^n C^{n+r}}{n!r!}\prod_{\ell}\gamma^{(d-2)/2h_\ell}\prod_{v}\gamma^{-\mathrm{d}h_v(s_v-1)} \qquad [16]$$

where, $C$ being a suitable constant, the first product is over the half-lines $\ell$ composing the graph lines and the second is over the tree nodes (i.e., over the clusters of the graph $G$), $s_v$ is the number of subclusters contained in the cluster $v$ but not in inner clusters; and in [16] the scale of a half-line $\ell$ is $h_\ell$ if $\ell$ is paired with another half-line to form a line $\ell$ (in the graph $G$) of scale label $h_\ell$.

Denoting by $v'$ the cluster immediately containing $v$ in $G$, by $n_v^{\text{inner}}$ the number of half-lines in the cluster $v$, by $n_v, r_v$ the numbers of graph elements of the first type or of the fourth type in Figure 1 with vertices in the cluster $v$, and denoting by $n_v^e$ the number of lines which are not in the cluster $v$ but have one extreme on a vertex in $v$ ("lines external to $v$"), the identities ($k=0$)

$$\begin{aligned}&\sum_{v>\text{root}}(h_v-k)(s_v-1)\\&\quad\equiv\sum_{v>\text{root}}(h_v-h_{v'})(n_v+r_v-1)\\&\sum_{v>\text{root}}(h_v-k)n_v^{\text{inner}}\equiv\sum_{v>\text{root}}(h_v-h_{v'})\widetilde{n}_v^{\text{inner}}\end{aligned} \qquad [17]$$

with

$$\widetilde{n}_v^{\text{inner}} \stackrel{\text{def}}{=} 4n_v + r_v - n_v^e$$

hold, so that the estimate [16] can be elaborated into

$$I \le \prod_{v>r} \gamma^{-\rho_v(h_v - h_{v'})}$$
$$\rho_v \overset{\text{def}}{=} -d + (4-d)n_v + r_v\frac{d+2}{2} + \frac{d-2}{2}n_v^e \qquad [18]$$

where $h_{v'} = k = 0$ if $v$ is the first nontrivial node (i.e., $v' = \text{root}$), and an estimate of the integral of the absolute value of the graphs $G$ with given tree structure but different scale labels is proportional to $\Sigma_{\{h_v\}} I < \infty$ if (and only if) $\rho_v > 0, \forall v$.

But there may be clusters $v$ with only two external lines $n_v^e = 2$ and two graph vertices inside: for which $\rho_v = 0$. However, this can happen only if $d = 3$ and in only one case: namely if the graph $G$ contains a subgraph of the second type in Figure 2 and the three intermediate lines form a cluster $v$ of scale $h_v$ while the other two lines are external to it: hence on scale $h' > h_v$. In this case, one has to remember that the subtraction in the previous section has led to a modification of the contribution of such a subgraph to the value of the graph (integrated over the position labels of the vertices). As discussed in the previous section, the change amounts to replacing the propagator $C^{(h')}_{\eta,\beta}$ by $C^{(h')}_{\eta,\beta} - C^{(h')}_{\xi,\beta}$.

This improves, in [18], the estimate of the contribution of the line joining $\boldsymbol{\eta}$ to $\boldsymbol{\beta}$ from being proportional to $\int C^{(\le h_v)3}_{\xi\eta} C^{(\le h')}_{\eta\beta}\, d\boldsymbol{\eta}$ to being proportional to $\int C^{(\le h_v)3}_{\xi\eta}(C^{(\le h')}_{\eta\beta} - C^{(\le h')}_{\xi\beta})\, d\boldsymbol{\eta}$; and this changes the contribution of the line $\boldsymbol{\eta\beta}$ from $\gamma^{(d-2)h'}$ to $\int e^{-m\gamma^{h_v}|\boldsymbol{\xi}-\boldsymbol{\eta}|} (\gamma^{h'}|\boldsymbol{\xi}-\boldsymbol{\eta}|)^{1/2}\, d\boldsymbol{\eta}$ because $C^{(h')}$ is regular on scale $\gamma^{-h'}m^{-1}$, see [10] with $\varepsilon = 1/2$.

Since $\boldsymbol{\xi}, \boldsymbol{\eta}$ are in a cluster of higher scale $h_v$ this means that the estimate is improved by $\gamma^{-(1/2)(h_v - h')}$. In terms of the final estimate, this means that $\rho_v$ in [18] can be improved to $\overline{\rho}_v = \rho_v + 1/2$ for the clusters for which $\rho_v = 0$. Hence, the integrated value of the graph $G$ (after taking also into account the integration over the initially selected vertex $\boldsymbol{\xi}_1$, trivially giving a further factor $|\Lambda|$ by translation invariance), and summed over the possible scale labels is bounded proportionally to $|\Lambda|\Sigma_{\{h_v\}} I < \infty$ once the estimate of $I$ is improved as described.

Note that the graphs contributing to the perturbation series for $(1/|\Lambda|)\log Z_N(\Lambda, f)$ to order $\lambda^n$ are finitely many because the number $r$ of external vertices is $r \le 2n + 2$ (since graphs must be connected). Hence, the perturbation series is finite to all orders in $\lambda$.

The above is the renormalizability proof of the scalar $\varphi^4$-fields in dimension $d = 2, 3$. The theory is renormalizable even if $d = 4$ as mentioned in the remark at the end of the previous section. The analysis would be very similar to the above: it is just a little more involved power-counting argument.

For more details, the reader is referred to Hepp (1966), Gallavotti (1985), sections 8 and 16.

## Asymptotic Freedom ($d = 2, 3$). Heuristic Analysis

Finiteness to all orders of the perturbation expansions is by no means sufficient to prove the existence of the ultraviolet limit for $Z_N(\Lambda, f)$ or for $(1/|\Lambda|) \log Z_N(\Lambda, f)$: and *a priori* it might not even be necessary. For this purpose, the first step is to check uniform (upper and lower) boundedness of $Z_N(\Lambda, f)$ as $N \to \infty$.

The reason behind the validity of a bound $e^{|\Lambda| E_-(\lambda,f)} \le Z_N(\Lambda, f) \le e^{|\Lambda| E_+(\lambda,f)}$ with $E_\pm(\lambda, f)$ cutoff independent has been made very clear after the introduction of the renormalization group methods in field theory. The approach studies the integral $Z_N(\Lambda, f)$, recursively, decomposing the field $\varphi^{(\le N)}_{\xi}$ into its regular components $z^{(h)}_{\xi}$, see [7], and integrating first over $z^{(N)}$, then over $z^{(N-1)}$ and so on.

The idea emerges naturally if the potential $V_N$ in [1] and [4] is written in terms of the "normalized" variables $X^{(N)}_{\xi} \overset{\text{def}}{=} \gamma^{-N(d-2)/2}\varphi^{(\le N)}_{\xi}$, see [6]; here if $d = 2$ the factor $\gamma^{(d-2)/2N}$ is interpreted as $N^{1/2}$.

The key remark is that as far as the integration over the small-scale component $z^{(N)}$ is concerned the field $X^{(N)}_{\xi}$ is a sum of two fields of size of order 1 (statistically),

$$X^{(N)}_{\xi} \equiv z^{(N)}_{\gamma^N \xi} + \gamma^{-(d-2)/2} X^{(N-1)}_{\xi}$$

if $d = 2$ this becomes

$$X^{(N)}_{\xi} \equiv \frac{1}{N^{1/2}} z^{(N)}_{\gamma^N \xi} + \frac{(N-1)^{1/2}}{N^{1/2}} X^{(N-1)}_{\xi}$$

and it can be considered to be smooth on scale $m^{-1}\gamma^{-N}$ (also statistically). Hence, approximately constant and of size of order O(1) on the small cubes $\Delta$ of volume $\gamma^{-dN} m^{-d}$ of the pavement $\mathcal{Q}_N$ introduced before [7]; at the same time it can be considered to take (statistically) independent values on different cubes of $\mathcal{Q}_N$. This is suggested by the inequalities [8]–[10].

Therefore, it is natural to decompose the potential $V_N$, see [5], as a sum over the small cubes $\Delta$ of volume $\gamma^{-dN} m^{-d}$ of the pavement $\mathcal{Q}_N$ as (see [14] for the definition of $\mu_N, \nu_N$), taking henceforth $m = 1$,

$$V_N(z^{(N)}) \overset{\text{def}}{=} -\sum_{\Delta \in \mathcal{Q}_N} \gamma^{-Nd} \int_\Delta \Big( \lambda \gamma^{2(d-2)N} X^{(N)\,4}_{\xi} + \mu_N \gamma^{(d-2)N} X^{(N)\,2}_{\xi} + \nu_N + f_\xi \gamma^{(d-2)/2N} X^{(N)}_{\xi} \Big) \frac{d\xi}{|\Delta|} \qquad [19]$$

where $\gamma^{(d-2)N}$ is interpreted as $N$ if $d=2$. Hence, if $d=3$ it is

$$V_N(z^{(N)}) \stackrel{\text{def}}{=} -\sum_{\Delta\in\mathcal{Q}_N} \gamma^{-N} \int_\Delta \Big(\lambda X_\xi^{(N)\,4} + \overline{\mu}_N X_\xi^{(N)\,2} + \overline{\nu}_N + f_\xi \gamma^{-\frac{3}{2}N} X_\xi^{(N)}\Big) \frac{\mathrm{d}\xi}{|\Delta|} \qquad [20]$$

where

$$\overline{\mu}_N \stackrel{\text{def}}{=} (-6\lambda c_N + \lambda^2 N \gamma^{-N} c'_N),$$
$$\overline{\nu}_N \stackrel{\text{def}}{=} 3\lambda c_N^2 + \lambda^2 \gamma^{-N} b_N + \lambda^3 N \gamma^{-2N} b'_N$$

and $c_N, c'_N, b_N, b'_N$, computable from [15] and [14], admit a limit as $N\to\infty$. While if $d=2$ it is

$$V_N(z^{(N)}) \stackrel{\text{def}}{=} -\sum_{\Delta\in\mathcal{Q}_N} N^2\gamma^{-2N} \int_\Delta \Big(\lambda X_\xi^{(N)\,4} + \overline{\mu}_N X_\xi^{(N)\,2} + \overline{\nu}_N + f_\xi N^{-\frac{3}{2}} X_\xi^{(N)}\Big) \frac{\mathrm{d}\xi}{|\Delta|} \qquad [21]$$

where $\overline{\mu}_N \stackrel{\text{def}}{=} -6\lambda c_N$ and $\overline{\nu}_N = 3\lambda c_N^2$ and $c_N$, computable from [13], admits a limit as $N\to\infty$.

The fields $z^{(N)}$ and $X^{(N-1)}$ can be considered constant over boxes $\Delta\in\mathcal{Q}_N$: $z_\xi^{(N)} = s_\Delta, X_\xi^{(N-1)} = x_\Delta$ for $\xi\in\Delta$ and the $s_\Delta$ can be considered statistically independent on the scale of the lattice $\mathcal{Q}_N$.

Therefore, [20] and [21] show that integration over $z^{(N)}$ in the integral defining $Z_N(\Lambda, f)$ is not too different from the computation of a partition function of a lattice continuous spin model in which the "spins" are $s_\Delta$ and, most important, interact extremely weakly if $N$ is large. In fact, the coupling constants are of order of a power of $|X^{(N-1)}|$ times $O(\gamma^{-N})$ if $d=3$ ($O(N^2\gamma^{-2N})$ if $d=2$), or of order $O(\gamma^{-N(d+2)/2}\max|f_\xi|)$, no matter how large $\lambda$ and $f$.

This says that the smallest scale fields are extremely weakly coupled. The fields $X^{(N-1)}$ can be regarded as external fields of size that will be called $B_{N-1}$, of order 1 or even allowed to grow with a power of $N$, see [6]. Their presence in $V_N$ does not affect the size of the couplings, as far as the analysis of the integral over $z^{(N)}$ is concerned, because the couplings remain exponentially small in $N$, see [20] and [21], being at worst multiplied by a power of $B_{N-1}$, i.e., changed by a factor which is a power of $N$.

The smallness of the coupling at small scale is a property called "asymptotic freedom." Once fields and coordinates are "correctly scaled," the real size of the coupling becomes manifest, that is, it is extremely small and the addends in $V_N$ proportional to the "counter-terms" $\mu_N, \nu_N$, which looked divergent when the fields were not properly scaled, are in fact of the same order or much smaller than the main $\varphi^4$-term.

Therefore, the integration over $z^{(N)}$ can be, heuristically, performed by techniques well established in statistical mechanics (i.e., by straightforward perturbation expansions): at least if the field $X_\xi^{(\leq N-1)}$ is smooth and bounded, as prescribed by [6], with $B=B_{N-1}$ growing as a power of $N$. In this case, denoting symbolically the integration over $z^{(N)}$ by $P$ or by $\langle\ldots\rangle$, it can be expected that it should give

$$\int \mathrm{e}^{V_N}\,\mathrm{d}P\Big(z^{(N)}\Big) \equiv \mathrm{e}^{V_{j;N-1}+\overline{\mathcal{R}}(j,N)|\Lambda|} \qquad [22]$$

where $V_{j;N-1}$ is the Taylor expansion of $\log\int \mathrm{e}^{V_N}\,\mathrm{d}P(z^{(N)})$ in powers of $\lambda$ (hence essentially in the very small parameter $\lambda\gamma^{-(4-d)N}$) truncated at order $j$, that is,

$$V_{1;N-1} = [\langle V_N\rangle]^{\leq 1}$$
$$V_{2;N-1} = \left[\langle V_N\rangle + \frac{(\langle V_N^2\rangle - \langle V_N\rangle^2)}{2!}\right]^{\leq 2}$$
$$V_{3;N-1} = \left[\langle V_N\rangle + \frac{(\langle V_N^2\rangle - \langle V_N\rangle^2)}{2!} + \frac{\Big(\langle V_N(\langle V_N^2\rangle - \langle V_N\rangle^2)\rangle - \langle V_N(\langle V_N^2\rangle - \langle V_N\rangle^2)\rangle\Big)}{3!}\right]^{\leq 3}, \ldots \qquad [23]$$

where $[\cdot]^{\leq j}$ denotes truncation to order $j$ in $\lambda$, and $\overline{\mathcal{R}}(j,N)$ is a remainder (depending on $\varphi_\xi^{(\leq N-1)}$) which can be expected to be estimated, for $d=2, 3$, by

$$|\overline{\mathcal{R}}(j,N)| \leq \mathcal{R}(j,N) \stackrel{\text{def}}{=} C_j B_N^{4j} (\lambda N^2 \gamma^{-(4-d)N})^{j+1} \gamma^{dN} \qquad [24]$$

for suitable constants $C_j$, that is, a remainder estimated by the $(j+1)$th power of the coupling times the number of boxes of scale $N$ in $\Lambda$. The relations [22]–[24] result from a naive Taylor expansion (in $\lambda$ of the $\log\int \mathrm{e}^{V_N}\,\mathrm{d}P(z^{(N)})$, taking into account that, in $V_N$ as a function of $z^{(N)}$, the $z^{(N)}$'s appear multiplied by quantities at most of size $\leq \lambda\gamma^{4-d}N^2B_N^3$, by [20] and [21] if $|X^{(N-1)}|\leq B_{N-1}$). In a statistical mechanics model for a lattice spin system, such a calculation of $Z_N$ would lead to a mean-field equation of state once the remainder was neglected.

The peculiarity of field theory is that a relation like [22] and [24] has to be applied again to $V_{j;N-1}$ to perform the integration over $z^{(N-1)}$ and define $V_{j;N-2}$ and, then, again to $V_{j;N-2}\ldots$. Therefore, it will be essential to perform the integral in [22] to an order (in $\lambda$) high enough so that the bound $\mathcal{R}(j,N)$ can be

summed over $N$: this requires (see [24]) an explicit calculation of [23] pushed at least to order $j=1$ if $d=2$ or to order $j=3$ if $d=3$; furthermore it is also necessary to check that the resulting $V_{j;N-1}$ can still be interpreted as low-coupling spin model so that [22] can be iterated with $N-1$ replacing $N$ and then with $N-2$ replacing $N-1, \ldots$.

The first necessary check towards a proof of the discussed heuristic "expectations" is that, defining recursively $V_{j;h}$ from $V_{j,h+1}$ for $h=N-1,\ldots,1,0$ by [23] with $V_N$ replaced by $V_{j;h+1}$ and $V_{j;N-1}$ replaced by $V_{j;h}$, the couplings between the variables $z^{(h)}$ do not become "worse" than those discussed in the case $h=N$. Furthermore, the field $\varphi_\xi^{(\leq N-1)}$ has a high probability of satisfying [6], but fluctuations are possible: hence the $\mathcal{R}$-estimate has to be combined with another one dealing with the large fluctuations of $X_\xi^{(N-1)}$ which has to be shown to be "not worse."

For more details, the reader is referred to Gallavotti (1978, 1985) and Benfatto and Gallavotti (1995).

## Effective Potentials and Their Scale (In)Dependence

To analyze the first problem mentioned at the end of the previous section, define $V_{j;h}$ by [23] with $V_N$ replaced by $V_{j;h+1}$ for $h=N-1,N-2,\ldots,0$. The quantities $V_{j;h}$, which are called "effective potentials" on scale $h$ (and order $j$), turn out to be in a natural sense scale independent: this is a consequence of renormalizability, realized by Wilson as a much more general property which can be checked, in the very special cases considered here with $d=2,3$, at fixed $j$ by induction, and in the super-renormalizable models considered here it requires only an elementary computation of a few Gaussian integrals as the case $j=3$ (or even $j=1$ if $d=2$) is already sufficient for our purposes.

It can also be (more easily) proved for general $j$ by a dimensional argument parallel to the one presented earlier to check finiteness of the renormalized series. The derivation is elementary but it should be stressed that, again, it is possible only because of the special choice of the counter-terms $\mu_N,\nu_N$. If $d=3$, the boundedness and smoothness of the fields $\varphi^{(\leq h)}$ and $z^{(h)}$ expressed by the second of [6] and of [10] is essential; while if $d=2$ the smoothness is not necessary.

The structure of $V_{j;h}$ is conveniently expressed in terms of the fields $X_\xi^{(h)}$, as a sum of three terms $V_h^{(\mathrm{rel})}$ (standing for "relevant" part), $V_h^{(\mathrm{irr})}$ (standing for "irrelevant" part), and a "field independent" part $E(j,h)|\Lambda|$.

The relevant part in $d=2$ is simply of the form [21] with $h$ replacing $N$: call it $V_h^{(\mathrm{rel},1)}$. If $d=3$, it is given by [20] with $h$ replacing $N$ plus, for $h<N$, a second "nonlocal" term

$$V_h^{(\mathrm{rel},2)} \stackrel{\mathrm{def}}{=} \frac{4^2\,3!}{2!\,2!}\lambda^2 \int \left(C_{\eta\eta'}^{(\leq h)\,3} - C_{\eta\eta'}^{(\leq N)\,3}\right) \times \left(\varphi_{\eta}^{(\leq h)} - \varphi_{\eta'}^{(\leq h)}\right)^2 \mathrm{d}\eta\mathrm{d}\eta'$$

which is conveniently expressed in terms of a "nonlocal" field

$$Y_{\eta\eta'}^{(h)} \stackrel{\mathrm{def}}{=} \frac{\varphi_{\eta}^{(\leq h)} - \varphi_{\eta'}^{(\leq h)}}{(\gamma^h|\eta-\eta'|)^{\frac{1}{4}}}$$

as $V_h^{(\mathrm{rel})} = V_h^{(\mathrm{rel},1)} + V_h^{(\mathrm{rel},2)}$ with

$$V_h^{(\mathrm{rel},2)} \stackrel{\mathrm{def}}{=} -\lambda^2\gamma^{-2h} \sum_{\Delta,\Delta'\in\mathcal{Q}_h} \int_{\Delta\times\Delta'} Y_{\eta\eta'}^{(h)2} A_{\eta\eta'}^{(h)} \times \mathrm{e}^{-c'\gamma^h|\eta-\eta'|} \frac{\mathrm{d}\eta\mathrm{d}\eta'}{|\Delta|\,|\Delta'|} \qquad [25]$$

where

$$0 < a \leq \left(\frac{A_{\eta\eta'}^{(h)}}{(\gamma^h|\eta-\eta'|)^{3-(1/2)}}\right)_N < a'$$

with $a,a',c'>0$ and the subscript $N$ means that the expression in parenthesis "saturates at scale $N$", i.e., its denoninator becomes $\gamma^{(3-(1/2))(h-N)}$ as $|\eta-\eta'|\to 0$.

The expression [25] is not the full part of the potential $V_{j;h}$ which is of second order in the fields: there are several other contributions which are collected below as "irrelevant."

It should be stressed that "irrelevant" is a traditional technical term: by no means it should suggest "negligibility." On the contrary, it could be maintained that the whole purpose of the theory is to study the irrelevant terms. The irrelevant part of the potential can be better designated as the "driven part," as its behavior is "controlled" by the relevant part: although initially $V_{j;h}$, $h=N$, contains no irrelevant terms, it eventually contains them for $h<N$ and they keep getting generated as $h$ diminishes. Furthermore, the part of the irrelevant terms generated at scale $h_0 \leq N$ becomes very small at scales $h \ll h_0$ so that the irrelevant part of $V_{j;h}$ at small $h$ (e.g., at $h=0$, i.e., on the "physical scale" of the observer) only depend on the relevant terms in a few scales near $h$.

It also turns out that the Schwinger functions are simply related to the irrelevant terms.

The irrelevant part of the effective potential can be expressed as a finite sum of integrals of

monomials in the fields $X^{(h)}_\xi$ if $d=2$, or in the fields $X^{(h)}_\xi$ and $Y^{(h)}_{\eta\eta'}$ if $d=3$, which can be written as $V^{(\mathrm{irr})}_{j;h}$ given by

$$\int \left( \prod_{k=1}^{p} X^{(h)\, n_k}_{\xi_k} \prod_{k'=1}^{q} Y^{(h)\, n'_{k'}}_{\eta_{k'}\eta'_{k'}} \right) \mathrm{e}^{-\gamma^h c' d(\xi_1,\ldots,\eta'_q)} \lambda^n \gamma^{-ht} \times W(\xi_1,\ldots,\eta'_q) \prod_{k=1}^{p} \frac{\mathrm{d}\xi_k}{|\Delta_k|} \prod_{k'=1}^{q} \frac{\mathrm{d}\eta_{k'}\mathrm{d}\eta'_{k'}}{|\Delta^1_{k'}|\,|\Delta^2_{k'}|} \qquad [26]$$

with the integral extended to products $\Delta_1 \times \cdots \times \Delta_p \times \cdots \times (\Delta^1_q \times \Delta^2_q)$ of boxes $\Delta \in \mathcal{Q}_h$, and $d(\xi_1,\ldots,\eta'_q)$ is the length of the shortest tree graph that connects all the $p+2q>0$ points, the exponents $n,t$ are $\geq 2$, and $t$ is $\geq 3$ if $q>0$; the kernel $W$ depends on all coordinates $\xi_1,\ldots,\eta'_q$ and it is bounded above by $C_j \prod_{k'=1}^{q} A_{\eta_{k'}\eta'_{k'}}$ for some $C_j$; the sums $\sum n_k + \sum n'_{k'}$ cannot exceed $4j$. The test functions $f$ do not appear in [26] because by assumption they are bounded by 1: but $W$ depends on the $f$'s as well.

The field-independent part is simply the value of $\log Z_N(\Lambda,f)$ computed by the perturbation analysis in the section "Perturbation theory" up to order $j$ in $\lambda$ but using as propagator $(C^{(\leq N)} - C^{(\leq h)})$: thus, $E(j,h)$ is a constant depending on $N$ but uniformly bounded as $N\to\infty$ (because of the renormalizability proved in the section "Perturbation theory").

If $d=2$, there is no need to introduce the nonlocal fields $Y^{(h)}$ and in [26] one can simply take $q=0$, and the relevant part also can be expressed by omitting the term $V^{(\mathrm{rel},2)}_h$ in [25]: unlike the $d=3$ case, the estimate on the kernels $W$ by an $N$-independent $C_j$ holds uniformly in $h$ without having to introduce $Y$. For $d=2$, it will therefore be supposed that $V^{(\mathrm{rel},2)}_h \equiv 0$ in [25] and $q=0$ in [26].

It is not necessary to have more information on the structure of $V_{j;h}$ even though one can find simple graphical rules, closely related to the ones in the section "Perturbation theory," to construct the coefficients $W$ in full detail. The $W$ depend, of course, on $h$ but the uniformity of the bound on $W$ is the only relevant property and in this sense the effective potentials are said to be (almost) "scale independent."

The above bounds on the irrelevant part can be checked by an elementary direct computation if $j\leq 3$: in spite of its "elementary character," the uniformity in $h\leq N$ is a result ultimately playing an essential role in the theory together with the dominance of the relevant part over the irrelevant one which, once the fields are properly scaled, is "much smaller" (by a factor of order $\gamma^{-h}$, see [26]), at least if $h$ is large.

**Remarks**

(i) Checking scale independence for $j=1$ is just checking that $\int P(\mathrm{d}z^{(h)}) V_{1;h} = V_{1;h-1}$. Note that

$$V_{1;h} \stackrel{\mathrm{def}}{=} \int_\Lambda \lambda\left(\varphi_\xi^{(\leq h)4} - 6C_{00}^{(\leq h)}\varphi_\xi^{(\leq h)2} + 3C_{00}^{(\leq h)2}\right)\mathrm{d}\xi$$

hence, calling $:\varphi_\xi^{(\leq h)4}:$ the polynomial in the integral (Wick's monomial of order 4), we have here an elementary Gaussian integral ("martingale property of Wick monomials"). Note the essential role of the counter-terms. For $j>1$, the computation is similar but it involves higher-order polynomials (up to $4j$) and the distinction between $d=2$ and $d=3$ becomes important.

(ii) $V_{j;0}$ contains only the field-independent part $E(j,0)|\Lambda|$ (see above) which is just a number (as there are no fields of scale 0): by the above definitions, it is identical to the perturbative expansion truncated to $j$th order in $\lambda$ of $\log Z_N(\Lambda,f)$, well defined as discussed earlier.

## Nonperturbative Renormalization: Small Fields

Having introduced the notion of effective potential $V_{j;h}$, of order $j$ and scale $h$, satisfying the bounds (described after [26]) on the kernels $W$ representing it, the problem is to estimate the remainder in [22] and find its relation with the value [24] given by the heuristic Taylor expansion. Assume $\lambda<1$ to avoid distinguishing this case from that with $\lambda\geq 1$ which would lead to very similar estimates but to different $\lambda$-dependence on some constants.

Define $\chi_B(z^{(h)})=1$ if $\|z^{(h)}\|_\Delta \leq Bh^2$ for all $\Delta\in\mathcal{Q}_h$, see [8], and 0 otherwise; then the following lemma holds:

**Lemma 1** *Let $\|X^{(h)}\|_\Delta$ be defined as [8] with $z$ replaced by $X$ and suppose $\|X^{(h)}\|_\Delta \leq Bh^4$ for all $\Delta$ then, for all $j\geq 1$, it is*

$$\int \mathrm{e}^{V_{j;h+1}}\chi_B(z^{(h+1)})\mathrm{d}P(z^{(h+1)}) = \mathrm{e}^{V_{j;h}+\mathcal{R}'(j,h+1)|\Lambda|} \qquad [27]$$

*with, for suitable constants $c_-, c'_-$,*

$$|\mathcal{R}'_-(j;h+1)| \leq \mathcal{R}_-(j;h+1) \stackrel{\mathrm{def}}{=} \mathcal{R}(j;h+1) + c_-\mathrm{e}^{-c'_-B^2(h+1)^2}$$

*and $\mathcal{R}(j;h+1)$ given by [24] with $h+1$ in place of $N$.*

Since $Z_N(\Lambda,f) \geq \int \mathrm{e}^{V_N}\prod_{h=1}^N \chi_B(z^{(h)})P(\mathrm{d}z^{(h)})$ this immediately gives a lower bound on $E=(1/|\Lambda|)\log Z_N(\Lambda,f)$: in fact if $\chi_B(\|z^{(h')}\|)=1$ for

$h'=1,\ldots,h$, then $\|X^{(h)}\|_\Delta \le c\,Bh'^4$ for some $c$ so that, by recursive application of Lemma 1, $Z_N(\Lambda,f)\ge e^{V_{j,0}-\sum_{h=1}^{N}\mathcal{R}_-(j,h)|\Lambda|}$. By the remark at the end of the previous section, given $j$ the lower bound on $E$ just described agrees with the perturbation expansion of $E=(1/|\Lambda|)\log Z_N(\Lambda,f)$ truncated to order $j$ (in $\lambda$) up to an error bounded by $\sum_{h=1}^{\infty}\mathcal{R}_-(j,h)$.

**Remark** The problem solved by Lemma 1 is usually referred to as the small-field problem, to contrast it with the large-field problem discussed later. The proof of the lemma is a simple Taylor expansion in $\lambda\gamma^{-h}$ if $d=3$ or in $\lambda h^2\gamma^{-2h}$ if $d=2$ to order $j$ (in $\lambda$). The constraint on $z^{(h+1)}$ makes the integrations over $z^{(h+1)}$, necessary to compute $V_{j;h}$ from $V_{j;h+1}$, not Gaussian. But the tail estimates [9], together with the Markov property of the distribution of $z^{(h)}$ can be used to estimate the difference with respect to the Gaussian unconstrained integrations of $z^{(h+1)}$: and the result is the addition of the small "tail error" changing $\mathcal{R}$ into $\mathcal{R}_-$ in [27]. The estimate of the main part of the remainder $\mathcal{R}$ would be obvious if the fields $z^{(h)}$ were independent on boxes of scale $\gamma^{-h}$: they are not independent but they are Markovian and the estimate can be done by taking into account the Markov property.

For more details, the reader is referred to Wilson (1970, 1972), Gallavotti (1978, 1981, 1985), and Benfatto *et al.* (1978).

## Nonperturbative Renormalization: Large Fields, Ultraviolet Stability

The small-field estimates are not sufficient to obtain ultraviolet stability: to control the cases in which $|X^{(h)}_{\boldsymbol{\xi}}|>Bh^4$ for some $\boldsymbol{\xi}$ or some $h$, or $|Y^{(h)}_{\boldsymbol{\xi}\boldsymbol{\eta}}|>Bh^4$ for some $|\boldsymbol{\xi}-\boldsymbol{\eta}|<\gamma^{-h}$, a further idea is necessary and it rests on making use of the assumption that $\lambda>0$ which, in a sense to be determined, should suppress the contribution to the integral defining $Z_N(\Lambda,f)$ coming from very large values of the field. Assume also $\lambda<1$ for the same reasons advanced in the section "Effective potentials and their scale (in)dependence."

Consider first $d=2$. Let $\mathcal{D}_N$ be the "large-field region" where $|X^{(N)}_{\boldsymbol{\xi}}|>BN^4$ and let $V_N(\Lambda/\mathcal{D}_N)$ be the integral defining the potential in [21] extended to the region $\Lambda/\mathcal{D}_N$, complement of $\mathcal{D}_N$. This region is typically very irregular (and random as $X$ itself is random with distribution $P_N$).

An upper bound on the integral defining $Z_N(\Lambda,f)$ is obtained by simply replacing $e^{V_N}$ by $e^{V_N(\Lambda/\mathcal{D}_N)}$ because in $\mathcal{D}_N$ the first term in the integrand in [21] is $\le -\lambda N^2\gamma^{2N}(BN^4)<0$ and it *overwhelmingly* dominates on the remaining terms whose value is bounded by a similar expression with a smaller power of $N$. Then if $\mathcal{E}^c\stackrel{\text{def}}{=}\Lambda/\mathcal{E}$ denotes the complement in $\Lambda$ of a set $\mathcal{E}\subset\Lambda$:

**Lemma 2** *Let $d=2$. Define $V_h(\mathcal{D}^c_h)$ to be given by the expression [22] with the integrals extending over $\Delta_j/\mathcal{D}_h$ and define $\mathcal{R}(j,h+1)$ by [24]. Then*

$$\int e^{V_{h+1}(\mathcal{D}^c_{h+1})}\,dP\left(z^{(h+1)}\right)=e^{V_h(\mathcal{D}^c_h)+\overline{\mathcal{R}}_+(j,h+1)|\Lambda|}\qquad[28]$$

*where* $|\overline{\mathcal{R}}_+(j,h+1|\le\mathcal{R}_+(j,h+1\stackrel{\text{def}}{=}\mathcal{R}(j;h+1)+c_+e^{-c'_+B^2(h+1)^2}$ *with suitable* $c_+,c'_+$.

**Remark** Lemma 2 is genuinely not perturbative and making essential use of the positivity of $\lambda$. Below the analysis of the proof of the lemma, which consists essentially in its reduction to Lemma 1, is described in detail. It is perhaps the most interesting part and the core of the theory of the proof that truncating the expansion in $\lambda$ of $(1/|\Lambda|)\log Z_N(\Lambda,f)$ to order $j$ gives as a result an estimate exact to order $\lambda^{j+1}$ of $(1/|\Lambda|)\log Z_N(\Lambda,f)$.

Let $R_N$ be the cubes $\Delta\in\mathcal{Q}_N$ in which there is at least one point $\boldsymbol{\xi}$ where $|z^{(N)}_{\boldsymbol{\xi}}|\ge BN^2$. By definition, the region $\mathcal{D}_N/\mathcal{D}_{N-1}$ is covered by $R_N$.

Remark that in the region $\mathcal{D}_{N-1}/R_N$ the field $X^{(N-1)}$ is large but $z_N$ is not large so that $X^{(N)}$ is still very large: this is so because the bounds set to define the regions $\mathcal{D}$ and $R$ are quite different being $BN^4$ and $BN^2$, respectively. Hence, if a point is in $\mathcal{D}_{N-1}$ and not in $R_N$, then the field $X^{(N)}$ must be of the order $\gg BN^3$. Therefore, by positivity of the $\lambda\varphi^{(\le N)4}_{\boldsymbol{\xi}}$ term (which dominates all other terms so that $V^{(N)}(\varphi^{(\le N)}_{\boldsymbol{\xi}})<0$ for $\boldsymbol{\xi}\in\mathcal{D}_N\cup(\mathcal{D}_{N-1}/R_N))$ we can replace $V_N(\mathcal{D}^c_N)$ by $V((\mathcal{D}_N\cup(\mathcal{D}_{N-1}/R_N))^c)$, for the purpose of obtaining an upper bound.

Furthermore, modulo a suitable correction, it is possible to replace $V((\mathcal{D}_N\cup(\mathcal{D}_{N-1}/R_N))^c)$ by $V((\mathcal{D}_{N-1}\cup R_N)^c)$: because the integrand in $V_N$ is bounded below by

$$-b\lambda\gamma^{-2N}N^2$$

if $d=2$ (by $-b\lambda\gamma^{-N}$ if $d=3$), for some $b$, so that the points in $R_N$ can at most lower $V((\mathcal{D}_N\cup(\mathcal{D}_{N-1}/R_N))^c)$ by $-b\lambda N^2\ \gamma^{-(4-d)N}\#(R_N)$ if $\#R_N$ is the number of boxes of $\mathcal{Q}_N$ in $R_N$ and $V(\varphi_{\boldsymbol{\xi}})$ is bounded below by its minimum: thus,

$$V((\mathcal{D}_{N-1}\cup R_N)^c)+b\lambda N^2\gamma^{(4-d)N}\#(R_N)$$

is an upper bound to $V((\mathcal{D}_N\cup(\mathcal{D}_{N-1}/R_N))^c)$.

In the complement of $\mathcal{D}_{N-1}\cup R_N$, all fields are "small"; if $X^{(N-1)}$ and $R_N$ are fixed this region is not random (as a function of $z^{(N)}$) any more. Therefore,

if $X^{(N-1)}, R_N$ are fixed the integration over $z^{(N)}$, conditioned to having $z^{(N)}$ fixed (and large) in the region $R_N$, is performed by means of the same argument necessary to prove Lemma 1 (essentially a Taylor expansion in $\lambda\gamma^{-(4-d)N}$). The large size of $z^{(N)}$ in $R_N$ does not affect too much the result because on the boundary of $R_N$ the field $z^{(N)}$ is $\leq BN^2$ (recalling that $z^{(N)}$ is continuous) and since the variable $z^{(N)}$ is Markovian, the boundary effect decays exponentially from the boundary $\partial R_N$: it adds a quantity that can be shown to be bounded by the number of boxes in $R_N$ on the boundary of $R_N$, hence by $\#R_N$, times $b'(N-1)^2\gamma^{-(4-d)}(B(N-1)^4)^4$ for some $b'$.

The result of the integration over $z^{(N)}$ of $e^{V_N((\mathcal{D}_N \cup (\mathcal{D}_{N-1}/R_N))^c)}$ conditioned to the large-field values of $z^{(N)}$ in $R_N$ leads to an upper bound on $\int e^{V_N} P(dz^{(N)})$ as

$$\sum_{R_N} e^{V_{j;N-1}(\mathcal{D}^c_{N-1})+\mathcal{R}(j,N)|\Lambda|} \times \prod_{\Delta\in R_N} \left(c\, e^{-c'(BN^2)^2} e^{+c''\lambda\gamma^{-(4-d)N}N^2(BN^4)^4}\right)^{\#R_N} \qquad [29]$$

where $c, c', c''$ are suitable constants: this is explained as follows.

1. Taylor expansion (in $\lambda$) of the integral $e^{V_N((\mathcal{D}_{N-1}\cup R_N)^c)+b\lambda N^2\gamma^{-(4-d)N}\#(R_N)}$ (which, by construction, is an upper bound on $e^{V_N(\mathcal{D}^c_N)}$) with respect to the field $z^{(N)}$, conditioned to be fixed and large in $R_N$, would lead to an upper bound as

$$e^{V_{j;N-1}((\mathcal{D}_{N-1}\cup R_N)^c)+\mathcal{R}'(j,N)|\Lambda|+b''\lambda(BN^4)^4\gamma^{(4-d)N}\#(R_N)}$$

   with $\mathcal{R}'$ equal to [24] possibly with some $C'_j$ replacing $C_j$. The second exponential on the RHS of [29] arises partly from the above correction $b''\lambda(BN^4)^4\gamma^{-(4-d)N}\#(R_N)$ and partly from a contribution of similar form explained in (3) below.
2. Integration over the large conditioning fields fixed in $R_N$ is controlled by the second estimate in [9] (the tail estimate): the first factors in parentheses in [29] is the tail estimate just mentioned, i.e., the probability that $z^{(N)}$ is large in the region $R_N$. The second factor is only partly explained in (1) above.
3. Without further estimates, the bound [29] would contain $V_{j;N-1}((\mathcal{D}_{N-1}\cup R_N)^c)$ rather than $V_{j;N-1}(\mathcal{D}^c_{N-1})$. Hence, there is the need to change the potential $V_{j;N-1}((\mathcal{D}_{N-1}\cup R_N)^c)$ by "reintroducing" the contribution due to the fields in $R_N/\mathcal{D}_{N-1}$ in order to reconstruct $V_{j;N-1}(\mathcal{D}^c_{N-1})$. Reintroducing this part of the potential costs a quantity like $b'\lambda N^2\gamma^{(4-d)N}(BN^4)^4\#(R_N)$ (because the reintroduction occurs in the region $R_N/\mathcal{D}_{N-1}$ which is covered by $R_N$ and in such points the field $X^{(N-1)}_\xi$ is *not large*, being bounded by $B(N-1)^4$); so that their contribution to the effective potential is still dominated by the $\varphi^4$-term and therefore by $\gamma^{-(4-d)N}$ times a power of $BN^4$ times the volume of $R_N$ (in units $\gamma^{-N}$, i.e., $\#R_N$). All this is taken care of by suitably fixing $c''$.

Note that the sum over $R_N$ of [29] is

$$\left(1 + c\, e^{-c'B^2N^4} e^{+c''\lambda\gamma^{-(4-d)N}N^2(BN^4)^4}\right)^{\gamma^{dN}|\Lambda|}$$

(because $\Lambda$ contains $|\Lambda|\gamma^{dN}$ cubes of $\mathcal{Q}_N$); hence, it is bounded above by $e^{c_+ e^{-c'_+B^2N^2}}$ for suitably defined $c_+, c'_+$.

The same argument can be repeated for $V_{j;h}(\mathcal{D}^c_h)$ with any $h$ if $V_{j;h}(\mathcal{D}^c_h)$ is defined by the sum over $\Delta$'s in $\mathcal{Q}_h$ of the same integrals as those in [25] and [26] with $\Delta_j/\mathcal{D}_h$ replacing $\Delta_j$ in the integration domains.

Applying Lemma 1 recursively with $j \geq 1$ (if $d=3$ it would become necessary to take $j\geq 3$), it follows that there exist $N$-independent upper and lower bounds $E_\pm|\Lambda|$ on $\log Z(\Lambda, f)$ of the form $V_{j;0} \pm \sum_{h=1}^{\infty}(\mathcal{R}(j,h) + c_\pm e^{-c'_\pm B^2h^2})|\Lambda|$ for $c_\pm, c'_\pm > 0$ suitably chosen and $\lambda$-independent for $\lambda < 1$. By the remark at the end of Sec.6, given $j$, the bounds just described agree with the perturbation expansion $E(j,0)|\Lambda| \equiv V_{j;0}$ of $\log Z(\Lambda, f)$ truncated to order $j$ (in $\lambda$) up to the remainders $\pm\sum_{h=1}^{\infty}\mathcal{R}_\pm(j,h)$. Hence, if $B$ is chosen proportional to $\log_+\lambda^{-1} \stackrel{\text{def}}{=} \log(e+\lambda^{-1})$, the upper and lower bounds coincide to order $j$ in $\lambda$ with the value obtained by truncating to order $j$ the perturbative series.

The latter remark is important as it implies not only that the bounds are finite (by the section "Perturbation theory") but also that the function $(1/|\Lambda|)\log Z(\Lambda, f)$ is not quadratic in $f$: already to order 1 in $\lambda$ it is quartic in $f$ (containing a term equal to $-\lambda(\int C_{\xi,0}f_\xi d\xi)^4$).

The latter property is important as it excludes that the result is a "Gaussian" generating function. Thus, the outline of the proof of Lemma 2, which together with Lemma 1 forms the core of the analysis of the ultraviolet stability for $d=2$, is completed.

If $d=3$, more care is needed because (very mild) smoothness, like the considered Hölder continuity with exponent 1/4, of $z$, $X$ is necessary to obtain the key scale independence property discussed in earlier: therefore, the natural measure of the size of $z^{(h)}$ and $X^{(h)}$ in a box $\Delta \in \mathcal{Q}_h$ is no longer the maximum of $|z^{(h)}_\xi|$ or of $|X^{(h)}_\xi|$. The region $\mathcal{D}_h$ becomes more

involved as it has to consist of the points $\boldsymbol{\xi}$ where $|X^{(h)}_{\boldsymbol{\xi}}| > Bh^4$ *and* of the pairs $\boldsymbol{\eta}, \boldsymbol{\eta}'$ where

$$|Y_{\boldsymbol{\eta},\boldsymbol{\eta}'}| \equiv \frac{\left|X^{(h)}_{\boldsymbol{\eta}} - X^{(h)}_{\boldsymbol{\eta}'}\right|}{(\gamma^h|\boldsymbol{\eta} - \boldsymbol{\eta}'|)^{\frac{1}{4}}} > Bh^4$$

i.e., it is not just a subset of $\Lambda$.

However, if $d = 3$, the relevant part also contains the negative term $V^{(\mathrm{rel},2)}$, see [25]: and since it dominates over all other terms which contain a $Y$-field (because their couplings [25] are smaller by about $\gamma^{-h}$), the argument given for $d = 2$ can be adapted to the new situation. Two regions $\mathcal{D}^1_h, \mathcal{D}^2_h$ will be defined: the first consists of all the points $\boldsymbol{\xi}$ where $|X^{(h)}_{\boldsymbol{\xi}}| > Bh^4$ and the second of all the pairs $\boldsymbol{\eta}, \boldsymbol{\eta}'$ where $|Y^{(h)}_{\boldsymbol{\eta},\boldsymbol{\eta}'}| > Bh^4$. The region $R_h$ will be the collection of all $\Delta \in \mathcal{Q}_h$, where $\|z^{(h)}\|_\Delta > Bh^2$, see [8] with $\tau = 0$. Then $V(\mathcal{D}^c_h)$ will be defined as the sum of the integrals in [25] and [26] with the integrals over $\boldsymbol{\xi}_i$ further restricted to $\boldsymbol{\xi}_i \notin \mathcal{D}^1_h$ and those over the pairs $\boldsymbol{\eta}_i, \boldsymbol{\eta}'_i$ are further restricted to $(\boldsymbol{\eta}_i, \boldsymbol{\eta}'_i) \notin \mathcal{D}^2_h$. With the new settings, Lemma 2 can be proved also for $d = 3$ along the same lines as in the $d = 2$ case.

## Ultraviolet Limit, Infrared Behavior, and Other Applications

The results on the ultraviolet stability are nonperturbative, as no assumption is made on the size of $\lambda$ (the assumption $\lambda < 1$ has been imposed in the last two sections only to obtain simpler expressions for the $\lambda$-dependence of various constants): nevertheless the multiscale analysis has allowed us to use perturbative techniques (i.e., the Taylor expansion in Lemmata 1, 2) to find the solution. The latter procedure is the essence of the renormalization group methods: they aim at reducing a difficult multiscale problem to a sequence of simple single-scale problems. Of course, in most cases, it is difficult to implement the approach and the scalar quantum fields in dimensions 2, 3 are among the simplest examples. The analysis of the beta function and of the running couplings, which appear in essentially all renormalization group applications, does not play a role here (or, better, their role is so inessential that it has even been possible to avoid mentioning them). This makes the models somewhat special from the renormalization group viewpoint: the running couplings at length scale $h$, if introduced, would tend exponentially to 0 as $h \to \infty$; unlike what happens in the most interesting renormalization group applications in which they either tend to zero only as powers of $h$ or do not tend to zero at all.

The multiscale analysis method, i.e., the renormalization group method, in a form close to the one discussed here has been applied very often since its introduction in physics and it has led to the solution of several important problems. The following is not an exhaustive list and includes a few open questions.

1. The arguments just discussed imply, with minor extra work that $Z_N(\Lambda, f)$ as $N \to \infty$ not only admit uniform upper and lower bounds but also that the limit as $N \to \infty$ actually exists and it is a $C^\infty$ function of $\lambda$, $f$. Its $\lambda$ and $f$-derivatives at $\lambda = 0$ and $f = 0$ are given by the formal perturbation calculation. In some cases, it is even possible to show that the formal series for $Z_N(\Lambda, f)$ in powers of $\lambda$ is Borel summable.
2. The problem of removing the infrared cutoff (i.e., $\Lambda \to \infty$) is in a sense more a problem of statistical mechanics. In fact, it can be solved for $d = 2, 3$ by a typical technique used in statistical mechanics, the "cluster expansion." This is not intended to mean that it is technically an easy task: understanding its connection with the low-density expansions and the possibility of using such techniques has been a major achievement that is not discussed here.
3. The third problem mentioned in the introduction, that is, checking the axioms so that the theory could be interpreted as a quantum field theory is a difficult problem which required important efforts to control and which is not analyzed here. An introduction to it can be its analysis in the $d = 2$ case.
4. Also the problem of keeping the ultraviolet cutoff and removing the infrared cutoff while the parameter $m^2$ in the propagator approaches 0 is a very interesting problem related to many questions in statistical mechanics at the critical point.
5. Field theory methods can be applied to various statistical mechanics problems away from criticality: particularly interesting is the theory of the neutral Coulomb gas and of the dipole gas in two dimensions.
6. The methods can be applied to Fermi systems in field theory as well as in equilibrium statistical mechanics. The understanding of the ground state in not exactly soluble models of spinless fermions in one dimension at small coupling is one of the results. And via the transfer matrix theory it has led to the understanding of nontrivial critical behavior in two-dimensional models that are not exactly soluble (like Ising next-nearest-neighbor or Ashkin–Teller model). Fermi systems are of particular interest also because in their analysis the large-fields problem is absent, but this great

technical advantage is somewhat offset by the anticommutation properties of the fermionic fields, which do not allow us to employ probabilistic techniques in the estimates.

7. An outstanding open problem is whether the scalar $\varphi^4$-theory is possible and nontrivial in dimension $d=4$: this is a case of a renormalizable not asymptotically free theory. The conjecture that many support is that the theory is necessarily trivial (i.e., the function $Z_N(\Lambda, f)$ becomes necessarily a Gaussian in the limit $N \to \infty$). One of the main problems is the choice of the ultraviolet cut-off; unlike the $d=2,3$ cases in which the choice is a matter of convenience it does not seem that the issue of triviality can be settled without a careful analysis of the choice and of the role of the ultraviolet cut-off.
8. Very interesting problems can be found in the study of highly symmetric quantum fields: gauge invariance presents serious difficulties to be studied (rigorously or even heuristically) because in its naive forms it is incompatible with regularizations. Rigorous treatments have been in some cases possible and in few cases it has been shown that the naive treatment is not only not rigorous but it leads to incorrect results.
9. In connection with item (8) an outstanding problem is to understand relativistic pure gauge Higgs fields in dimension $d=4$: the latter have been shown to be ultraviolet stable but the result has not been followed by the study of the infrared limit.
10. The classical gauge theory problem is quantum electrodynamics, QED, in dimension 4: it is a renormalizable theory (taking into account gauge invariance) and its perturbative series truncated after the first few orders give results that can be directly confronted with experience, giving very accurate predictions. Nevertheless, the model is widely believed to be incomplete: in the sense that, if treated rigorously, the result would be a field describing free noninteracting assemblies of photons and electrons. It is believed that QED can make sense only if embedded in a model with more fields, representing other particles (e.g., the standard model), which would influence the behavior of the electromagnetic field by providing an effective ultraviolet cutoff high enough for not altering the predictions on the observations on the time and energy scales on which present (and, possibly, future over a long time span) experiments are performed. In dimension $d=3$, QED is super-renormalizable, once the gauge symmetry is properly taken into account, and it can be studied with the techniques described above for the scalar fields in the corresponding dimension.

In general, constructive quantum field theory seems to be in a deep crisis: the few solutions that have been found concern very special problems and are very demanding technically; the results obtained have often not been considered to contribute appreciably to any "progress." And many consider that the work dedicated to the subject is not worth the results that one can even hope to obtain. Therefore, in recent years, attempts have been made to follow other paths: an attitude that in the past usually did not lead, in general to great achievements but that is always tempting and worth pursuing because the rare major progresses made in physics resulted precisely by such changes of attitude, leaving aside developments requiring work which was too technical and possibly hopeless: just to mention an important case, one can recall quantum mechanics which disposed of all attempts at understanding the observed atomic levels quantization on the basis of refined developments of classical electromagnetism.

# Contact Manifolds

**J B Etnyre**, University of Pennsylvania, Philadelphia, PA, USA

## Introduction

Contact geometry has been seen to underly many physical phenomena and is related to many other mathematical structures. Contact structures first appeared in the work of Sophus Lie on partial differential equations. They reappeared in Gibbs' work on thermodynamics, Huygens' work on geometric optics, and in Hamiltonian dynamics. More recently, contact structures have been seen to have relations with fluid mechanics, Riemannian geometry, and low-dimensional topology, and these structures provide an interesting class of subelliptic operators.

After summarizing the basic definitions, examples, and facts concerning contact geometry, this article discusses the connections between contact geometry and symplectic geometry, Riemannian geometry, complex geometry, analysis, and dynamics. The article ends by discussing two of the most-studied connections with physics: Hamiltonian dynamics and geometric optics. References for other important topics in contact geometry (e.g., thermodynamics, fluid dynamics, holomorphic curves, and open book decompositions) are provided in the "Further reading" section.

## Basic Definitions and Examples

A hyperplane field $\xi$ on a manifold $M$ is a codimension-1 sub-bundle of the tangent bundle $TM$. Locally, a hyperplane field can always be described as the kernel of a 1-form. In other words, for every point in $M$ there is a neighborhood $U$ and a 1-form $\alpha$ defined on $U$ such that the kernel of the linear map $\alpha_x : T_xM \to \mathbb{R}$ is $\xi_x$ for all $x$ in $U$. The form $\alpha$ is called a local defining form for $\xi$. A contact structure on a $(2n+1)$-dimensional manifold $M$ is a "maximally nonintegrable hyperplane field" $\xi$. The hyperplane field $\xi$ is maximally nonintegrable if for any (and hence every) locally defining 1-form $\alpha$ for $\xi$ the following equation holds:

$$\alpha \wedge (\mathrm{d}\alpha)^n \neq 0 \qquad [1]$$

(this means that the form is, pointwise, never equal to 0). Geometrically, the nonintegrability of $\xi$ means that no hypersurface in $M$ can be tangent to $\xi$ along an open subset of the hypersurface. Intuitively, this means that the hyperplanes "twist too much" to be tangent to hypersurfaces (Figure 1). The pair $(M, \xi)$

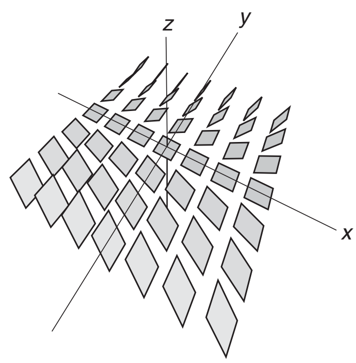

**Figure 1** The standard contact structure on $\mathbb{R}^3$ given as the kernel of $dz - y\,dx$. Courtesy of Stephan Schönenberger.

is called a contact manifold and any locally defining form $\alpha$ for $\xi$ is called a contact form for $\xi$.

**Example 1** The most basic example of a contact structure can be seen on $\mathbb{R}^{2n+1}$ as the kernel of the 1-form $\alpha = \mathrm{d}z - \sum_{i=1}^{n} y_i\, \mathrm{d}x_i$, where the coordinates on $\mathbb{R}^{2n+1}$ are $(x_1, y_1, \ldots, x_n, y_n, z)$. This example is shown in Figure 1 when $n = 1$.

**Example 2** Recall that on the cotangent space of any $n$-manifold $M$, there is a canonical 1-form $\lambda$, called the Liouville form. If $(q_1, \ldots, q_n)$ are local coordinates on $M$, then any 1-form can be expressed as $\sum_{i=1}^{n} p_i\, \mathrm{d}q_i$, so $(q_1, p_1, \ldots, q_n, p_n)$ are local coordinates on $T^*M$. In these coordinates,

$$\lambda = \sum_{i=1}^{n} p_i \pi^* \mathrm{d}q_i \qquad [2]$$

where $\pi : T^*M \to M$ is the natural projection map. The 1-jet space of $M$ is the manifold $J^1(M) = T^*M \times \mathbb{R}$ and can be considered as a bundle over $M$. The 1-jet space has a natural contact structure given as the kernel of $\alpha = \mathrm{d}z - \lambda$, where $z$ is the coordinate on $\mathbb{R}$. Note that if $M = \mathbb{R}^n$ then we recover the previous example.

**Example 3** The (oriented) projectivized cotangent space of a manifold $M$ is the set $P^*M$ of nonzero covectors in $T^*M$ where two covectors are identified if they differ by a positive real number, that is,

$$P^*M = (T^*M \setminus \{0\})/\mathbb{R}_+ \qquad [3]$$

where $\{0\}$ is the zero section of $T^*M$ and $\mathbb{R}_+$ denotes the positive real numbers. If $M$ has a metric then $P^*M$ can be easily identified with the space of unit covectors. Considering $P^*M$ as unit covectors, we can restrict the canonical 1-form $\lambda$ to $P^*M$ to get a 1-form $\alpha$ whose kernel defines a contact structure $\xi$ on $P^*M$. (Although there is no canonical contact form on $P^*M$, the contact structure $\xi$ is still well defined.) Note that if $M$ is compact then so is $P^*M$; so this gives examples of contact structures on compact manifolds.

If $\alpha$ and $\alpha'$ are two locally defining 1-forms for $\xi$, then there is a nonzero function $f$ such that $\alpha' = f\alpha$. Thus, $\alpha' \wedge (\mathrm{d}\alpha')^n = f^{n+1}\alpha \wedge (\mathrm{d}\alpha)^n$ is a nonzero top dimensional form on $M$ and if $n$ is odd then the orientation defined by the local defining form is independent of the actual form. Hence, when $n$ is odd, a contact structure defines an orientation on $M$ (this is independent of whether or not $\xi$ is orientable!). If $M$ had a preassigned orientation (and $n$ is odd), then the contact structure is called "positive" if it induces the given orientation and "negative" otherwise. One should be careful when reading the literature, as some authors build positive into their definition of contact structure, especially when $n = 1$. If there is a globally defined 1-form $\alpha$ whose kernel defines $\xi$, then $\xi$ is called transversally orientable or co-orientable. This is equivalent to the bundle $\xi$ being orientable when $n$ is odd or when $n$ is even and $M$ is orientable. In this article the discussion is restricted to transversely orientable contact structures.

Suppose that $\alpha$ is a contact form for $\xi$, then eqn [1] implies that $\mathrm{d}\alpha|_\xi$ is a symplectic form on $\xi$. This is one sense in which a contact structure is like an odd-dimensional analog of a symplectic structure.

A submanifold $L$ of a contact manifold $(M, \xi)$ is called Legendrian if $\dim M = 2\dim L + 1$ and $T_pL \subset \xi_p$.

**Example 4** A fiber in the unit cotangent bundle with the contact structure from Example 3 is a Legendrian sphere.

**Example 5** Let $f : M \to \mathbb{R}$ be a function. Then $j_1(f)(q) = (q, \mathrm{d}f_q, f(q))$ is a section of the 1-jet space $J^1(M)$ of $M$; it is called the 1-jet of $f$. If $s$ is any section of the 1-jet space, then it is Legendrian if and only if it is the 1-jet of a function.

This observation is the basis for Lie's study of partial differential equations. More specifically, a first-order partial differential equation on $M$ can be considered as giving an algebraic equation on $J^1(M)$. Then, a section of $J^1(M)$ satisfying this algebraic equation corresponds to the 1-jet of a solution to the original partial differential equation if and only if it is Legendrian.

Recently, Legendrian submanifolds have been much studied. There are various classification results in three dimensions and several striking existence results in higher dimensions.

## Local Theory

The natural equivalence between contact structures is contactomorphism. Two contact structures $\xi_0$ and

$\xi_1$ on manifolds $M_0$ and $M_1$, respectively, are contactomorphic if there is a diffeomorphism $f: M_0 \to M_1$ such that $f_*(\xi_0) = \xi_1$. All contact structures are locally contactomorphic. In particular, we have the following theorem.

**Theorem 1** (Darboux's Theorem). *Suppose $\xi_i$ is a contact structure on the manifold $M_i, i = 0, 1$, and $M_0$ and $M_1$ have the same dimension. Given any points $p_0$ and $p_1$ in $M_0$ and $M_1$, respectively, there are neighborhoods $N_i$ of $p_i$ in $M_i$ and a contactomorphism from $(N_0, \xi_0|_{N_0})$ to $(N_1, \xi_1|_{N_1})$. Moreover, if $\alpha_i$ is a contact form for $\xi_i$ near $p_i$, then the contactomorphism can be chosen to pull $\alpha_1$ back to $\alpha_0$.*

Thus, locally all contact structures (and contact forms!) look like the one given in Example 1 above.

Furthermore, contact structures are "local in time." That is, compact deformations of contact structures do not produce new contact structures.

**Theorem 2** (Gray's theorem). *Let $M$ be an oriented $(2n+1)$-dimensional manifold and $\xi_t, t \in (0, 1)$, a family of contact structures on $M$ that agree off of some compact subset of $M$. Then there is a family of diffeomorphisms $\phi_t : M \to M$ such that $(\phi_t)_* \xi_t = \xi_0$.*

In particular, on a compact manifold, all deformations of contact structures come from diffeomorphisms of the underlying manifold. The theorem is not true if the contact structures do not agree off of a compact set. For example, there is a one-parameter family of noncontactomorphic contact structures on $S^1 \times R^2$.

## Existence and Classification

The existence of contact structures on closed odd-dimensional manifolds is quite difficult. However, Gromov has shown that contact structures on open manifolds obey an h-principle. To explain this, we note that if $(M^{2n+1}, \xi)$ is a co-oriented contact manifold then the tangent bundle of $M$ can be written as $\xi \oplus \mathbb{R}$ and thus the structure group of $TM$ can be reduced to $U(n)$ (since $\xi$ has a conformal symplectic structure on it). Such a reduction of the structure group is called an almost contact structure on $M$. Clearly, a contact structure on $M$ induces an almost contact structure. If $M$ is an open manifold, Gromov proved that the inclusion of the space of co-oriented contact structures on $M$ into the space of almost contact structures on $M$ is a weak homotopy equivalence. In particular, if an open manifold meets the necessary algebraic condition for the existence of an almost contact structure, then the manifold has a co-oriented contact structure.

Lutz and Martinet proved a similar, but weaker, result for oriented closed 3-manifolds. More specifically, every closed oriented 3-manifold admits a co-oriented contact structure and in fact has at least one for every homotopy class of plane field. There has been much progress on classifying contact structures on 3-manifolds and here an interesting dichotomy has appeared. Contact structures break into one of two types: tight or overtwisted. Overtwisted contact structures obey an h-principle and are in general easy to understand. Tight contact structures have a more subtle, geometric nature. In higher dimensions there is much less known about the existence (or classification) of contact structures.

## Relations with Symplectic Geometry

Let $(X, \omega)$ be a symplectic manifold. A vector field $v$ satisfying

$$L_v \omega = \omega \qquad [4]$$

(where $L_v \omega$ is the Lie derivative of $\omega$ in the direction of $v$) is called a symplectic dilation. A compact hypersurface $M$ in $(X, \omega)$ is said to have "contact type" if there exists a symplectic dilation $v$ in a neighborhood of $M$ that is transverse to $M$. Given a hypersurface $M$ in $(X, \omega)$, the characteristic line field $LM$ in the tangent bundle of $M$ is the symplectic complement of $TM$ in $TX$. (Since $M$ is codimension 1, it is coisotropic; thus, the symplectic complement lies in $TM$ and is one dimensional.)

**Theorem 3** *Let $M$ be a compact hypersurface in a symplectic manifold $(X, \omega)$ and denote the inclusion map $i: M \to X$. Then $M$ has contact type if and only if there exists a 1-form $\alpha$ on $M$ such that $d\alpha = i^* \omega$ and the form $\alpha$ is never zero on the characteristic line field.*

If $M$ is a hypersurface of contact type, then the 1-form $\alpha$ is obtained by contracting the symplectic dilation $v$ into the symplectic form: $\alpha = \iota_v \omega$. It is easy to verify that the 1-form $\alpha$ is a contact form on $M$. Thus, a hypersurface of contact type in a symplectic manifold inherits a co-oriented contact structure.

Given a co-orientable contact manifold $(M, \xi)$, its symplectization $\mathrm{Symp}(M, \xi) = (X, \omega)$ is constructed as follows. The manifold $X = M \times (0, \infty)$, and given a global contact form $\alpha$ for $\xi$ the symplectic form is $\omega = d(t\alpha)$, where $t$ is the coordinate on $\mathbb{R}$. (The symplectization is also equivalently defined as $(M \times \mathbb{R}, d(e^t \alpha))$.)

**Example 6** The symplectization of the standard contact structure on the unit cotangent bundle

(see Example 3) is the standard symplectic structure on the complement of the zero section in the cotangent bundle.

The symplectization is independent of the choice of contact from $\alpha$. To see this, fix a co-orientation for $\xi$ and note the manifold $X$ which can be identified (in many ways) with the sub-bundle of $T^*M$ whose fiber over $x \in M$ is

$$\{\beta \in T_x^*M : \beta(\xi_x) = 0 \text{ and } \beta > 0 \text{ on vectors positively transverse to } \xi_x\} \quad [5]$$

and restricting $d\lambda$ to this subspace yields a symplectic form $\omega$, where $\lambda$ is the Liouville form on $T^*M$ defined in Example 2. A choice of contact form $\alpha$ fixes an identification of $X$ with the sub-bundle of $T^*M$ under which $d(t\alpha)$ is taken to $d\lambda$.

The vector field $v = \partial/\partial t$ on $(X, \omega)$ is a symplectic dilation that is transverse to $M \times \{1\} \subset X$. Clearly, $\iota_v \omega|_{M\times\{1\}} = \alpha$. Thus, we see that any co-orientable contact manifold can be realized as a hypersurface of contact type in a symplectic manifold. In summary, we have the following theorem.

**Theorem 4** *If $(M, \xi)$ is a co-oriented contact manifold, then there is a symplectic manifold* $\mathrm{Symp}(M, \xi)$ *in which $M$ sits as a hypersurface of contact type. Moreover, any contact form $\alpha$ for $\xi$ gives an embedding of $M$ into* $\mathrm{Symp}(M, \xi)$ *that realizes $M$ as a hypersurface of contact type.*

We also note that all the hypersurfaces of contact type in $(X, \omega)$ look locally, in $X$, like a contact manifold sitting inside its symplectification.

**Theorem 5** *Given a compact hypersurface $M$ of contact type in a symplectic manifold $(X, \omega)$ with the symplectic dilation given by $v$, there is a neighborhood of $M$ in $X$ symplectomorphic to a neighborhood of $M \times \{1\}$ in* $\mathrm{Symp}(M, \xi)$ *where the symplectization is identified with $M \times (0, \infty)$ using the contact form $\alpha = \iota_v \omega|_M$ and $\xi = \ker \alpha$.*

## The Reeb Vector Field and Riemannian Geometry

Let $(M, \xi)$ be a contact manifold. Associated to a contact form $\alpha$ for $\xi$ is the Reeb vector field $v_\alpha$. This is the unique vector field satisfying

$$\iota_{v_\alpha} \alpha = 1 \quad \text{and} \quad \iota_{v_\alpha} d\alpha = 0 \quad [6]$$

One may readily check that $v_\alpha$ is transverse to the contact hyperplanes and the flow of $v_\alpha$ preserves $\xi$ (in fact, it preserves $\alpha$). These two conditions characterize Reeb vector fields; that is, a vector field $v$ is the Reeb vector field for some contact form for $\xi$ if and only if it is transverse to $\xi$ and its flow preserves $\xi$.

The fundamental question concerning Reeb vector fields asks if its flow has a (contractible) periodic orbit. A paraphrazing of the Weinstein conjecture asserts a positive answer to this question. Most progress on this conjecture has been made in dimension 3 where H Hofer has proved the existence of periodic orbits for all Reeb fields on $S^3$ and on 3-manifolds with essential spheres (i.e., embedded $S^2$'s that do not bound a 3-ball in the manifold). Relations with Hamiltonian dynamics are discussed below.

Recall, from Example 3, that a Riemannian metric $g$ on a manifold $M$ provides an identification of the (oriented) projectivized cotangent bundle $P^*M$ with the unit cotangent bundle. Considered as a subset of $T^*M$, $P^*M$ inherits not only a contact structure but also a contact form $\alpha$ (by restricting the Liouville form). Let $v_\alpha$ be the associated Reeb vector field. The metric $g$ also provides an identification of the tangent and cotangent bundles of $M$. Thus, $P^*M$ may be considered as the unit tangent bundle of $M$. Let $w_g$ be the vector field on the unit tangent bundle generating the geodesic flow on $M$.

**Theorem 6** *The Reeb vector field $v_\alpha$ is identified with geodesic flow field $w_g$ when $P^*M$ is identified with the unit tangent space using the metric $g$.*

## Relations with Complex Geometry and Analysis

Let $X$ be a complex manifold with boundary and denote the induced complex structure on $TX$ by $J$. The complex tangencies $\xi$ to $M = \partial X$ are described by the equation $d\phi \circ J = 0$, where $\phi$ is a function defined in a neighborhood of the boundary such that 0 is a regular value and $\phi^{-1}(0) = M$. The form $L(v, w) = -d(d\phi \circ J)(v, Jw)$, for $v, w \in \xi$, is called the Levi form, and when $L(v, w)$ is positive (negative) definite, then $X$ is said to have strictly pseudoconvex (pseudoconcave) boundary. The hyperplane field $\xi$ will be a contact structure if and only if $d(d\phi \circ J)$ is a nondegenerate 2-form on $\xi$ (if and only if $L(v, w)$ is definite). A well-studied source of examples comes from Stein manifolds.

**Example 7** Let $X$ be a complex manifold and again let $J$ denote the induced complex structure on $TX$. From a function $\phi : X \to \mathbb{R}$, we can define a 2-form $\omega = -d(d\phi \circ J)$ and a symmetric form $g(v, w) = \omega(v, Jw)$. If this symmetric form is positive definite, the function $\phi$ is called "strictly plurisubharmonic." The manifold $X$ is a Stein manifold if $X$

admits a proper strictly plurisubharmonic function $\phi : X \to \mathbb{R}$. An important result says that $X$ is Stein if and only if it can be realized as a closed complex submanifold of $C^n$. Clearly any noncritical level set of $\phi$ gives a contact manifold.

Contact manifolds also give rise to an interesting class of differential operators. Specifically, a contact structure $\xi$ on $M$ defines a symbol-filtered algebra of pseudodifferential operators $\Psi_\xi^*(M)$, called the "Heisenberg calculus." Operators in this algebra are modeled on smooth families of convolution operators on the Heisenberg group. An important class of operators of this type are the "sum-of-squares" operators. Locally, the highest-order part of such an operator takes the form

$$L = \sum_{j=1}^{2n} v_j^2 + \mathrm{i} a v_\alpha \qquad [7]$$

where $\{v_1, \ldots, v_{2n}\}$ is a local framing for the contact field and $v_\alpha$ is a Reeb vector field. This operator belongs to $\Psi_\xi^2(M)$ and is subelliptic for $a$ outside a discrete set.

## Hamiltonian Dynamics

Given a symplectic manifold $(X, \omega)$, a function $H : X \to \mathbb{R}$ will be called a Hamiltonian. (Only autonomous Hamiltonians are discussed here.) The unique vector field satisfying

$$\iota_{v_H} \omega = -\mathrm{d}H$$

is called the Hamiltonian vector field associated to $H$. Many problems in classical mechanics can be formulated in terms of studying the flow of $v_H$ for various $H$.

**Example 8** If $(X, \omega) = (\mathbb{R}^{2n}, \mathrm{d}\lambda)$, where $\lambda$ is from Example 2, then the flow of the Hamiltonian vector field is given by

$$\dot{q} = \frac{\partial H}{\partial p}, \qquad \dot{p} = -\frac{\partial H}{\partial q}$$

A standard fact says that the flow of $v_H$ preserves the level sets of $H$.

**Theorem 7** *If $M$ is a level set of $H$ corresponding to a regular value and $M$ is a hypersurface of contact type, then the trajectories of $v_H$ and of the Reeb vector field (associated to $M$ in Theorem 3) agree.*

Thus under suitable hypothesis, Hamiltonian dynamics is a reparametrization of Reeb dynamics. In particular, searching for periodic orbits in such a Hamiltonian system is equivalent to searching for periodic orbits in a Reeb flow. Thus in this context, Weinstein's conjecture asserts a positive answer to the questions: Does the Hamiltonian flow along a regular level set of contact type have a periodic orbit? Viterbo proved that the answer was yes if the hypersurface is compact and in $(\mathbb{R}^{2n}, \omega = \mathrm{d}\alpha)$. Other progress has been made by studying Reeb dynamics.

## Geometric Optics

In this section, we study the propagation of light (or various other disturbances) in a medium (for the moment, we do not specify the properties of this medium). The medium will be given by a three-dimensional manifold $M$. Given a point $p$ in $M$ and $t > 0$, let $I_p(t)$ be the set of all points to which light can travel in time $\leq t$. The wave front of $p$ at time $t$ is the boundary of this set and is denoted as $\Phi_p(t) = \partial I_p(t)$.

**Theorem 8** (Huygens' principle). *$\Phi_p(t + t')$ is the envelope of the wave fronts $\Phi_q(t')$ for all $q \in \Phi_p(t)$.*

This is best understood in terms of contact geometry. Let $\pi : (T^*M \backslash \{0\}) \to P^*M$ be the natural projection (see Example 3) and let $S$ be any smooth sub-bundle of $T^*M \backslash \{0\}$ that is transverse to the radial vector field in each fiber and for which $\pi|_S : S \to P^*M$ is a diffeomorphism. The restriction of the Liouville form to $S$ gives a contact form $\alpha$ and a corresponding Reeb vector field $v$. Given a subset $F$ of $M$ with a well-defined tangent space at every point set

$$L_F = \{p \in S : \pi(p) \in F \ \text{and} \ p(w) = 0 \ \text{for all} \ w \in T_{\pi(p)}F\} \qquad [8]$$

The set $L_F$ is a Legendrian submanifold of $S$ and is called the "Legendrian lift" of $F$. If $L$ is a generic Legendrian submanifold in $S$, then $\pi(L)$ is called the front projection of $L$ and $L_{\pi(L)} = L$. Given a Legendrian submanifold $L$, let $\Psi_t(L)$ be the Legendrian submanifold obtained from $L$ by flowing along $v$ for time $t$.

**Example 9** Given a metric $g$ on $M$, Fermat's principle says that light travels along geodesics. Thus, if $S$ is the unit cotangent bundle, then using $g$ to identify the geodesic flow with the Reeb flow one sees that light will travel along trajectories of the Reeb vector field. Given a point $p$ in $M$, the Legendrian submanifold $L_p$ is a sphere sitting in $T_p^*M$. The Huygens principle follows from the observation that $\Phi_p(t) = \pi(\Psi_t(L_p))$.

Using the more general $S$ discussed above, one can generalize this example to light traveling in a medium that is nonhomogeneous (i.e., the speed differs from point to point in $M$) and anisotropic (i.e., the speed differs depending on the direction of travel).

# Control Problems in Mathematical Physics

**B Piccoli**, Istituto per le Applicazioni del Calcolo, Rome, Italy

## Introduction

Control Theory is an interdisciplinary research area, bridging mathematics and engineering, dealing with physical systems which can be "controlled," that is, whose evolution can be influenced by some external agent. A general model can be written as

$$y(t) = A(t, y(0), u(\cdot)) \qquad [1]$$

where $y$ describes the state variables, $y(0)$ the initial condition, and $u(\cdot)$ the control function. Thus, eqn [1] means that the state at time $t$ depends on the initial condition but also on some parameters $u$ which can be chosen as function of time. To be precise, there are some control problems which are not of evolutionary type; however, in this presentation we restrict ourselves to this case.

One has to distinguish among the control set $U$ where the control function can take values: $u(t) \in U$, and the space of control functions, $\mathcal{U}$, to which each control function should belong: $u(\cdot) \in \mathcal{U}$. Thus, for example, we may have $U = R^m$ and $\mathcal{U} = L^\infty([0, T], R^m)$.

There are various problems one can formulate regarding systems of type [1], among which:

*Controllability* Given any two states $y_0$ and $y_1$ determine a control function $u(\cdot)$ such that for some time $t > 0$ we have $y_1 = A(t, y_0, u(\cdot))$.

*Optimal control* Consider a cost function $J(y(\cdot), u(\cdot))$ depending both on the evolutions of $y$ and $u$ and determine a control function $\tilde{u}(\cdot)$ and a trajectory $\tilde{y}(t) = A(t, y_0, \tilde{u}(\cdot))$ such that $\tilde{y}(\cdot)$ steers the system from $y_0$ to $y_1$, as before, and the cost $J$ is minimized (or maximized).

*Stabilization* We say that $\bar{y}$ is an equilibrium if there exists $\bar{u} \in U$ such that $A(t, \bar{y}, \bar{u}) = \bar{y}$ for every $t > 0$ (here $\bar{u}$ indicates also the constant in time control function). Determine the control $u$ as function of the state $y$ so that $\bar{y}$ is a (Lyapunov) stable equilibrium for the uncontrolled dynamical system $y(t) = A(t, y(0), u(y(\cdot)))$.

*Observability* Assume that we can observe not the state $y$, but a function $\phi(y)$ of the state. Determine conditions on $\phi$ so that the state $y$ can be reconstructed from the evolution of $\phi(y)$ choosing $u(\cdot)$ suitably.

For the sake of simplicity, we restrict ourselves mainly to the first two problems and just mention

some facts about the others. Also, we focus on two cases:

*Control of ordinary differential equations* (*ODEs*) In this case $t \in R, y \in R^n$, $U$ is a set, typically $U \subset R^m$, and $A$ is determined by a controlled ODE

$$\dot{y} = f(t, y, u) \qquad [2]$$

A typical example in mathematical physics is the control of mechanical systems (Bloch 2003, Bullo and Lewis 2005).

*Control of partial differential equations* (*PDEs*) In this case $t \in R, x \in R^n, y(x)$ belongs to a Banach functional space, for example, $H^s(R^{n+1}, R), U$ is a functional space, and $A$ is determined by a controlled PDE,

$$F(t, x, y, y_t, y_{x_1}, \ldots, y_{x_n}, y_t, \ldots, u) = 0 \qquad [3]$$

A typical example in mathematical physics is the control of wave equation using boundary conditions, see below.

There are various other possible situations we do not treat here: "stochastic control," when $y$ is a random variable and $A$ defined by a (controlled) stochastic differential equation; "discrete time control," where $t \in N$; "hybrid control," where $t$ and $y$ may have both discrete and continuous components, and so on.

As shown above, the control law can be assigned in (at least) two basically different ways. In open-loop form, as a function of time: $t \to u(t)$, and in closed-loop form or feedback, as a function of the state: $y \to u(y)$. For example, in optimal control we look for a control $\tilde{u}(t)$ in open-loop form, while in stabilization we search for a feedback control $u(y)$. The open-loop control depends on $y(0)$, while a feedback control can stabilize regardless of the initial condition.

**Example 1** A point with unit mass moves along a straight line; if a controller is able to apply an external force $u$, then, calling $y_1(t), y_2(t)$, respectively, the position and the velocity of the point at time $t$, the motion is described by the control system

$$(\dot{y}_1, \dot{y}_2) = (y_2, u) \qquad [4]$$

It is easy to check that the feedback control $u(y_1, y_2) = -y_1 - y_2$ stabilizes the system asymptotically to the origin, that is, for every initial data $(\bar{y}_1, \bar{y}_2)$, the solution of the corresponding Cauchy problem satisfies $\lim_{t\to\infty}(y_1, y_2)(t) = (0, 0)$.

Another simple problem consists in driving the point to the origin with zero velocity in minimum time from given initial data. It is quite easy to see that the optimal strategy is to accelerate towards the

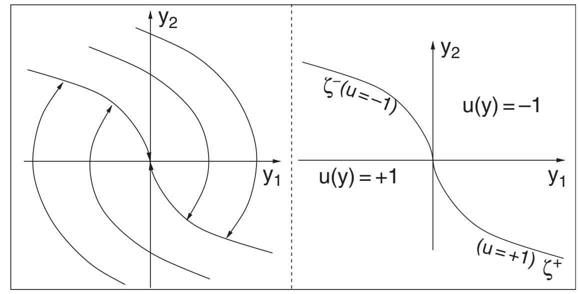

**Figure 1** Example 1. The simplest example of (a) optimal synthesis and (b) corresponding feedback.

origin with maximum force on some interval $[0, t]$ and then to decelerate with maximum force to reach the origin at velocity zero. The set of optimal trajectories is depicted in Figure 1a: they can be obtained using the following discontinuous feedback, see Figure 1b. Define the curves $\zeta^{\pm} = \{(y_1, y_2) : \mp y_2 > 0, y_1 = \pm y_2^2\}$ and let $\zeta$ be defined as the union $\zeta^{\pm} \cup \{0\}$. We define $A^+$ to be the region below $\zeta$ and $A^-$ the one above. Then the feedback is given by

$$u(x) = \begin{cases} +1 & \text{if } (y_1, y_2) \in A^+ \cup \zeta^+ \\ -1 & \text{if } (y_1, y_2) \in A^- \cup \zeta^- \\ 0 & \text{if } (y_1, y_2) = (0, 0) \end{cases}$$

**Example 2** Consider a (one-dimensional) vibrating string of unitary length with a fixed endpoint. The model for the motion of the displacement of the string with respect to the rest position is given by

$$y_{tt} + \Delta y = 0, \qquad y(t, 0) = 0 \qquad [5]$$

with initial data

$$y(0, \cdot) = y_0, \qquad y_t(0, \cdot) = y_1 \qquad [6]$$

Assume that we can control the position of the second endpoint; then,

$$y(t, 1) = u(t) \qquad [7]$$

for some control function $u(\cdot) \in R$.

Let us introduce another key concept: the reachable set at time $t$ from $\bar{y}$ is the set

$$R(t; \bar{y}) = \{A(t, \bar{y}, u(\cdot)) : u(\cdot) \in \mathcal{U}\}$$

Various problems can be formulated in terms of reachable sets, for example, controllability requires that for every $\bar{y}$ the union of all $R(t; \bar{y})$ as $t \to \infty$ includes the entire space. The dependence of $R(t; \bar{y})$ on time $t$ and on the set of controls $\mathcal{U}$ is also a subject of investigation: one may ask whether the same points in $R(t; \bar{y})$ can be reached by using controls which are piecewise constant, or take values within some subsets of $U$.

## Control of ODEs

For most proofs we refer to Agrachev and Sachkov (2004) and Sontag (1998).

### Controllability

Consider first the case of a linear system:

$$\dot{y} = Ay + Bu, \quad u \in U, \ \ y(0) = y_0 \qquad [8]$$

where $y, y_0 \in R^n$, $U \subset R^m$, $A$ is an $n \times n$ matrix and $B$ an $n \times m$ matrix. We have the following property of reachable sets:

**Theorem 1** *If $U$ is compact convex then the reachable set $R(t)$ for [8] is compact and convex.*

A control system [8] is controllable if taking $U = R^m$ we have $R(t) = R^n$ for every $t > 0$. By linearity, this is equivalent to requiring the reachable set to be a neighborhood of the origin in case of bounded controls. Define the controllability matrix to be the $n \times nm$ matrix

$$C(A, B) = (B, AB, \ldots, A^{n-1}B)$$

Controllability is characterized by the following:

**Theorem 2** (Kalman controllability theorem). *The linear system [8] is controllable if and only if* $\mathrm{rank}(C(A, B)) = n$.

For linear systems, there exists a duality between controllability and observability in the sense of the following theorem:

**Theorem 3** *Consider the linear control system [8] and assume to observe the variable $z(y) = Cy$ for some $p \times n$ matrix $C$. Then, observability holds if and only if the linear system $\dot{y} = A^t y + C^t v$ is controllable.*

There exists no characterization of controllability for nonlinear systems as for linear ones, but we have the linearization result:

**Theorem 4** *A nonlinear system is locally controllable if its linearization is. The converse is false.*

There are many results for the important class of control–affine systems

$$\dot{y} = f_0(y) + \sum_{i=1}^{m} f_i(y) u_i \qquad [9]$$

where $f_0, \ldots, f_m$ are smooth vector fields on $R^n$ and $U = R^m$. In general, there exists no explicit representation for the trajectories of [9], in terms of integrals of the control as it happens for linear systems. Still, a rich mathematical theory has been developed applying techniques and ideas from differential geometry: the so-called geometric control theory. The main idea is that controllability (and properties of optimal trajectories) is determined by the Lie algebra generated by vector fields $f_i$. For example:

**Theorem 5** (Lie-algebraic rank condition). *Let $\mathcal{L}$ be the Lie algebra generated by the vector fields $f_i, i = 1, \ldots, m$, and assume $f_0 = 0$. If $\mathcal{L}(y)$ is of dimension $n$ at every point $y$ then the system is controllable.*

We refer to Agrachev and Sachkov (2004) and Jurdjevic (1997) for general presentation of geometric control theory and give a simple example to show how Lie brackets characterize reachable directions.

**Example 3** Consider the Brockett integrator

$$\dot{y}_1 = u_1, \qquad \dot{y}_2 = u_2, \qquad \dot{y}_3 = u_1 y_2 - u_2 y_1$$

Starting from the origin, using constant controls, we can move along curves tangent to the $y_1 y_2$ plane. However, let $f_1 = (1, 0, y_2)$ and $f_2 = (0, 1, -y_1)$ (fields corresponding to constant controls); then their Lie bracket is given by

$$[f_1, f_2](0) = (Df_2 \cdot f_1 - Df_2 \cdot f_2)(0) = (0, 0, -2)$$

Moving for time $t$ first along the integral curve of $f_1$, then of $f_2$, then of $-f_1$, and finally of $-f_2$, we reach a point $t^2[f_1, f_2](0) + o(t^2)$ along the vertical direction $y_3$. This corresponds to say that the system satisfies LARC.

### Optimal Control

The theory of optimal control has developed in three main directions:

*Existence* of optimal controls, under various assumptions on $L, f, U$. When the sets $F(t, y)$ are convex, optimal solutions can be constructed following the direct method of Tonelli for the calculus of variations, that is, as limits of minimizing sequences: the two main ingredients are compactness and lower-semicontinuity. If convexity does not hold, existence is not granted in general but for special cases.

*Necessary conditions* for the optimality of a control $u(\cdot)$. The major result in this direction is the celebrated "Pontryagin maximum principle" (PMP) which extends the Euler–Lagrange equation to control systems, and the Weierstrass necessary conditions for a strong local minimum in the calculus of variations. Various extensions and other necessary conditions are now available (Agrachev and Sachkov 2004).

*Sufficient conditions* for optimality. The standard procedure resorts to embedding the optimal control problem in a family of problems, obtained by

varying the initial conditions. One defines the value function $V$ by

$$V(t, \bar{y}) = \inf J(y(\cdot), u(\cdot))$$

where the inf is taken over the set of trajectories and controls satisfying $y(t) = \bar{y}$. Under suitable assumptions, $V$ is the solution to a first-order Hamilton–Jacobian PDE. The lack of regularity of the value function $V$ has long provided a major obstacle to a rigorous mathematical analysis, solved by the theory of viscosity solutions (Bardi and Capuzzo Dolcetta 1997). Another method consists in building an optimal synthesis, that is, a collection of trajectory–control pairs.

**Pontryagin maximum principle** Consider a general autonomous control system:

$$\dot{y} = f(y, u) \qquad [10]$$

where $y \in R^n$ and $u \in U$ compact subset of $R^m$. We assume to have regularity of $f$ guaranteeing existence and uniqueness of trajectories for every $u(\cdot) \in \mathcal{U}$. For a fixed $T > 0$, an optimal control problem in Mayer form is given by

$$\min_{u(\cdot)\in\mathcal{U}} \psi(y(T, u)), \quad y(0) = \bar{y} \qquad [11]$$

where $\psi$ is the final cost and $\bar{y}$ the initial condition. More generally, one can consider also the Lagrangian cost $\int L(y, u)\mathrm{d}t$ and reduce to this case by adding a variable $y_0(0) = 0$ and $\dot{y}_0 = L$.

The well-known PMP provides, under suitable assumptions, a necessary condition for optimality in terms of a lift of the candidate optimal trajectory to the cotangent bundle. For problems as [11], PMP can be stated as follows:

**Theorem 6** *Let $u^*(\cdot)$ be a (bounded) admissible control whose corresponding trajectory $y^*(\cdot) = y(\cdot, u^*)$ is optimal. Call $p : [0, T] \mapsto R^n$ the solution of the adjoint linear equation*

$$\begin{aligned} \dot{p}(t) &= -p(t) \cdot D_y f(y^*(t), u^*(t)) \\ p(T) &= \nabla\psi(y^*(T)) \end{aligned} \qquad [12]$$

*Then the maximality condition*

$$p(t) \cdot f(y^*(t), u^*(t)) = \max_{\omega\in U} p(t) \cdot f(y^*(t), \omega) \qquad [13]$$

*holds for almost every time $t \in [0, T]$.*

Notice that the conclusion of the theorem can be interpreted by saying that the pair $(y, p)$ satisfies the system:

$$\dot{y} = \frac{\partial H(y^*, p, u^*)}{\partial p}, \qquad \dot{p} = -\frac{\partial H(y^*, p, u^*)}{\partial y}$$

where $H(y, p, u) = \langle p, f(y, u)\rangle$. This is a pseudo–Hamiltonian system, since $H$ also depends on $u^*$. Alternatively, one can define the maximized Hamiltonian

$$\mathcal{H}(y, p) = \max_u \langle p, f(y, u)\rangle$$

but $\mathcal{H}$ may fail to be smooth. Another difficulty lies in the fact that an initial condition is given for $y$ and a final condition is given for $\lambda$.

The proof of PMP relies on a special type of variations, called needle variations, of a reference trajectory. Given a candidate optimal control $u^*$ and corresponding trajectory $y^*$, a time $\tau$ of approximate continuity for $f(y^*(\cdot), u^*(\cdot))$ and $\omega \in U$, a needle variation is a family of controls $u_\varepsilon$ obtained by replacing $u^*$ with $\omega$ on the interval $[\tau - \varepsilon, \tau]$. A needle variation gives rise to a variation $v$ of the trajectory satisfying the variational equation

$$\dot{v}(t) = D_y f(y^*(t), u^*(t)) \cdot v(t) \qquad [14]$$

in classical sense only after time $\tau$. Recently Piccoli and Sussmann (2000) introduced a setting in which needle and other variations happen to be differentiable.

One may also consider some final (or initial) constraint:

$$(T, y(T)) \in S \qquad [15]$$

where $S \subset R \times R^n$ (and $T$ not fixed). In this case, the final condition for $p$ is more complicated as well as the proof of PMP. It is interesting to note the many connections between PMP and classical mechanics framework well illustrated by Bloch (2003) and Jurdjevic (1997).

**Value function and HJB equation** In this section we consider the minimization problem

$$\inf_{u\in\mathcal{U}} \psi(T, y(T, u)) \qquad [16]$$

for the control system

$$\dot{y} = f(t, y, u), \quad u(t) \in U \quad \text{a.e.} \qquad [17]$$

subject to the terminal constraints [15], where $S \subset R^{n+1}$ is a closed target set.

**Theorem 7** (PDE of dynamic programming). *Assume that the value function $V$, for [15]–[17], is $C^1$ on some open set $\Omega \subseteq R \times R^n$, not intersecting the target set $S$. Then $V$ satisfies the Hamilton–Jacobi equation*

$$\begin{aligned} &V_s(s, y) + \min_{\omega\in U}\{V_y(s, y) \cdot f(s, y, \omega)\} = 0 \\ &\forall (s, y) \in \Omega \end{aligned} \qquad [18]$$

Equation [18] is called the Hamilton–Jacobi–Bellman (HJB) equation, after Richard Bellman. In general,

however, $V$ fails to be differentiable: this is the case for Example 1 along the lines $\zeta^{\pm}$. To isolate $V$ as the unique solution of the HJB equation, one has to resort to the concept of viscosity solution. The dynamic programming and HJB equation apparatus applies also to stochastic problems for which the equation happens to be parabolic, because of the Ito formula.

**Optimal syntheses** Roughly speaking, an optimal synthesis is a collection of optimal trajectories, one for each initial condition $\bar{y}$. Geometric techniques provide a systematic method to construct syntheses:

**Step 1** Study the properties of optimal trajectories via PMP and other necessary conditions.
**Step 2** Determine a (finite-dimensional) sufficient family for optimality, that is, a class of trajectories (satisfying PMP) containing all possible optimal ones.
**Step 3** Construct a synthesis selecting one trajectory for every initial condition in such a way as to cover the state space in a regular fashion.
**Step 4** Prove that the synthesis of Step 3 is indeed optimal.

One of the main problems in step 2 is the possible presence of optimal controls with an infinite number of discontinuities, known as Fuller phenomenon. The key concept of regular synthesis, of step 3, was introduced by Boltianskii and recently refined by Piccoli and Sussmann (2000) to include Fuller phenomena. The above strategy works only in some special cases, for example for two-dimensional minimum-time problems (Boscain and Piccoli 2004): we report below an example.

**Example 4** Consider the problem of orienting in minimum time a satellite with two orthogonal rotors: the speed of one rotor is controlled, while the second rotor has constant speed. This problem is modelled by a left-invariant control system on SO(3):

$$\dot{y} = y(F + uG), \quad y \in \mathrm{SO}(3), \quad |u| \leq 1$$

where $F$ and $G$ are two matrices of so(3), the Lie algebra of SO(3). Using the isomorphism of Lie algebras $(\mathrm{SO}(3), [.,.]) \sim (R^3, \times)$, the condition that the rotors are orthogonal reads: $\mathrm{trace}(F \cdot G) = 0$. If we are interested to orient only a fixed semi-axis then we project the system on the sphere $S^2$:

$$\dot{y} = y(F + uG), \quad y \in S^2, \quad |u| \leq 1$$

In this case, $F + G$ and $F - G$ are rotations around two fixed axes and, if the angle between these two axes is less than $\pi/2$, every optimal trajectory is a finite concatenation of arcs corresponding to constant control +1 or –1. The "optimal synthesis" can be obtained by the feedback shown in **Figure 2**.

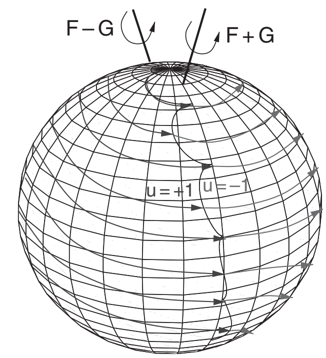

**Figure 2** Optimal feedback for Example 4.

## Control of PDEs

The theory for control of models governed by PDEs is, as expected, much more ramified and much less complete. An exhaustive resume of the available results is not possible in short space, thus we focus on Example 2 and few others to illustrate some techniques to treat control problems and give various references (see also Fursikov and Imanuvilov (1996), Komornik (1994), and Lasiecka and Triggiani (2000), and references therein).

Besides the variety of control problems illustrated in the Introduction, for PDE models one can consider different ways of applying the control, for example:

*Boundary control* One consider the system [3] (with $F$ independent of $u$) and impose the condition $y(t,x) = u(t,x)$ to hold for every time $t$ and every $x$ in some region. Usually, we assume $y(t)$ to be defined bounded region $\Omega$ and the control acts on some set $\Gamma \subset \partial\Omega$. Obviously, also Neumann conditions are natural as $\partial_\nu y = u$ where $\nu$ is the exterior normal to $\Omega$.

*Internal control* One consider the system [3] with $F$ depending on $u$. Thus, the control acts on the equation directly.

*Other controls* There are various other control problems one may consider as Galerkin-type approximation and control of some finite family of modes. An interesting example is given by Coron (2002), where the position of a tank is controlled to regulate the water level inside.

### Control of a Vibrating String

We consider Example 2, but various results hold for hyperbolic linear systems in general. First consider the uncontrolled system

$$z_{tt} = \Delta z, \quad z(0,t) = z(1,t) = 0 \qquad [19]$$

A first integral is the energy given by

$$E(t) = \frac{1}{2} \int \left[ |z_x|^2 + |z_t|^2 \right] \mathrm{d}x$$

Then we say that the system [19] is observable at time $T$ if there exists $C(T)$ such that

$$E(0) \leq C(T) \int_0^T |z_x(1,t)|^2 \, dt$$

which means that if we observe zero displacement on the right end for time $T$ then the solution has zero energy and hence vanishes. In this case, the system is observable for every time $T \geq 2$: this is precisely the time taken by a wave to travel from the right end point to the left one and backward.

Thanks to a duality as for the finite-dimensional case, observability of [19] is equivalent to null controllability for [5]–[7], that is, to the property that for every initial conditions $y_0, y_1$ there exists a control $u(\cdot)$ such that the corresponding solution verifies $y(x,T) = y_t(x,T) = 0$. More precisely, the desired control is given by $u(t) = \tilde{z}_x(1,t)$, where $\tilde{z}$ is the solution of [19] minimizing the functional (over $L^2 \times H^{-1}$)

$$J(z(\cdot,0), z_t(\cdot,0)) = \frac{1}{2}\int_0^T |z_x(1,t)|^2 \, dt + \int y_0 z_t(\cdot,0) dx - \int y_1 z(\cdot,0) \, dx$$

One can check that this functional is continuous and convex, and the coercivity is granted by the observability of [19]; thus, a minimum exists by the direct method of Tonelli. This is an example of the method known as Hilbert's uniqueness method introduced by Lions (1988).

In the multidimensional case, controllability can be characterized by imposing a condition on the region $\Gamma \subset \partial\Omega$ on which the control acts. More precisely, rays of geometric optics in $\Omega$ should intersect $\Gamma$ (Zuazua 2005).

If we consider infinite-time horizon $T = +\infty$ and introduce the functional

$$J = \int_0^{+\infty} \|y\|^2 \, dt + N \int u^2 \, dt \, dx$$

then the optimal control is determined as follows. If $(y, p)$ is a solution of the optimality system: [5]–[6] with $y = 0$ outside $\Gamma$ and

$$p_{tt} - \Delta p + y = 0, \ \partial_\nu p + Ny = 0 \quad \text{on } \Gamma$$
$$p = 0 \quad \text{on } \partial\Omega$$

then $u = y$ on $\Gamma$ (Lions 1988, Zuazua 2005).

### Controllability via Return Method of Coron

As we saw in Theorem 4, a nonlinear system may be controllable even if its linearization is not. In this case, controllability can be proved by the return method of Coron, which consists in finding a trajectory $y$ such that the following hold:

1. $y(0) = y(T) = 0$;
2. the linearized system around $y$ is controllable.

Then by implicit-function theorem, local controllability is granted, that is, there exits $\varepsilon > 0$ such that for every data $y_0, y_1$ of norm less than $\varepsilon$, there exists a control steering the system from $y_0$ to $y_1$ in time $T$.

This method does not give many advantages in the finite-dimensional case, but permits to obtain excellent results for PDE systems such as Euler, Navier–Stokes, Saint–Venant, and others (Coron 2002).

### Control of Schrödinger Equation

Consider the issue of designing an efficient transfer of population between different atomic or molecular levels using laser pulses. The mathematical description consists in controlling the Schrödinger equation. Many results are available in the finite-dimensional case. Finite-dimensional closed quantum systems are in fact left-invariant control systems on SU($n$), or on the corresponding Hilbert sphere $S^{2n-1} \subset \mathbf{C}^n$, where $n$ is the number of atomic or molecular levels, and powerful techniques of geometric control are available both for what concerns controllability and optimal control (Agrachev and Sachkov 2004, Boscain and Piccoli 2004, Jurdjevic 1997).

Recent papers consider the minimum-time problem with unbounded controls as well as minimization of the energy of transition. Boscain *et al.* (2002) have applied the techniques of sub-Riemannian geometry on Lie groups and of optimal synthesis on two-dimensional manifolds to the population transfer problem in a three-level quantum system driven by two external fields of arbitrary shape and frequency.

Although many results are available for finite-dimensional systems, only few controllability properties have been proved for the Schrödinger equation as a PDE, and in particular no satisfactory global controllability results are available at the moment.

# Convex Analysis and Duality Methods

**G Bouchitté**, Université de Toulon et du Var, La Garde, France

## Introduction

Convexity is an important notion in nonlinear optimization theory as well as in infinite-dimensional functional analysis. As will be seen below, very simple and powerful tools will be derived from elementary duality arguments (which are by-products of the Moreau–Fenchel transform and Hahn–Banach theorem). We will emphasize on applications to a large range of variational problems. Some arguments of measure theory will be skipped.

## Basic Convex Analysis

In the following, we denote by $X$ a normed vector space, and by $X^*$ the topological dual of $X$. If a topology different from the normed topology is used on $X$, we will denote it by $\tau$. For every $x \in X$ and $A \subset X$, $\mathcal{V}_x$ denotes the open neighborhoods of $x$ and $\operatorname{int} A$, $\operatorname{cl} A$, respectively, the interior and the closure of $A$. We deal with extended real-valued functions $f : X \to \mathbb{R} \cup \{+\infty\}$. We denote by $\operatorname{dom} f = f^{-1}(\mathbb{R})$ and by $\operatorname{epi} f = \{(x,\alpha) \in X \times \mathbb{R} : f(x) \le \alpha\}$ the domain and the epigraph of $f$, respectively. We say that $f$ is proper if $\operatorname{dom} f \neq \emptyset$. Recall that $f$ is convex if for every $(x,y) \in X^2$ and $t \in [0,1]$, there holds

$$f(tx + (1-t)y) \le tf(x) + (1-t)f(y)$$
$$\text{(by convention } \infty + a = +\infty)$$

The notion of convexity for a subset $A \subset X$ is recovered by saying that $\chi_A$ is convex, where its indicator function $\chi_A$ is defined by setting

$$\chi_A(x) = \begin{cases} 0 & \text{if } x \in A \\ +\infty & \text{otherwise} \end{cases}$$

### Continuity and Lower-Semicontinuity

A first consequence of the convexity is the continuity on the topological interior of the domain. We refer for instance to Borwein and Lewis (2000) for a proof of

**Theorem 1** *Let $f : X \to \mathbb{R} \cup \{+\infty\}$ be convex and proper. Assume that $\sup_U f < +\infty$, where $U$ is a suitable open subset of $X$. Then $f$ is continuous and locally Lipschitzian on all* $\operatorname{int}(\operatorname{dom} f)$.

As an immediate corollary, a convex function on a normed space is continuous provided it is majorized by a locally bounded function. In the finite-dimensional case, it is easily deduced that a finite-valued convex function $f : \mathbb{R}^d \to \mathbb{R}$ is locally Lipschitz. Furthermore, by Aleksandrov's theorem, $f$ is almost everywhere twice differentiable and the non-negative Hessian matrix $\nabla^2 f$ coincides with the absolutely continuous part of the distributional Hessian matrix $D^2 f$ (it is a Radon measure taking values in the non-negative symmetric matrices).

However, in infinite-dimensional spaces, for ensuring compactness properties (as, e.g., in condition (ii) of Theorem 4 below), we need to use weak topologies and the situation is not so simple. A major idea consists in substituting the continuity property with lower-semicontinuity.

**Definition 2** A function $f : X \to \mathbb{R} \cup \{+\infty\}$ is $\tau$-l.s.c. at $x_0 \in X$ if for all $\alpha \in \mathbb{R}$, there exists $U \in \mathcal{V}_{x_0}$ such that $f > \alpha$ on $U$. In particular, $f$ will be l.s.c. on all $X$ provided $f^{-1}((r, +\infty))$ is open for every $r \in \mathbb{R}$.

**Remark 3**

(i) The following sequential notion can be also used: $f$ is $\tau$-sequentially l.s.c. at $x_0$ if

$$\forall (x_n) \subset X \; x_n \xrightarrow{\tau} x_0 \implies \liminf_{n \to +\infty} f(x_n) \geq f(x_0)$$

It turns out that this notion (weaker in general) is equivalent to the previous one provided $x_0$ admits a countable basis of neighborhoods.

(ii) A well-known consequence of Hahn–Banach theorem is that, for convex functions, the lower-semicontinuity property with respect to the normed topology of $X$ is equivalent to the weak (or weak sequential) lower-semicontinuity.

**Theorem 4** (Existence). *Let* $f : X \to \mathbb{R} \cup \{+\infty\}$ *be proper, such that*

(i) $f$ *is* $\tau$*-l.s.c.,*
(ii) $\forall r \in \mathbb{R}, f^{-1}((-\infty, r])$ *is* $\tau$*-relatively compact.*

*Then there is* $\bar{x} \in X$ *such that* $f(\bar{x}) = \inf f$ *and* $\operatorname{argmin} f := \{x \in X | f(x) = \inf f\}$ *is* $\tau$*-compact.*

In practice, the choice of the topology $\tau$ is ruled by the condition (ii) above. For example, if $X$ is a reflexive infinite-dimensional Banach space and if $f$ is coercive (i.e., $\lim_{\|x\| \to \infty} f(x) = +\infty$), we may take for $\tau$ the weak topology (but never the normed topology). This restriction implies in practice that the first condition in Theorem 4 may fail. In this case, it is often useful to substitute $f$ with its lower-semicontinuous (l.s.c.) envelope.

**Definition 5** Given a topology $\tau$, the relaxed function $\bar{f} (= \bar{f}^\tau)$ is defined as

$$\bar{f}(x) = \sup\{g(x) | g : X \to \mathbb{R} \cup \{+\infty\},\; g \text{ is } \tau\text{-}l.s.c., g \leq f\}$$

It is easy to check that $f$ is $\tau$-l.s.c. at $x_0$ if and only if $\bar{f}(x_0) = f(x_0)$. Futhermore,

$$\bar{f}(x) = \sup_{U \in \mathcal{V}_u} \inf_U f, \quad \operatorname{epi} \bar{f} = \operatorname{cl}_{(X \times \mathbb{R})} (\operatorname{epi} f)$$

We can now state the relaxed version of Theorem 1.4.

**Theorem 6** (Relaxation). *Let* $f : X \to \mathbb{R} \cup \{+\infty\}$, *then*: $\inf f = \inf \bar{f}$. *Assume further that, for all real* $r$, $f^{-1}((-\infty, r])$ *is* $\mathcal{T}$*-relatively compact; then* $f$ *attains its minimum and* $\operatorname{argmin} f = \operatorname{argmin} \bar{f} \cap \{x \in X | f(x) = \bar{f}(x)\}$.

### Moreau–Fenchel Conjugate

The duality between $X$ and $X^*$ will be denoted by the symbol $\langle \cdot | \cdot \rangle$. If $X$ is a Euclidian space, we identify $X^*$ with $X$ via the scalar product denoted $(\cdot | \cdot)$.

**Definition 7** Let $f : X \to \mathbb{R} \cup \{+\infty\}$. The Moreau–Fenchel conjugate $f^* : X^* \to \mathbb{R} \cup \{+\infty\}$ of $f$ is defined by setting, for every $x^* \in X^*$:

$$f^*(x^*) = \sup\{\langle x | x^* \rangle - f(x) | x \in X\}$$

In a symmetric way, if $f^*$ is proper on $X^*$, we define the biconjugate $f^{**} : X \to \mathbb{R} \cup \{+\infty\}$ by setting

$$f^{**}(x) = \sup\{\langle x | x^* \rangle - f^*(x^*) | x^* \in X^*\}$$

As a consequence, the so-called Fenchel inequality holds:

$$\langle x | x^* \rangle \leq f(x) + f^*(x^*), \quad (x, x^*) \in X \times X^*$$

Notice that $f$ does not need to be convex. However, if $f$ is convex, then $f^*$ agrees with the Legendre–Fenchel transform.

**Definition 8** Let $f : X \to \mathbb{R} \cup \{+\infty\}$. The subdifferential of $f$ at $x$ is the possibly void subset of $\partial f(x) \subset X^*$ defined by

$$\partial f(x) := \{x^* \in X^* \colon f(x) + f^*(x^*) = \langle x, x^* \rangle\}$$

It is easy to check that $\partial f(x)$ is convex and weak-star closed. Moreover, if $f$ is convex and has a differential (or Gateaux derivative) $f'(x)$ at $x$, then $\partial f(x) = \{f'(x)\}$. After summarizing some elementary properties of the Fenchel transform, we give examples in $\mathbb{R}^d$ or in infinite-dimensional spaces.

**Lemma 9**

(i) $f^*$ *is convex, l.s.c. with respect to the weak star topology of* $X^*$.
(ii) $f^*(0) = -\inf f$ *and* $f \geq g \Rightarrow f^* \leq g^*$.
(iii) $(\inf_i f_i)^* = \sup_i f_i^*$, *for every family* $\{f_i\}$.
(iv) $f^{**}(x) = \sup\{g(x)$: $g$ affine continuous on $X$ and $g \leq f\}$ (*by convention, the supremum is identically* $-\infty$ *if no such* $g$ *exists*).

**Proof** (i) This assertion is a direct consequence of the fact that $f^*$ can be written as the supremum of functions $g_x$, where $g_x := \langle x | \cdot \rangle - f(x)$. Clearly, these functions are affine and weakly star-continuous on $X^*$. The assertions (ii), (iii) are trivial. To obtain (iv), it is enough to observe that an affine function $g$ of the form $g(x) = \langle x, x^* \rangle - \beta$ satisfies $g \leq f$ iff $f^*(x^*) \leq \beta$. □

**Example 1** Let $f : X \to \mathbb{R}$, be defined by

$$f(x) = \frac{1}{p} \|x\|_X^p, \quad 1 < p < +\infty$$

then,

$$f^*(x^*) = \frac{1}{p'} \|x^*\|_{X^*}^{p'}, \quad \text{with } \frac{1}{p} + \frac{1}{p'} = 1$$

whereas, for $p=1$, we find $f^* = \chi_{B^*}$, where $B^* = \{\|x^*\| \le 1\}$.

**Example 2** Let $A \in \mathbb{R}^{d^2}_{\mathrm{sym}}$ be a symmetric positive-definite matrix and let $f(x) := (1/2)(Ax\,|\,x)(x \in \mathbb{R}^d)$. Then, for all $y \in \mathbb{R}^d$, we have $f^*(y) = (1/2)(A^{-1}y\,|\,y)$. Notice that if $A$ has a negative eigenvalue, then $f^* \equiv +\infty$.

Particular examples on $R^d$ are also very popular. For instance:

**Minimal surfaces**

$$f(x) = \sqrt{1+|x|^2}$$

$$f^*(y) = \begin{cases} -\sqrt{1-|y|^2} & \text{if } |y| \le 1 \\ +\infty & \text{otherwise} \end{cases}$$

**Entropy**

$$f(x) = \begin{cases} x \log x & \text{if } x \in \mathbb{R}_+ \\ +\infty & \text{otherwise} \end{cases}, \quad f^*(y) = \exp(y-1)$$

**Example 3** Let $C \subset X$ be convex, and let $f = \chi_C$. Then,

$$f^*(x^*) = \sigma_C(c^*) = \sup_{x\in C} \langle x | x^* \rangle$$
$$\text{(support function of } C)$$

Notice that if $M$ is a subspace of $X$, then $(\chi_M)^* = \chi_{M^\perp}$. We specify now a particular case of interest.

Let $\Omega$ be a bounded open subset of $\mathbb{R}^n$. Take $X = C_0(\bar{\Omega}; \mathbb{R}^d)$ to be the Banach space of continuous functions on the compact $\bar{\Omega}$) with values in $\mathbb{R}^d$. As usual, we identify the dual $X^*$ with the space $\mathcal{M}_b(\bar{\Omega}; \mathbb{R}^d)$ of $\mathbb{R}^d$-valued Borel measures on $\bar{\Omega}$ with finite total variation. Let $K$ be a closed convex of $R^d$ such that $0 \in K$. Then $\rho^0_K(\xi) := \sup\{(\xi\,|\,z) \colon z \in K\}$ is a non-negative convex l.s.c. and positively 1-homogeneous function on $\mathbb{R}^d$ (e.g., $\rho_K$ is the Euclidean norm if $K$ is the unit ball of $\mathbb{R}^d$). Let us define $C := \{\varphi \in X \colon \varphi(x) \in K, \forall x \in \Omega\}$. Then, we have

$$(\chi_C)^*(\lambda) = \int_\Omega \rho^0_K(\lambda) := \int_\Omega \rho^0_K\left(\frac{d\lambda}{d\theta}\right)\theta(dx) \qquad [1]$$

where $\theta$ is any non-negative Radon measure such that $\lambda \ll \theta$ (the choice of $\theta$ is indifferent). In the case where $K$ is the unit ball, we recover the total variation of $\lambda$.

**Example 4** (Integral functionals). Given $1 \le p < +\infty$, $(\Omega, \mu, \mathcal{T})$ a measured space and $\varphi : \Omega \times \mathbb{R}^d \to [0, +\infty]$ a $\mathcal{T} \otimes B_{\mathbb{R}^d}$-measurable integrand. Then the partial conjugate $\varphi^*(x, z^*) := \sup\{\langle z\,|\,z^*\rangle - \varphi(x,z) \colon z \in \mathbb{R}^d\}$ is a convex measurable integrand. Let us define

$$I_\varphi : u \in (L^p_\mu)^d \to \int_\Omega \varphi(x, u(x))d\mu \in \mathbb{R} \cup \{+\infty\}$$

and assume that $I_\varphi$ is proper. Then there holds $(I_\varphi)^* = I_{\varphi^*}$, where

$$(I_\varphi)^* : v \in (L^{p'}_\mu)^d \to \int_\Omega \varphi^*(x, v(x))d\mu$$

## Duality Arguments

### Two Key Results

The first result related to the biconjugate $f^{**}$ is a consequence of the Hahn–Banach theorem. Recalling the assertion (v) of Lemma 9, we notice that the existence of an affine minorant for $f$ is equivalent to the properness of $f^*$ (i.e., $\exists x^*_0 \in X^* \colon f^*(x^*_0) < +\infty$).

**Theorem 10** *Let $f : X \to \mathbb{R} \cup \{+\infty\}$ be convex and proper. Then*

(i) *$f$ is l.s.c. at $x_0$ if and only if $f^*$ is proper and $f^{**}(x_0) = f(x_0)$. In particular, the lower-semicontinuity of $f$ on all $X$ is equivalent to the identity $f \equiv f^{**}$.*
(ii) *If $f^*$ is proper, then $f^{**} = \bar{f}$.*

**Proof** We notice that by Lemma 9, $f^{**} \le f$ and $f^{**}$ is l.s.c (even for the weak topology). Therefore, $f^{**} \le \bar{f}$ and, moreover, $f$ is l.s.c. at $x_0$ if $f^{**}(x_0) \ge f(x_0)$. Conversely, if $f$ is l.s.c. at $x_0$, for every $\alpha_0 < f(x_0)$, there exists a neighborhood $V$ of $x_0$ such that $V \times (-\infty, \alpha_0) \cap \operatorname{epi} f = \emptyset$. It follows that $\overline{\operatorname{epi} f}$ is a proper closed convex subset of $X \times \mathbb{R}$ which does not intersect the compact singleton $\{(x_0, \alpha_0)\}$. By applying the Hahn–Banach strict separation theorem, there exists $(x^*_0, \beta_0) \in X^* \times \mathbb{R}$ such that

$$\langle x_0, x^*_0\rangle + \alpha_0\beta_0 < \langle x, x^*_0\rangle + \alpha\beta_0$$
$$\text{for all } (x, \alpha) \in \operatorname{epi} f$$

Taking $\alpha \to \infty$ and $x \in \operatorname{dom} f$, we find $\beta_0 \ge 0$. In fact, $\beta_0 > 0$ as the strict inequality above would be violated for $x = x_0$. Eventually, we obtain that $f$ is minorized by the affine continuous function $g(x) = -\langle x - x_0, x^*_0/\beta\rangle + \alpha_0$. Thus, we conclude that $f^*$ is proper and that $f^{**}(x_0) \ge \alpha_0$.

The assertion (ii) is a direct consequence of the equivalence in (i). □

**Theorem 11** *Let X be a normed space and let $f: X \to [0, +\infty]$ be a convex and proper function; assume that f is continuous at 0, then*

(i) *$f^*$ achieves its minimum on $X^*$*
(ii) *$f(0) = f^{**}(0) = -\inf f^*$*

**Proof**

(i) Let $M$ be an upper bound of $f$ on the ball $\{\|x\| \leq R\}$. Then

$$f^*(x^*) \geq \sup\{\langle x, x^*\rangle - f(x) \colon \|x\| \leq R\} \\ \geq R\|x^*\|_{X^*} - M$$

Hence, for every $r$, the set $\{x^* \in X^* \colon f^*(x^*) \leq r\}$ is bounded, thus $\tau$-relatively compact, where $\tau$ is the weak-star topology on $X^*$. By assertion (i) of Lemma 9, $f^*$ is $\tau$-l.s.c. and Theorem 4 applies.

(ii) By Theorem 10, since $f$ is convex proper and l.s.c. at $x_0 = 0$, we have $f(0) = f^{**}(0) = -\inf f^*$.

□

### Some Useful Consequences

**Proposition 12** (Conjugate of a sum). *Let $f, g: X \to \mathbb{R} \cup \{+\infty\}$ be convex such that*

$$\exists x_0 \in X : f \text{ is continuous at } x_0 \text{ and } g(x_0) < +\infty \qquad [2]$$

*Then*

(i) $$(f+g)^*(x^*) = \inf_{x_1^* + x_2^* = x^*} \{f^*(x_1^*) + g^*(x_2^*)\}$$

*(the equality holds in $\bar{\mathbb{R}}$).*

(ii) *If both sides of the equality in* (i) *are finite, then the infimum in the right-hand side is achieved.*

**Proof** Without any loss of generality, we may assume that $x^* = 0$ (we reduce to this case by substituting $g$ with $g - \langle \cdot, x^*\rangle$). We let

$$h(p) = \inf\{f(x+p) + g(x) | x \in X\}$$

Noticing that $(p, x) \mapsto f(x+p) + g(x)$ is convex, we infer that $h(p)$ is convex as well. As $h$ is majorized by the function $p \mapsto f(x_0 + p) + g(x_0)$, which by [2] continuous at 0, we deduce from Theorems 1 and 11 that $h(0) = h^{**}(0)$ and that $h^*$ achieves its infimum. Now $h(0) = \inf(f+g) = -(f+g)^*(0)$ and

$$h^*(p^*) = \sup\{\langle p, p^*\rangle - h(p) \colon p \in X\} \\ = \sup\{\langle p, p^*\rangle - f(x+p) - g(x) \colon x \in X, p \in X\} \\ = g^*(-p^*) + f^*(p^*)$$

The assertions (i), (ii) follow since $-h^{**}(0) = \min h^* = \min\{g^*(-p^*) + f^*(p^*)\}$.

□

**Proposition 13** (Composition). *Let $X, Y$ be two Banach spaces and $A: X \mapsto Y$ a linear operator with dense domain $D(A)$. Let $\Psi: Y \to \mathbb{R} \cup \{+\infty\}$ be a convex l.s.c. function and let $F \mapsto X$ be the convex functional defined by*

$$F(u) = \begin{cases} \Psi(Au) & \text{if } u \in D(A) \\ +\infty & \text{otherwise} \end{cases}$$

*Assume that there exists $u_0 \in D(A)$ such that $\Psi$ is continuous at $Au_0$. Then*

(i) *The Fenchel conjugate of F is given by*

$$\forall f \in X^*, \quad F^*(f) = \inf\{\Psi^*(\sigma) \colon \sigma \in Y^*, A^*\sigma = f\}$$

*where, if both sides of the equality are finite, the infimum on the right-hand side is achieved.*

(ii) *If, in addition, Y is reflexive and $\Psi$ is l.s.c. coercive, we have*

$$\bar{F}(u) = F^{**}(u) = \inf\{\Psi(p) | (u, p) \in \overline{G(A)}\} \qquad [3]$$

*where G(A) denotes the graph of A.*

**Proof**

(i) Define $H, K: X \times Y \to \mathbb{R} \cup \{+\infty\}$ by

$$H(u, p) = \chi_{G(A)}(u, p), \qquad K(u, p) = \Psi(p)$$

Then we have the identity $F^*(f) = (H+K)^*(f, 0)$, where the conjugate of $H + K$ is taken with respect to the duality $(X \times Y, X^* \times Y^*)$. From the assumption, $K$ is continuous at $(u_0, Au_0) \in \operatorname{dom} H$. By Proposition 12, we obtain

$$(H+K)^*(f, 0) \\ = \inf_{(g,\sigma) \in X^* \times Y^*} \{K^*(f - g, \sigma) + H^*(g, -\sigma)\}$$

After a simple computation, it is easy to check that

$$H^*(g, -\sigma) = \begin{cases} 0 & \text{if } A^*\sigma = f \\ +\infty & \text{otherwise} \end{cases}$$
$$K^*(f - g, \sigma) = \begin{cases} \Psi^*(\sigma) & \text{if } g = f \\ +\infty & \text{otherwise} \end{cases}$$

(ii) Let $J(u) := \inf\{\Psi(p) \colon (u, p) \in \overline{G(A)}\}$. As observed for $F^*$ in the proof of (i), we have the identity $J^*(f) = (H+K)^*(f, 0)$. Therefore, in view of Theorem 10, $\bar{F} = F^{**} = J^{**}$ and it is enough to prove that $J$ is convex l.s.c. proper. Let us consider a sequence $(u_n)$ in $X$ converging to some $u \in X$. Without any loss of generality, we may assume that $\liminf J(u_n) = \lim J(u_n) < +\infty$. Then there is a sequence $(p_n)$ such that, for every $n$, $(u_n, p_n) \in \bar{G}(A)$ and $J(u_n) \geq \psi(u_n) - 1/n$. As $\psi$ is coercive, $\{p_n\}$ is bounded in the reflexive space $Y$ and possibly passing to a subsequence,

we may assume that $p_n$ converges weakly to some $p$. Since $\overline{G(A)}$ is a (weakly) closed subspace of $X \times Y$, we infer that $(u, p)$ as the limit of $(u_n, p_n)$ still belongs to $\overline{G(A)}$. Thus, we conclude, thanks to the (weak) lower-semicontinuity of $\Psi$

$$\liminf_n J(u_n) = \lim_n \Psi(p_n) \geq \Psi(p) \geq J(u)$$

□

An immediate consequence of Propositions 12 and 13 is the following variant:

**Proposition 14** *Under the same notation as in Proposition 13, let $\Phi : X \to \mathbb{R} \cup \{+\infty\}$ be a convex function and assume that there exists $u_0 \in D(A)$ such that $F(u_0) < +\infty$ and $\Psi$ is continuous at $Au_0$. Then we have*

$$\inf_{u \in X}\{\phi(u) + \Psi(Au)\} = \sup_{\sigma \in Y^*}\{-\phi^*(-A^*\sigma) - \Psi^*(\sigma)\}$$

*where the supremum on the right-hand side is achieved. Furthermore, a pair $(\bar{u}, \bar{\sigma})$ is optimal if and only if it satisfies the relations: $\bar{\sigma} \in \partial\Psi(A\bar{u})$ and $-A^*\bar{\sigma} \in \partial\phi(\bar{u})$.*

**Remark 15** From the assertion (ii) of Proposition 13, we may conclude that $F$ is l.s.c. whenever the operator $A$ is closed. If now $A$ is merely closable (with closure denoted by $\bar{A}$), we obtain

$$\bar{F}(u) = \begin{cases} G(\bar{A}u) & \text{if } u \in \text{ dom } \bar{A} \\ +\infty & \text{otherwise} \end{cases}$$

This is the typical situation when $F$ is an integral functional defined on smooth functions of the kind

$$F(u) = \int_\Omega f(x, \nabla u)\, dx$$

where $\Omega$ is an bounded open subset of $\mathbb{R}^n, f : \Omega \times \mathbb{R}^n \to \mathbb{R}$ is a convex integrand with quadratic growth (i.e., $c|z|^2 \leq f(x,z) \leq C(1 + |z|^2$ for suitables $C \geq c > 0$). Then $X = L^2(\Omega), Y = L^2(\Omega; \mathbb{R}^n)$,

$$G(v) = \int_\Omega f(x, v(x))\, dx$$

and $A : u \in C^1(\Omega) \mapsto \nabla u \in L^2(\Omega; \mathbb{R}^n)$. It turns out that $A$ is closable and that the domain of $\bar{A}$ characterizes the Sobolev space $W^{1,2}(\Omega)$ on which $\bar{A}$ coincides with the distributional gradient operator.

The situation is more involved if we consider

$$F(u) = \int_\Omega f(x, \nabla u)\, d\mu$$

$\mu$ is a possibly concentrated Radon measure supported on $\Omega$. In general, the operator $A : u \in C^1(\Omega) \subset L^2_\mu(\Omega) \mapsto \nabla u \in L^2_\mu(\Omega; \mathbb{R}^n)$ is not closable and we need to come back to the general formula [3]. The general structure of $\overline{G(A)}$ has been given in Bouchitté *et al.* (1997) and Bouchitté and Fragalà (2002, 2003), namely

$$(u, \xi) \in \overline{G(A)} \Longleftrightarrow u \in W^{1,2}_\mu, \exists \eta \in L^2_\mu(\Omega; \mathbb{R}^n):$$
$$\xi = \nabla_\mu u + \eta, \ \eta(x) \in T_\mu(x)^\perp$$

where $T_\mu(x), \nabla_\mu(x)$ are suitable notions of tangent space and tangential gradient with respect to $\mu$, and $W^{1,2}_\mu$ denotes the domain of the extended tangential gradient operator.

**Remark 16** The assertion (ii) of Proposition 13 is not valid in the nonreflexive case. In particular, for

$$F(u) = \int_\Omega f(x, \nabla u) dx$$

where $f(x, \cdot)$ has a linear growth at infinity, we need to take $Y$ as the space of $\mathbb{R}^n$-values vector measures on $\Omega$ and the relaxed functional $F^{**}$ needs to be indentified on the space $BV(\Omega)$ of integrable functions with bounded variations. The computation of $F^{**}$ is a delicate problem for which we refer to Bouchitté and Dal Maso (1993) and Bouchitté and Valadier (1998).

**Remark 17** By duality techniques, it is possible also to handle variational integrals of the kind

$$F(u) = \int_\Omega f(x, u(x), \nabla u(x)) dx$$

even if the dependence of $f(x, u, z)$ with respect to $u$ is nonconvex. The idea consists in embedding the space $BV(\Omega)$ in the larger space $BV(\Omega \times \mathbb{R})$ through the map $u \mapsto 1_u$, where $1_u$ is the characteristic function defined on $\Omega \times R$ by setting

$$1_u(x, t) := \begin{cases} 1 & \text{if } u(x) > t \\ 0 & \text{otherwise} \end{cases}$$

Then it is possible to show, under suitable conditions on the integrand $f$, that there exists a convex l.s.c., 1-homogeneous functional $G : BV(\Omega \times \mathbb{R}) \to \mathbb{R} \cup \{+\infty\}$ such that $\bar{F}(u) = G(1_u)$. This functional $G$ is constructed as in the Example 3 taking $C$ to be a suitable convex subset of $C^0(\Omega \times \mathbb{R})$. This nice new idea has been the key tool of the calibration method developed recently (Alberti *et al.* 2003).

## Convex Variational Problems in Duality

### Finite-Dimensional Case

We sketch the duality scheme in two cases.

**Linear programming** Let $c \in \mathbb{R}^n, b \in \mathbb{R}^m$ and $A$ an $m \times n$ matrix. We denote by $A^{\mathrm{T}}$ the transpose matrix. We consider the linear program

$$(\mathcal{P}) \qquad \inf\{(c|x)\colon x \geq 0,\ Ax \leq b\}$$

and its perturbed version ($p \in \mathbb{R}^m$)

$$h(p) := \inf\{(c|x)\colon x \geq 0,\ Ax + p \leq b\}$$

An easy computation gives

$$\forall y \in \mathbb{R}^m, \quad h^*(y) = \begin{cases} -(b|y) & \text{if } A^{\mathrm{T}}y + c \leq 0, y \geq 0 \\ +\infty & \text{otherwise} \end{cases} \qquad [4]$$

**Lemma 18** *Assume that* $\inf(\mathcal{P})$ *is finite. Then*:

(i) $h$ *is convex proper and l.s.c. at* 0.
(ii) $(\mathcal{P})$ *has at least one solution.*

**Proof** We introduce the $(n+m) \times (m+1)$ matrix $B$ defined by

$$B := \begin{pmatrix} c^{\mathrm{T}} & 0 \\ A & I_m \end{pmatrix}$$

($I_m$ is the $m$-dimensional identity matrix). Denote $\{b_1, b_2, \ldots, b_{n+m}\} \subset \mathbb{R}^{m+1}$ the columns of $B$ and $K$ the convex cone $K := \{\sum_{j=1}^{j=n+m} \lambda_j b_j\colon \lambda_j \geq 0\}$. By Farkas lemma, this cone $K$ is closed.

(i) Let $\alpha := \liminf\{h(p)\colon p \to 0\}$. We have to prove that $\alpha \geq h(0) = \inf \mathcal{P}$. Let $\{p_\varepsilon\}$ be a sequence in $\mathbb{R}^m$ such that $p_\varepsilon \to 0$ and $h(p_\varepsilon) \to \alpha$. By the definition of $h$, we may choose $x_\varepsilon \geq 0$ such that $Ax_\varepsilon \leq b$ and $(c\,|\,x_\varepsilon) \to \alpha$. Then we see that the column vector $\tilde{x_\varepsilon}$ associated with $(x_\varepsilon, b - Ax_\varepsilon) \in \mathbb{R}^{n+m}$ satisfies: $B\tilde{x_\varepsilon} \in K$ and

$$B\tilde{x_\varepsilon} \to \begin{pmatrix} \alpha \\ b \end{pmatrix}$$

Therefore,

$$\begin{pmatrix} \alpha \\ b \end{pmatrix} \in K$$

and there exists $\tilde{x} = (x, x')$ such that $x \geq 0, x' \geq 0$, $(c\,|\,x) = \alpha$ and $Ax + x' = b$. It follows that $x$ is admissible for $(\mathcal{P})$ and then $(c\,|\,x) = \alpha \geq h(0)$.

(ii) We repeat the proof of (i) choosing $p_\varepsilon = 0$ so that $\alpha = \inf(\mathcal{P})$. □

Thanks to the assertion (i) in Lemma 18, we deduce from Theorem 10 that $\inf(\mathcal{P}) = h(0) = h^{**}(0) = \sup -h^*$. Recalling [4], we therefore consider the dual problem:

$$(\mathcal{P}^*) \qquad \sup\{-b \cdot y\colon\ y \geq 0,\ A^{\mathrm{T}} + c \geq 0\}$$

**Theorem 19** *The following assertions are equivalent*:

(i) $(\mathcal{P})$ *has a solution.*
(ii) $(\mathcal{P}^*)$ *has a solution.*
(iii) *There exists* $(x_0, y_0) \in \mathbb{R}^n_+ \times \mathbb{R}^m_+$ *such that* $Ax_0 \leq b, A^{\mathrm{T}}y_0 + c \geq 0$.

*In this case, we have* $\min(\mathcal{P}) = \max(\mathcal{P}^*)$ *and an admissible pair* $(\bar{x}, \bar{y})$ *is optimal if and only if* $c \cdot \bar{x} = -b \cdot \bar{y}$ *or, equivalently, satisfies the complementarity relations*: $(A\bar{x} - b) \cdot \bar{y} = (A^{\mathrm{T}}\bar{y} + c) \cdot \bar{x} = 0$.

**Convex programming** Let $f, g_1, \ldots, g_m : X \to \mathbb{R}$ be convex l.s.c. functions and the optimization problem

$$(\mathcal{P}) \qquad \inf\{f(x)\colon\ g_j(x) \leq 0,\ j = 1, 2 \ldots, m\}$$

Here $X = \mathbb{R}^n$ or any Banach space. As before, we introduce the value function

$$p \in \mathbb{R}^m, \quad h(p) := \inf\{f(x)\colon g_j(x) + p_j \leq 0\ j \in 1, 2, \ldots, m\}$$

and compute its Fenchel conjugate:

$$\lambda \in \mathbb{R}^m, \quad h^*(\lambda) = \begin{cases} -\inf\limits_{x \in X}\{L(x, \lambda)\} & \text{if } \lambda \geq 0 \\ +\infty & \text{otherwise} \end{cases}$$

where $L(x, \lambda) := f(x) + \sum \lambda_i g_i(x)$ is the so-called Lagrangian. We notice that $h$ is convex and that the equality $h(0) = h^{**}(0)$ is equivalent to the zero-duality gap relation

$$\inf_x \sup_\lambda L(x, \lambda) = \sup_\lambda \inf_x L(x, \lambda)$$

This condition is fulfilled, in particular, if we make the following qualification assumption (ensuring that $h$ is continuous at 0 and Theorem 11 applies):

$$\exists x_0 \in X : f \text{ continuous at } x_0, g_j(x_0) < 0, \forall j \qquad [5]$$

**Theorem 20** *Assume that* [5] *holds. Then* $\bar{x}$ *is optimal for* $(\mathcal{P})$ *if and only if there exist Lagrangian multipliers* $\bar{\lambda}_1, \bar{\lambda}_2, \ldots \bar{\lambda}_m$ *in* $\mathbb{R}_+$ *such that*

$$\bar{x} \in \operatorname*{argmin}_X \left( f + \sum_j \bar{\lambda}_j g_j \right), \quad \bar{\lambda}_j g_j(\bar{x}) = 0, \ \forall j$$

Notice that the existence of such a solution $\bar{x}$ is ensured if, for example, $X = \mathbb{R}^n$ and if, for some $k > 0$, the function $f + k\sum_j g_j$ is coercive.

#### Primal–Dual Formulations in Mechanics

We present here the example of elasticity which motivated the pioneering work by J J Moreau on convex duality techniques. Further examples can be found in Ekeland and Temam (1976). An elastic body is placed in a bounded domain $\Omega \subset \mathbb{R}^n$ whose boundary $\Gamma$ consists of two disjoint parts $\Gamma = \Gamma_0 \cup \Gamma_1$. The unknown $u : \Omega \to \mathbb{R}^n$ (deformation) satisfies a Dirichlet condition $u = 0$ on $\Gamma_0$, where the body is clamped. The system is subjected to a surface load $g \in L^2(\Gamma_1; \mathbb{R}^n)$ and to a volumic load $f \in L^2(\Omega; \mathbb{R}^n)$. The static equilibrium problem has the following variational formulation:

$$(\mathcal{P}) \qquad \inf_{u=0 \text{ on } \Gamma_0} \left\{ \int_\Omega j(x, e(u))\, dx - \int_\Omega f \cdot u\, dx - \int_{\Gamma_1} g \cdot u\, d\mathcal{H}^{n-1} \right\}$$

where $e(u) := (1/2)(u_{i,j} + u_{j,i})$ denotes the symmetric strain tensor and $j : (x, z) \in \Omega \times \mathbb{R}^{n^2}_{\text{sym}} \to \mathbb{R}_+$ is a convex integrand representing the local elastic behavior of the material. We assume a quadratic growth as in Remark 15 (in the case of linear elasticity, an isotropic homogeneous material is characterized by the quadratic form

$$j(x, z) = \frac{\lambda}{2} |\text{tr}(z)|^2 + \mu |z|^2$$

$\lambda, \mu$ being the Lamé constants).

We apply Proposition 14 with $X = W^{1,2}(\Omega; \mathbb{R}^n)$, $Y = L^2(\Omega; \mathbb{R}^{n^2}_{\text{sym}})$, $Au = e(u)$ and where we set

$$\Phi(u) = \begin{cases} -\int_\Omega f \cdot u\, dx \\ \quad -\int_{\Gamma_1} g \cdot u\, d\mathcal{H}^{n-1} & \text{if } u = 0 \text{ on } \Gamma_0 \\ +\infty & \text{otherwise} \end{cases}$$

$$\Psi(v) = \int_\Omega j(x, v)\, dx$$

After some computations, we may write the supremum appearing in Proposition 14 as our dual problem

$$(\mathcal{P}^*) \qquad \sup \left\{ -\int_\Omega j^*(x, \sigma)\, dx : \ \sigma \in L^2(\Omega; \mathbb{R}^{n^2}_{\text{sym}}), -\text{div}\, \sigma = f \text{ on } \Omega, \sigma \cdot n = g \text{ on } \Gamma_1 \right\}$$

where $j^*$ is the Moreau–Fenchel conjugate with respect to the second argument and $n(x)$ denotes the exterior unit normal on $\Gamma$. The matrix-valued map $\sigma$ is called the stress tensor and $j^*$ the stress potential. Note that the boundary conditions for $\sigma n$ have to be understood in the sense of traces.

**Theorem 21** *The problems* $(\mathcal{P})$ *and* $(\mathcal{P}^*)$ *have solutions and we have the equality*: $\inf(\mathcal{P}) = \sup(\mathcal{P}^*)$. *Futhermore, a pair* $(\bar{u}, \bar{\sigma})$ *is optimal if and only if it satisfies the following system*:

$$\begin{array}{lll} -\text{div}\, \bar{\sigma} = f & \text{on } \Omega & (\textit{equlibrium}) \\ \bar{\sigma}(x) \in \partial j(x, e(\bar{u})) & \text{a.e. on } \Omega & (\textit{constitutive law}) \\ \bar{u} = 0 & \text{a.e. on } \Gamma_0 & \\ \bar{\sigma} n = g & \text{on } \Gamma_1 & \end{array}$$

## Duality in Mass Transport Problems

#### General Cost Functions

Let $X, Y$ be a compact metric space and $c : X \times Y \to [0, +\infty)$ a continuous cost function. We denote by $\mathcal{P}(X), \mathcal{P}(X \times Y)$ the sets of probability measures on $X$ and $X \times Y$, respectively. Given two elements $\mu \in \mathcal{P}(X), \nu \in \mathcal{P}(Y)$, we denote by $\Gamma(\mu, \nu)$ the subset of probability measures in $\mathcal{P}(X \times Y)$ whose marginals are, respectively, $\mu$ and $\nu$. Identified as a subset of $(C^0(X \times Y))^*$ (the space of signed Radon measures on $X \times Y$), it is convex and weakly-star compact. The Monge–Kantorovich formulation of the mass transport problem reads as follows:

$$T_c(\mu, \nu) := \inf \left\{ \int_{X \times Y} c(x, y) \gamma(dx dy) : \gamma \in \Gamma(\mu, \nu) \right\} \qquad [6]$$

This formulation, where the infimum is achieved (as we minimize an l.s.c. functional on a compact set for the weak star topology), is already a relaxation of the initial Monge mass transport problem,

$$\inf_T \left\{ \int_X c(x, Tx) \mu(dx) : T^\#(\mu) = \nu \right\}$$

where the infimum is searched among all transports maps $T : X \mapsto Y$ pushing forward $\mu$ on $\nu$ (i.e., such that $\mu(T^{-1}(B) = \nu(B)$ for all Borel subset $B \subset Y$). This is equivalent to restricting the infimum in [6] to the subclass $\{\gamma_T\} \subset \Gamma(\mu, \nu)$, where

$$\langle \gamma_T, \phi(x, y) \rangle := \int_X \phi(x, Tx) \mu(dx)$$

In order to find a dual problem for [6], we fix $\nu \in \mathcal{P}(Y)$ and consider the functional $F : \mathcal{M}_b(X) \to [0, +\infty)$ defined by

$$F(\mu) = \begin{cases} T_c(\mu, \nu) & \text{if } \mu \geq 0, \mu(X) = 1 \\ +\infty & \text{otherwise} \end{cases}$$

($\mathcal{M}_b(X)$ denote the Banach space of (bounded) signed Radon measures on X).

**Lemma 22** *F is convex, weakly-star l.s.c. and proper. Its Moreau–Fenchel conjugate is given by*

$$\forall \varphi \in C^0(X), \quad F^*(\varphi) = -\int_Y \varphi^c(y) \nu(dy)$$

*where*

$$\varphi^c(y) := \inf\{c(x,y) - \varphi(x) \colon x \in X\}$$

**Proof** The convexity property is obvious and the properness follows from the fact that

$$F(\mu) \le \int_{X\times Y} c(x,y)\ \mu\otimes\nu(\mathrm{d}x\mathrm{d}y)$$

Let $\mu_n$ be such that $\mu_n \rightharpoonup \mu$ (weakly star). We may assume that $\liminf_n F(\mu_n) = \lim_n F(\mu_n) := \alpha$ is finite. Then $\mu_n$ and the associated optimal $\gamma_n$ are probability measures on $X$ and on $X\times Y$, respectively. As $X$ and $Y$ are compact, possibly passing to a subsequence, we may assume that $\gamma_n \rightharpoonup \gamma$, and clearly we have $\gamma \in \Gamma(\mu,\nu)$. Since $c(x,y)$ is l.s.c. non-negative, we conclude that

$$\begin{aligned}\liminf_n F(\mu_n) &= \liminf_n \int_{X\times Y} c(x,y)\gamma_n(\mathrm{d}x\mathrm{d}y)\\ &\ge \int_{X\times Y} c(x,y)\,\gamma(\mathrm{d}x\mathrm{d}y)\\ &= F(\mu)\end{aligned}$$

Let us compute now $F^*(\varphi)$. We have

$$\begin{aligned}-F^*(\varphi) &= \inf\left\{\int_{X\times Y} c(x,y)\gamma(\mathrm{d}x\mathrm{d}y) - \int_X \varphi\,\mathrm{d}\mu \colon \mu\in\mathcal{P}(X), \gamma\in\Gamma(\mu,\nu)\right\}\\ &= \inf\left\{\int_{X\times Y}(c(x,y)-\varphi(x))\gamma(\mathrm{d}x\mathrm{d}y)\colon \gamma\in\Gamma(\mu,\nu)\right\}\\ &\ge \int_Y \varphi^c(y)\,\nu(\mathrm{d}y)\end{aligned}$$

To prove that the last inequality is actually an equality, we observe that, for every $y\in Y$ and $\varphi\in C^0(X)$, the minimum of the l.s.c. function $c(\,\cdot\,,y)-\varphi$ is attained on the compact set $X$ and there exists a Borel selection map $S(y)$ such that $\varphi^c(y) = c(S(y),y) - \varphi(S(y)$ for all $y\in Y$. We obtain the desired equality by choosing $\gamma$ defined, for every test $\psi$, by

$$\int_{X\times Y}\psi(x,y)\gamma(\mathrm{d}x\mathrm{d}y) := \int_Y \psi(S(y),y)\nu(\mathrm{d}y)$$

□

We observe that, for every $\varphi\in C^0(X)$, the function $\varphi^c$ introduced in Lemma 22 is continuous (use the uniform continuity of $c$) and therefore the pair $(\varphi,\varphi^c)$ belong to the class

$$\mathcal{F}_c := \{(\varphi,\Psi)\in C^0(X)\times C^0(Y)\colon \varphi(x)+\psi(y)\le c(x,y)\}$$

Let us introduce the dual problem of [6]:

$$\sup\left\{\int_X \varphi\,\mathrm{d}\mu + \int_Y \psi\,\mathrm{d}\nu \colon (\varphi,\psi)\in\mathcal{F}_c\right\} \qquad [7]$$

We will say that $(\varphi,\psi)\in\mathcal{F}_c$ is a pair of c-concave conjugate functions if $\psi=\varphi^c$ and $\psi^c=\varphi$ (where symmetrically $\psi^c(x) := \inf\{c(x,y)-\psi(x)\colon y\in Y\}$). Checking the latter condition amounts to verifying that $\varphi$ enjoys the so-called c-concavity property $\varphi^{cc}=\varphi$ (in general, we have only $\varphi^{cc}\ge\varphi$, whereas $\varphi^{ccc}=\varphi^c$). We refer for instance to Villani (2003) for further details about this $c$-duality.

Now, by exploiting Theorem 10 and Lemma 22, we obtain a very simple proof of Kantorovich duality theorem:

**Theorem 23** *The following duality formula holds*:

$$T_c(\mu,\nu) = \sup\left\{\int_X \varphi\,\mathrm{d}\mu + \int_Y \psi\,\mathrm{d}\nu \colon (\varphi,\psi)\in\mathcal{F}_c\right\}$$

*Moreover, the supremum in the right-hand side member is achieved by a pair* $(\bar\varphi,\bar\psi)$ *of conjugate c-concave functions such that, for any optimal* $\bar\gamma$ *in* [6], *there holds* $\bar\varphi(x)+\bar\psi(y) = c(x,y)$, $\bar\gamma$*-a.e.*

**Proof** By Theorem 10 and Lemma 22, we have

$$\begin{aligned}T_c(\mu,\nu) &= F^{**}(\mu)\\ &= \sup\left\{\int_X \varphi\,\mathrm{d}\mu + \int_Y \varphi^c\,\mathrm{d}\nu \colon \varphi\in C^0(X)\right\}\\ &\le \sup\left\{\int_X \varphi\,\mathrm{d}\mu + \int_Y \psi\,\mathrm{d}\nu\colon\ (\varphi,\psi)\in\mathcal{F}_c\right\}\\ &\le T_c(\mu,\nu)\end{aligned}$$

where the last inequality follows from the definition of $\mathcal{F}_c$. Therefore, $\inf[6] = \sup[7]$. Furthermore, on the right-hand side of first equality, we increase the supremum by substituting $\varphi$ with $\varphi^{cc}$ (recall that $\varphi^{ccc}=\varphi^c$). Thus,

$$\sup[7] = \sup\left\{\int_X \varphi\,\mathrm{d}\mu + \int_Y \varphi^c\,\mathrm{d}\nu \colon \varphi\in C^0(X),\ \varphi\ c\text{-concave}\right\}$$

Take a maximizing sequence $(\varphi_n,\varphi_n^c)$ of $c$-concave conjugate functions. It is easy to check that $\{f_n\}$ is equicontinuous on $X$: this follows from the $c$-concavity property and from the uniform continuity of $c$ (observe that $\varphi_n(x_1)-\varphi_n(x_2) = \varphi_n^{cc}(x_1)-\varphi_n^{cc}(x_2) \le \sup_Y\{c(x_1,\,\cdot\,)-c(x_2,\,\cdot\,)\}$). Then, by Ascoli's theorem, possibly passing to subsequences, we may assume that: $\varphi_n - c_n$ converges uniformly to some continuous function $\bar\varphi$ where $\{c_n\}$ is a suitable sequence of reals. Then, one checks that $\bar\varphi$ is still $c$-concave and that $(\varphi_n-c_n)^c = \varphi_n^c + c_n$ converges uniformly to

$\bar{\varphi}^c$. Thus, recalling that $\mu(X) = \nu(Y) = 1$, we deduce that

$$\begin{aligned}\sup[7] &= \lim_n \left( \int_X \varphi_n \,\mathrm{d}\mu + \int_Y \varphi_n^c \,\mathrm{d}\nu \right) \\ &= \lim_n \left[ \int_X (\varphi_n - c_n) \,\mathrm{d}\mu + \int_Y (\varphi_n^c + c_n) \,\mathrm{d}\nu \right] \\ &= \int_X \bar{\varphi} \,\mathrm{d}\mu + \int_Y \bar{\varphi}^c \,\mathrm{d}\nu\end{aligned}$$

The last assertion is a consequence of the extremality relation:

$$\begin{aligned}0 &= \inf[6] - \sup[7] \\ &= \int_{X\times Y} \big(c(x,y) - \bar{\varphi}(x) - \bar{\psi}(y)\big)\bar{\gamma}(\mathrm{d}x\mathrm{d}y)\end{aligned}$$

□

**Remark 24**

(i) In their discrete version (i.e., $\mu, \nu$ are atomic measures), problems [6] and [7] can be seen as particular linear programming problems (see the section "Finite-dimensional case").

(ii) The case $X = Y \subset \mathbb{R}^n$ and $c(x,y) = (1/2)|x-y|^2$ is important. In this case, the notion of $c$-concavity is linked to convexity and the Fenchel transform since, for every $\varphi \in C^0(X)$, one has

$$\frac{|\cdot|^2}{2} - \varphi^c = \left( \frac{|\cdot|^2}{2} - \varphi \right)^*$$

Then if $(\bar{\varphi}, \bar{\varphi}^c)$ is a solution of [7], we find that

$$\varphi_0(x) := \frac{|x|^2}{2} - \bar{\varphi}(x)$$

is convex continuous and that the extremality condition: $\bar{\varphi}(x) + \bar{\varphi}^c(y) = c(x,y)$ is equivalent to Fenchel equality $\varphi_0(x) + \varphi_0^*(y) = (x|y)$. Therefore, any optimal $\bar{\gamma}$ is supported in the graph of the subdifferential map $\partial\varphi_0$. In the case where $\mu$ is absolutely continuous with respect to the Lebesgue measure, it is then easy to deduce that the optimal $\bar{\gamma}$ is unique and that $\bar{\gamma} = \gamma_{T_0}$, where $T_0 = \nabla\varphi_0$ is the unique gradient (a.e. defined) of a convex function such that $\nabla\varphi_0^\sharp(\mu) = \nu$. This is a celebrated result by Y Brenier (see, e.g., the monographs by Evans (1997) and Villani (2003)).

### The Distance Case

In the following, we assume that $X = Y$ and that $c(x,y)$ is a semidistance. As an immediate consequence of the triangular inequality, we have the following equivalence:

$$\begin{aligned}\varphi \quad c\text{-concave} &\Leftrightarrow \varphi(x) - \varphi(y) \le c(x,y), \ \forall (x,y) \\ &\Leftrightarrow \ \varphi^c = -\varphi\end{aligned}$$

Let us denote $\mathrm{Lip}_1(X) := \{u \in C^0(X) \colon u(x) - u(y) \le c(x,y)\}$. The first assertion of Theorem 23 becomes the Kantorovich–Rubintein duality formula:

$$T_c(\mu,\nu) = \max\left\{ \int_X u \,\mathrm{d}(\mu - \nu) \colon u \in \mathrm{Lip}_1(X) \right\} \qquad [8]$$

As it appears, $T_c(\mu,\nu)$ depends only on the difference $f = \mu - \nu$, which belongs to the space $\mathcal{M}_0(X)$ of signed measure on $X$ with zero average. Defining $N(f) := T_c(f^+, f^-)$ provides a seminorm (Kantorovich norm) on $\mathcal{M}_0(X)$ (it turns out that $\mathcal{M}_0(X)$ is not complete and that in general its completion is a strict subspace of the dual of $\mathrm{Lip}(X)$).

We will now specialize to the case where $X$ is a compact manifold equipped with a geodesic distance. This will allow us to link the original problem to another primal–dual formulation closer to that considered in the section "Primal–dual formulation in mechanics" and yielding to a connection with partial differential equations. As a model example, let us assume that $K = \bar{\Omega}$, where $\Omega$ is a bounded connected open subset of $\mathbb{R}^n$ with a Lipschitz boundary. Let $\Sigma \subset \bar{\Omega}$ be a compact subset (on which the transport will have zero cost) and define

$$\begin{aligned}c(x,y) := \inf\{ &\mathcal{H}^1(S \setminus \Sigma) \colon \\ &S \text{ Lipschitz curve joining } x \text{ to } y, S \subset \bar{\Omega}\}\end{aligned} \qquad [9]$$

where $\mathcal{H}^1$ denotes the one-dimensional Hausdorff measure (length). It is easy to check that

$$c(x,y) = \min\{\delta_\Omega(x,y), \delta_\Omega(x,\Sigma) + \delta_\Omega(y,\Sigma)\}$$

where $\delta_\Omega(x,y)$ is the geodesic distance on $\Omega$ (induced by the Euclidean norm). Furthermore, the following characterization holds:

$$\begin{aligned}&u \in \mathrm{Lip}_1(X) \Longleftrightarrow u \in W^{1,\infty}(\Omega), \\ &\quad |\nabla u| \le 1 \text{ a.e. in } \Omega, \ u = cte \text{ on } \Sigma\end{aligned} \qquad [10]$$

Since $f := \mu - \nu$ is balanced, the value of the constant on $\Sigma$ in [10] is irrelevant and can be set to 0. Thus we may rewrite the right hand side member of [8] in a equivalent way as

$$\max\left\{ \int_{\bar{\Omega}} u \,\mathrm{d}f \colon u \in W^{1,\infty}(\Omega), \right. \left. |\nabla u| \le 1 \text{ a.e. on } \Omega, \ u = 0 \text{ on } \Sigma \right\} \qquad [11]$$

We will now derive a new dual problem for [11] by using Proposition 14. To this aim, we consider

$X = C^1(\bar{\Omega})$ (as a closed subspace of $W^{1,\infty}(\Omega)$), $Y = C^0(\bar{\Omega};\mathbb{R}^n)$, $Y^* = \mathcal{M}_b(\bar{\Omega};\mathbb{R}^n)$ and the operator $A: u \in X \mapsto \nabla u \in Y$.

**Theorem 25** *Let* $\mu, \nu \in \mathcal{P}(\bar{\Omega})$, $f = \mu - \nu$ *and* $c$ *defined by* [9]. *Then,*

$$T_c(\mu,\nu) = \min\left\{ \int_{\bar{\Omega}} |\lambda| : \lambda \in \mathcal{M}_b(\bar{\Omega};\mathbb{R}^n), -\operatorname{div}\lambda = f \text{ on } \bar{\Omega}\setminus\Sigma \right\} \quad [12]$$

*where the divergence condition is intended in the sense that*

$$\int_{\bar{\Omega}} \lambda \cdot \nabla\varphi = \int_{\bar{\Omega}} \varphi\, df$$

*for all* $\varphi \in C^\infty$ *compactly supported in* $\mathbb{R}^n \setminus \Sigma$.

**Proof** (*sketch*) We apply Proposition 14 with $\phi(u) = -\int_{\bar{\Omega}} u\, df$ if $u = 0$ on $\Sigma$ ($+\infty$ otherwise), $A = \nabla$, and $\psi(v) = 0$ if $|v| \le 1$ on $\bar{\Omega}$ ($+\infty$ otherwise). We obtain that the minimum $\alpha$ in [12] is reached and that $\alpha = \beta$, where

$$-\beta := \inf\left\{ -\int_{\bar{\Omega}} u\, df : u \in C^1(\bar{\Omega}), |\nabla u| \le 1 \text{ on } \Omega\ u = 0 \text{ on } \Sigma \right\}$$

To prove that $\beta = T_c(\mu,\nu) = \sup$ (11), we consider a maximizer $\bar{u}$ in [11] and prove that it can be approximated uniformly by a sequence $\{u_n\}$ of functions in $C^1(\bar{\Omega})$ which satisfy the same constraints. This technical part is done by truncation and convolution arguments (we refer to Bouchitté *et al.* (2003) for details). □

**Remark 26** By localizing the integral identity associated with [12], it is possible to deduce the optimality conditions which characterize optimal pairs $(\bar{u}, \bar{\lambda})$ for [11], [12] (without requiring any regularity). This is done by using a weak notion of tangential gradient with respect to a measure (see Bouchitté *et al.* (1997) and Bouchitté and Fragalà (2002)). If $\bar{\lambda} = \bar{\sigma}\, dx$ where $\sigma \in L^1(\Omega;\mathbb{R}^n)$ and if $\Sigma \subset \partial\Omega$, then we find that $\bar{\sigma} = a\nabla\bar{u}$, where the pair $(\bar{u}, a)$ solves the following system:

$$\begin{aligned} -\operatorname{div}(a\nabla\bar{u}) &= f \text{ on } \Omega && (\textit{diffusion equation}) \\ |\nabla\bar{u}| &= 1 \text{ a.e. on } \{a > 0\} && (\textit{eikonal equation}) \\ u &= 0 \text{ a.e. on } \Sigma && \\ \frac{\partial u}{\partial n} &= 0 \text{ on } \Sigma && \end{aligned}$$

**Remark 27** Given a solution $\bar{\gamma}$ for [6], we can construct a solution $\bar{\lambda}$ for [12] by selecting for every $(x,y) \in \operatorname{spt}(\bar{\gamma})$ a geodesic curve $S_{xy}$ joining $x$ and $y$ (possibly passing through the free-cost zone $\Sigma$) and by setting, for every test $\phi$:

$$\langle \bar{\lambda}, \phi \rangle := \int_{\bar{\Omega}\times\bar{\Omega}} \left( \int_{S_{xy}} \phi \cdot \tau_{S_{xy}}\, d\mathcal{H}^1 \right) \bar{\lambda}(dx dy)$$

where $\tau_{S_{xy}}$ denote the unit oriented tangent vector (see Bouchitté and Buttazzo (2001)). It is also possible to show (see Ambrosio (2003)) that any solution $\bar{\lambda}$ can be represented as before through a particular solution $\bar{\gamma}$. As a consequence, the support of any solution $\bar{\gamma}$ of [12] is supported in the geodesic envelope of the set $\operatorname{spt}(\mu) \cup \operatorname{spt}(\nu) \cup \Sigma$. However, we stress the fact that, in general, there is no uniqueness at all of the optimal triple $(\bar{\gamma}, \bar{u}, \bar{\lambda})$ for [6], [11] and [12].

**Remark 28** An approximation procedure for particular solutions of problems [11], [12] can be obtained by solving a $p$-Laplace equation and then by sending $p$ to infinity. Precisely, consider the solution $u_p \in W^{1,p}(\Omega)$ of

$$\begin{aligned} -\operatorname{div}(|\nabla u|^{p-2}\nabla u) &= f && \text{on } \bar{\Omega}\setminus\Sigma \\ u &= 0 && \text{on } \Sigma \end{aligned}$$

which, for $p > n$, exists (due to the compact embedding $W^{1,p}(\Omega) \subset C^0(\bar{\Omega})$) and is unique. In Bouchitté *et al.* (2003) it is proved that the sequence $\{(u_p, \sigma_p)\}$, where $\sigma_p = |\nabla u_p|^{p-2}\nabla u_p$, is relatively compact in $\mathcal{M}_b(\bar{\Omega};\mathbb{R}^n) \times C^0(\bar{\Omega}$ (weakly star with respect to the first component) and that every cluster point $(\bar{u}, \bar{\lambda})$ solves [11], [12]. It is an open problem to know whether or not such a cluster point is unique. If the answer is "yes," the process described above would select one optimal pair among all possible solutions. As far as problem [11] is concerned, this problem is connected with the theory of viscosity solutions for the infinite Laplacian (see Evans (1997)) although this theory does not provide an answer as it erases the role of the source term $f$. On the other hand, a new entropy selection principle should be found for the solutions of dual problem [12]. In fact, the following partial result holds: let $E: \mathcal{M}_b(\bar{\Omega};\mathbb{R}^n) \to \mathbb{R} \cup \{+\infty\}$ be the functional defined by

$$E(\lambda) := \begin{cases} \int_\Omega |\sigma| \log(|\sigma|)\, dx & \text{if } \lambda \ll dx \text{ and } \sigma = \dfrac{d\lambda}{d|\lambda|} \\ +\infty & \text{otherwise} \end{cases}$$

Assume that [12] admits at least one solution $\lambda_0$ such that $E(\lambda_0) < +\infty$. Then it can be shown that

the sequence $\{\sigma_p\}$ does converge weakly-star to $\bar{\lambda}$, the unique minimizer of the problem

$$\inf\{E(\lambda): \lambda \text{ solution of } [12]\}$$

The general case, in particular when all optimal measures are singular, is open.

**Remark 29** Variational problems [11], [12] have important counterparts in the theory of elasticity and in optimal design problems (see Bouchitté and Buttazo (2001)). They read, respectively, as

$$\max\left\{\int_{\bar{\Omega}} u \cdot \mathrm{d}f: \ u \in \cap_{p>1} W^{1,p}(\Omega; \mathbb{R}^n), \right.$$
$$\left. \nabla u(x) \in K \text{ a.e. on } \Omega, \ u = 0 \text{ on } \Sigma\right\}$$
$$\min\left\{\int_{\bar{\Omega}} \rho_K^0(\lambda): \lambda \in \mathcal{M}_b(\bar{\Omega}; \mathbb{R}^{n^2}_{\mathrm{sym}}), \right.$$
$$\left. -\operatorname{div}\lambda = f \text{ on } \bar{\Omega}\backslash\Sigma\right\}$$

where $K \subset \mathbb{R}^{n^2}_{\mathrm{sym}})$ is a convex compact subset of symmetric second-order tensors associated with the elastic material, $\rho_K^0(\xi) = \sup\{\xi \cdot z: z \in K\}$ is convex positively 1-homogeneous and the functional on measures $\int_{\bar{\Omega}} \rho_K^0(\lambda)$ is intended in the sense given in [1]. A celebrated example is given by Michell's problem (Michell 1904) where $n = 2$ and $K := \{z \in \mathbb{R}^{n^2}_{\mathrm{sym}}, |\rho(z)| \le 1\}$, $\rho(z)$ being the largest singular value of $z$. The potential $\rho_K^0$ is given by the nondifferentiable convex function $\rho_K^0(\xi) = \tau_1(\xi) + \tau_2(\xi)$, where the $\tau_i(\xi)$'s are the singular values of $\xi$.

Unfortunately, it is not known if the vector variational problem above can be linked to an optimal transportation problem of the type [6], even if the analogous of equivalence [10] does exist in the Michell's case, namely (for $\Omega$ convex):

$$\rho(e(u)) \le 1 \quad \text{on } \Omega$$
$$\iff |(u(x) - u(y)|x - y)| \le |x - y|^2, \ \forall (x, y)$$

Cape Town, South Africa

## Introduction

Mathematical cosmology focuses on the geometrical and mathematical aspects of the study of the universe as a whole. Because the structure of spacetime (with metric tensor $g_{ab}(x^j)$) is governed by gravity, with matter and energy causing spacetime curvature according to the nonlinear gravitational field equations of the theory of general relativity, it has its roots in differential geometry. It is to be distinguished from the three other major aspects of modern cosmology, namely astrophysical cosmology, high-energy physics cosmology, and observational cosmology; see Peacock (1999) for these aspects.

The Einstein field equations (EFEs) are

$$R_{ab} - \frac{1}{2}Rg_{ab} + \Lambda g_{ab} = \kappa T_{ab} \qquad [1]$$

where $R_{ab}$ is the Ricci tensor, $R$ the Ricci scalar, $T_{ab}$ the matter tensor, $\Lambda$ the cosmological constant, and $\kappa$ the gravitational constant. Cosmological models differ from generic solutions of these equations in that they have preferred world lines in spacetime associated with the motion of matter and distribution of radiation (Ellis 1971). This is a classic case of a broken symmetry: the underlying equations [1] are locally Lorentz invariant but their solutions are not. These preferred world lines, characterized by a unit 4-velocity vector $u^a$, are associated at late times with "fundamental observers," and a key aspect of cosmological modeling is determining the observational relations such observers would determine through astronomical observations.

The dynamics of cosmological models is determined by their matter content. This is usually represented in simplified form, often using the "perfect-fluid" approximation to represent the effect of matter or radiation; that is,

$$T_{ab} = (\rho + p)u_a u_b + p g_{ab} \qquad [2]$$

where $\rho$ is the energy density and $p$ the pressure, and the matter 4-velocity $u_b$ is the preferred cosmological 4-velocity. This description can include a scalar field $\phi$ with dynamics governed by the Klein–Gordon equation, provided $u_a$ is normal to spacelike surfaces $\{\phi = \text{const}\}$. Suitable equations of state describe the nature of the matter envisaged (e.g., $p = 0$ for baryons, whereas $p = \rho/3$ for radiation); in the case of a scalar field with potential $V(\phi)$ and spacelike surfaces $\{\phi = \text{const.}\}$, on choosing $u^a$ orthogonal to these surfaces, the stress tensor has a perfect-fluid form with $\rho = (1/2)\dot{\phi}^2 + V(\phi)$, $p = (1/2)\dot{\phi}^2 - V(\phi)$. A cosmological constant $\Lambda$ can be represented as a perfect fluid with $\rho + p = 0$, $\Lambda = p$. More general matter may involve a momentum flux density $q_a$ and anisotropic pressures $\pi_{ab}$ (Ehlers 1961). Whatever the nature of the matter, it will usually be required to satisfy energy conditions (Hawking and Ellis 1973). All realistic matter has a positive inertial mass density:

$$\rho + p > 0 \qquad [3]$$

(note that realistic cosmological models are nonempty), whereas all ordinary matter has a positive gravitational mass density:

$$\rho + 3p > 0 \qquad [4]$$

but this is not necessarily true for a scalar field or effective cosmological constant.

Mathematical cosmology (Ellis and van Elst 1999) studies (1) generic properties of solutions with a preferred 4-velocity field and matter content as indicated above, (2) the standard FLRW models, (3) approximate FLRW solutions, and (4) other exact and approximate cosmological solutions. The ultimate underlying issue is (5) the origin of the universe. We look at these in turn. We aim to use covariant methods as far as possible, to avoid being misled by coordinate effects, and to obtain exact solutions and exact results as far as possible, because approximate methods can be misleading in the case of these nonlinear field equations.

## Exact Properties

We can split the equations into spacelike and timelike parts relative to the 4-velocity $u^a$, obtaining the $(1+3)$ covariant dynamical equations and identities in terms of the fluid shear $\sigma_{ab}$, vorticity $\omega_{ab}$, expansion $\Theta = u^a{}_{;a}$, and acceleration $a^b = u_{a;b}u^b$ (Ehlers 1961, Ellis 1971, Ellis and van Elst 1999). The energy density of a perfect fluid obeys the conservation equation

$$\dot{\rho} = -3(\rho + p)\frac{\dot{S}}{S} \qquad [5]$$

with extra terms occurring in the case of more complex matter. From the momentum equations, pressure-free solutions are geodesic ($a^b = 0$). The crucial Raychaudhuri–Ehlers equation for the

time derivative of the expansion (Ehlers 1961) can be written as

$$3\frac{\ddot{S}}{S} = 2(\omega^2 - \sigma^2) + a^b_{;b} - \frac{\kappa}{2}(\rho + 3p) + \Lambda \qquad [6]$$

where the representative length scale $S$ is defined by $\Theta = 3\dot{S}/S$. This is the basis of the "fundamental singularity theorem": if in an expanding universe $\omega = 0 = a^b$ and the combined matter present satisfies [4], with $\Lambda \leq 0$, then there was a singularity where $S \to 0$ a finite time $t_0 < 1/H_0$ ago, $H_0 = (\dot{S}/S)_0$ being the present value of the Hubble constant. The energy density will diverge there, so this is a spacetime singularity: an origin of physics, matter, and spacetime itself. However, the deduction does not follow if there is rotation or acceleration, which could conceivably avoid the singularity, so this result is by itself inconclusive for realistic cosmologies.

The vorticity obeys conservation laws analogous to those in Newtonian theory (Ehlers 1961). Vorticity-free solutions ($\omega = 0$) occur whenever the fluid flow lines are hypersurface-orthogonal in spacetime, that is, there exists a cosmic time function for the comoving observers, which will measure proper time along the flow lines if additionally the fluid flow is geodesic. The rate of change of shear is related to the conformal curvature (Weyl) tensor, which represents the free gravitational field, and which splits into an electric part $E_{ab}$ and a magnetic part $H_{ab}$ in close analogy with electromagnetic theory. Shear-free solutions ($\sigma = 0$) are very special because they strongly constrain the Weyl tensor; indeed if the flow is shear free and geodesic, then it either does not expand ($\Theta = 0$), or does not rotate ($\omega = 0$) (Ellis 1967). The set of cosmological observations associated with generic cosmological models has been characterized in power series form by Kristian and Sachs (1966), and that result has been extended to general models by Ellis *et al.* (1985).

The local regularity of the theory is expressed in existence and uniqueness theorems for the EFEs, provided the matter behavior is well defined through prescription of suitable equations of state (Hawking and Ellis 1973). However, in general the theory breaks down in the large, and this feature is specified by the Hawking–Penrose singularity theorems, predicting the existence of a geodesic incompleteness of spacetime under conditions applicable to realistic cosmological models satisfying the energy conditions given by eqns [3] and [4] (Hawking and Ellis 1973, Tipler *et al.* 1980). However, the conclusion does not follow if the energy conditions are not satisfied. Furthermore, the deduction follows only if the gravitational field equations remain valid to arbitrarily early times; but we would in fact expect that, at high enough energy densities, quantum gravity would take over from classical gravity, so whether or not there was indeed a singularity would depend on the nature of the as yet unknown theory of quantum gravity. The cash value of the singularity theorems then is the implication that, when the energy conditions are satisfied, one would indeed be involved in such a quantum gravity realm in the very early universe.

## The Standard Friedmann–Lemaître Models

The standard models of cosmology are the Friedmann–Lemaître (FL) models with Robertson–Walker (RW) geometry: that is, they are exactly spatially homogeneous and locally isotropic, invariant under a $G_6$ of isometries (Robertson 1933, Ehlers 1961). They have a unique cosmic time function $t$, with space sections $\{t = \text{const.}\}$ of constant spatial curvature orthogonal to the uniquely preferred 4-velocity $u^a$. The fluid acceleration, vorticity, and shear all vanish, and all physical quantities depend only on the time coordinate $t$. They can be represented by a metric with scale factor $S(t)$:

$$\begin{aligned} ds^2 &\equiv g_{ab}dx^a dx^b \\ &= -dt^2 + S^2(t)\{dr^2 + f^2(r)(d\theta^2 + \sin^2\theta\, d\phi^2)\} \end{aligned} \qquad [7]$$

in comoving coordinates $(x^a) = (t, r, \theta, \phi)$, where $f(r) = \{\sin r, r, \sinh r\}$ if $\{k = +1, 0, -1\}$, and the matter is a perfect fluid with 4-velocity vector $u^a = dx^a/ds = \delta^a_0$. The curvature of the space sections $\{t = \text{const.}\}$ is $K = k/S^2$; these 3-spaces are necessarily closed (compact) if they are positively curved ($k = +1$), but may be open or closed in the flat ($k = 0$) and negatively curved ($k = -1$) cases, depending on their topology (Lachieze-Rey and Luminet 1995).

Matter obeys the conservation equation [5], whose outcome depends on the equation of state; for baryons $\rho = M/S^3$, whereas for radiation $\rho = M/S^4$, where $M$ is a constant. The dynamics of the models is governed by the Raychaudhuri equation

$$3\frac{\ddot{S}}{S} = -\frac{\kappa}{2}(\rho + 3p) + \Lambda \qquad [8]$$

which has the Friedmann equation

$$\frac{3\dot{S}^2}{S^2} = \kappa\rho + \Lambda - \frac{3k}{S^2} \qquad [9]$$

as a first integral whenever $\dot{S} \neq 0$. Depending on the matter components present, one can qualitatively

characterize the dynamical behavior of these models (Robertson 1933) and find exact and approximate solutions to these equations as well as phase planes representing the relation of the different models to each other; for example, Ehlers and Rindler (1989) give the phase planes for models with noninteracting matter and radiation and an arbitrary cosmological constant. Universes with maxima or minima in $S(t)$ can only occur if $k=+1$; when $\Lambda=0$, the universe recollapses in the future iff $k=+1$. Static solutions are possible only if $k=+1$ and (assuming [4]) $\Lambda>0$. The simplest expanding solutions are the Einstein–de Sitter universes with $k=0=\Lambda$.

Equation [8] is a special case of [6], with corresponding implications: if the combined matter present satisfies [4], with $\Lambda\leq 0$, then there must have been an initial singularity, or at least the universe must have emerged from a quantum gravity domain. The temperature would have been arbitrarily high in the past, so there was a hot big bang era in the early universe where matter and radiation were in equilibrium with each other at very high temperatures that rapidly fell as the universe expanded. Many physical processes took place then, in particular nucleosynthesis of light elements took place at $\sim 10^9$ K. Decoupling of matter and radiation took place at a temperature of $\sim 4000$ K, followed by formation of stars and galaxies (see Peacock (1999) for a discussion of these physical processes). The black-body radiation emitted by the surface of last scattering at 4000 K is observed by us today as cosmic black-body radiation (CBR) at a temperature of 2.75 K.

One can determine observational relations for these models such as the magnitude–redshift relation for "standard candles" at recent times from the EFEs (Sandage 1961). The aim of observations is to determine the Hubble constant $H_0$, dimensionless deceleration parameter $q_0=-(3/H_0^2)(\ddot{S}/S)_0$, and normalized density parameters $\Omega_{0i}=\kappa\rho_{0i}/3H_0^2$ for each component of matter present. The spatial curvature and the cosmological constant then follow from [6] and [9]; also the present scale factor $S_0$ is determined if $k\neq 0$. The universe is of positive spatial curvature $(k=+1)$ iff $\Omega_0\equiv\Omega_{\rm m}+\Omega_\Lambda>1$, where $\Omega_{\rm m}\equiv\sum_i\Omega_{0i}$, $\Omega_\Lambda=\Lambda/3H_0^2$. Current observations indicate $\Omega_{\rm m}\simeq 0.3, \Omega_\Lambda\simeq 0.7, \Omega_0\simeq 1.02\pm 0.02$. Because the nucleosynthesis results limit the baryon density to a very low value $(\Omega_{0\rm b}\simeq 0.02)$, which is about the same as the density of luminous matter, this indicates the dominant presence of both nonbaryonic dark matter and a repulsive force corresponding to either a cosmological constant or varying scalar field (dark energy).

Crucial causal limitations occur because of the existence of particle horizons (Rindler 1956), the nature of which is most clear when represented in conformal diagrams (Hawking and Ellis 1973, Tipler *et al.* 1980). These result from the fact that light can only proceed a finite distance in the finite time since the origin of the universe, and imply that for a standard radiation-dominated hot-big-bang early universe, regions of larger than $\sim 1^\circ$ angular size on the surface of last scattering, which emits the CBR, are causally disconnected: hence, no causal process since the start of the universe can account for the extreme isotropy of the CBR ($\Delta T/T\simeq 10^{-5}$ over the whole sky, once a dipole anisotropy $\Delta T/T\simeq 10^{-3}$ due to our local velocity relative to the cosmological rest frame is allowed for). This is the "horizon problem," one of the driving forces behind the theory of "inflation" (Guth 1981): the idea that, in the very early universe, a slow-rolling scalar field led to a brief exponential expansion through at least 50 e-folds (during which time the spacetime was approximately de Sitter), thus smoothing the universe and solving the horizon problem (Guth 1981, Peacock 1999). This is possible because a scalar field can violate the energy condition [3] and so allows acceleration: $\ddot{S}>0$. Consequently, there are now many studies of the dynamics of FLRW solutions driven by scalar fields and the subsequent decay of these scalar fields into radiation. One interesting point is that one can obtain exact solutions of this kind for arbitrarily chosen evolutions $S(t)$, provided they satisfy a restriction on the magnitude of $\dot{S}^2$, by running the field equations backwards to determine the needed potential $V(\phi)$ (Ellis and Madsen 1991). The inflationary paradigm is dominant in present-day theoretical cosmology, but suffers from the problem that it is not in fact a well-defined theory, for there is no single accepted proposal for the physical nature of the effective scalar field underlying the supposed exponential expansion; rather there are numerous competing proposals. As the inflaton has not yet been identified, this theory is not yet soundly linked to well-established physics.

## Approximate FL Solutions

The real universe is, of course, not exactly FL, and studies of structure formation depend on studies of solutions that are approximately FL models – they are realistic ("lumpy") universe models. These enable detailed studies of observable properties such as CBR anisotropies and gravitational lensing induced by matter inhomogeneities, and of the development of those inhomogeneities from quantum fluctuations in the very early universe that then get expanded to very large scales by inflation.

The key problem here is that apart from the standard coordinate freedom allowed in general relativity, there is a serious gauge issue: the background FL model is not uniquely determined by the realistic universe model; however, the magnitudes of many perturbed quantities depend on how it is fitted into the lumpy model. For example, the density perturbation $\delta\rho$ is determined pointwise by the equation

$$\delta\rho(x^i) \equiv \rho(x^i) - \overline{\rho}(x^i)$$

where $\overline{\rho}(x^i)$ is the background density. But by altering the correspondence between the background and realistic models (specifically, by the choice of surfaces $\overline{\rho}(x^i) = \text{const.}$ in the realistic model) one can assign that quantity any value, including zero (if one chooses $\overline{\rho}(x^i) = \rho(x^i)$). This is the "gauge problem."

One can handle it by using standard variables and keeping close track of the gauge freedom at all times. However, one then ends up with higher-order equations than necessary because some of the perturbation modes present are pure gauge modes with no physical significance. Alternatively, one can fix the gauge by some unique specification of how the background model is fitted into the realistic model, but there is no agreement on a unique way to do this, and different choices give different answers. The preferable resolution is to use gauge-invariant variables, either coordinate based (Bardeen 1980) or covariant, based on the $(1+3)$ covariant decomposition of spacetime quantities mentioned above (Ellis and Bruni 1989), in either case resulting in perturbation equations without gauge freedom and of order corresponding to the physical degrees of freedom. The key point in the latter approach is to choose covariant variables that vanish in the background spacetime; they are then automatically gauge invariant. Realistic structure formation studies carry out this process for a mixture of matter components with different average velocities, and extend to a kinetic theory description of the background radiation (see Ellis and van Elst (1999) and references therein). The outcome is a prediction of the CBR anisotropy power spectrum, determined by the inhomogeneities in the gravitational field and the motions of the matter components at decoupling (Sachs and Wolfe 1967). This spectrum can then be compared with observations and used in determining the values of the cosmological parameters mentioned above (see Peacock 1999).

One crucial issue is why it is reasonable to use a perturbed FL model for the observable region of the universe. The key argument is that this is plausible because of the high isotropy of all observations around us when averaged on a sufficiently large spatial scale, and particularly the very low anisotropy of the CBR. The Ehlers–Geren–Sachs (EGS) theorem (Ehlers *et al.* 1968) provides a sound basis for this argument: it shows that if freely propagating CBR (obeying the Liouville equation) is exactly isotropic in an expanding universe domain $\mathcal{U}$,then the universe is exactly FL in that domain (i.e., it has exactly the RW spatially homogenous and isotropic geometry there), the point being that any inhomogeneities in the matter distribution between us and the surface of last scattering will produce anisotropies in the CBR temperature we measure. But that result does not apply to the real universe, because the CBR is not exactly isotropic. The "almost EGS" theorem (Stoeger *et al.* 1995) shows that this result is stable: almost isotropic CBR in the domain $\mathcal{U}$ implies that the universe is almost-FL in that domain. The application to the real universe comes by making a weak Copernican assumption: "we assume we are not special, so all observers in $\mathcal{U}$ (taken to be the visible part of the universe) will also see almost isotropic CBR, just as we do." The result then follows. A further argument for homogeneity of the universe comes from postulating "uniform thermal histories" (Bonnor and Ellis 1986), but that argument is yet to be completed and applied in a practical way.

## Anisotropic and Inhomogeneous Models

The FL universes are geometrically extremely special. We wish further to understand the full range of possible universe models, their dynamical behaviors, and which of them might, at some epoch, realistically represent the real universe. This enables us to see how the approximate FL models fit into this wider set of possibilities, and under what circumstances they are attractors in this set of cosmologies.

Exact solutions are characterized by their spacetime symmetries. Symmetries are characterized by the dimension $s$ of the surfaces of homogeneity and the dimension $q$ of the isotropy group at a general point, together giving the dimension $r = s + t$ of the group of isometries $G_r$ (at special points, such as a center of symmetry, $s$ can decrease and $q$ increase but always so that $r$ stays unchanged). In the case of a cosmological model, because the 4-velocity $u^a$ is invariant under isotropies, the only possible dimensions for the isotropy group are $q = 3, 1, 0$; whereas the dimension $t$ of the surfaces of homogeneity can take any value from 4 to 0. This gives the basis for a classification of cosmological spacetimes (Ellis 1967, Ellis and van Elst 1999).

When $q = 3$, we have isotropic solutions – there are no preferred spatial directions – and it is then a theorem that they must be spatially homogeneous FL universes (Ehlers 1961). When $q = 1$, we

have locally rotationally symmetric (LRS) solutions, with precisely one preferred spacelike direction at a generic point (Ellis 1967). When $q = 0$, the solutions are anisotropic in that there can be no continuous group of rotations leaving the solution invariant; however, there can be discrete isotropies in some special cases.

When $t = 4$,we have spacetime homogeneous solutions, with all physical quantities constant; they cannot expand (by [5] and [3]). Nevertheless, two cases are of interest. For $q = 1$ ($r = 5$) we find the Gödel universe, rotating everywhere with constant vorticity, which illustrates important causal anomalies (Gödel 1949, Hawking and Ellis 1973). For $q = 3$ ($r = 6$), we find the Einstein "static universe" (Einstein 1917), the unique nonexpanding FL model with $k = 1$ and $\Lambda > 0$. It is of interest because it could possibly represent the asymptotic initial state of nonsingular inflationary universe models (Ellis *et al.* 2003). The higher-symmetry models (de Sitter and anti-de Sitter universes with higher-dimensional isotropy groups) are not included here because they do not obey the energy condition [3] – they are empty universes, which can be interesting asymptotic states but are not by themselves good cosmological models.

When $t = 3$, we have spatially homogeneous evolving universe models. For $q = 0$ ($r = 3$), there are a large family of Bianchi universes, spatially homogeneous but anisotropic, characterized into nine types according to the structure constants of the Lie algebra of the three-dimensional symmetry group $G_3$. These can be "orthogonal": the fluid flow is orthogonal to the surfaces of homogeneity, or "tilted"; the latter case can have fluid rotation or acceleration, but the former cannot. They exhibit a large variety of behaviors, including power-law, oscillatory, and nonscalar singularities (Tipler *et al.* 1980). A vexed question is whether truly chaotic behavior occurs in Bianchi IX models. The behavior of large families of these models has been characterized in dynamical systems terms (Wainwright and Ellis 1996), showing the intriguing way that higher-symmetry solutions provide a "skeleton" that guides the behavior of lower-symmetry solutions in the space of spacetimes. Many Bianchi models can be shown to isotropize at late times, particularly if viscosity is present; thus, they are asymptotic to the FL universes in the far future. In some cases, Bianchi models exhibit intermediate isotropization: they are much like FL models for a large part of their life, but are very different from it both at very early and very late stages of their evolution. These could be good models of the real universe. An important theorem by Wald (1983) shows that a cosmological constant will tend to isotropize Bianchi solutions at late times. This is an indication that inflation can succeed in making anisotropic early states resemble FL models at later times. Observational properties like element abundances and CBR anisotropy patterns can be worked out in these models (some of them develop a characteristic isolated "hot spot" in the CBR sky). For $q = 1$ ($r = 4$), we have spatially homogeneous LRS models, either Kantowski Sachs or Bianchi universes, and again observations can be worked out in detail and phase planes developed showing their dynamical behavior, often isotropizing at late times. There are orthogonal and tilted cases, the latter possibly involving nonscalar singularities. For $q = 3$ ($r = 6$), we have the isotropic FL models, discussed above. Both the LRS and isotropic cases could be good models of the real universe.

When $t = 2$, we have inhomogeneous evolving models. This is a very large family, but the LRS ($q = 1, r = 2$) cases have been examined in detail; in the case of pressure-free matter, these are the Tolman–Bondi inhomogeneous models (Bondi 1947) that can be integrated exactly, and have been used for many interesting astrophysical and cosmological studies. Krasiński (1997) gives a very complete catalog of these and lower-symmetry inhomogeneous models and their uses in cosmology. A considerable challenge is the dynamical systems analysis for generic inhomogeneous models, needed to properly understand the early evolution of generic universe models (Uggla *et al.* 2003), and hence to determine what is generic behavior.

## The Origin of the Universe

The issue underlying all this is what led to the initial conditions for the universe, for example, providing the starting conditions for inflation. There are many approaches to studying the quantum gravity phase of cosmology, including the Wheeler–de Witt equation, the path-integral approach, string cosmology, pre-big bang theory, brane cosmology, the ekpyrotic universe, the cyclic universe, and loop quantum gravity approaches. These lie beyond the purview of the present article, except to say that they are all based on unproven extrapolations of known physics. The physically possible paths will become clearer as the nature of quantum gravity is elucidated.

It is pertinent to note that there exist nonsingular realistic cosmological solutions, possible in the light of the violations of the energy condition enabled by the supposed scalar fields that underlie inflationary universe theory. These nonsingular solutions can even avoid the quantum gravity era (Ellis *et al.* 2003). However, they have very fine-tuned initial conditions, which is nowadays considered as a disadvantage; but

there is no proof that whatever processes led to the existence of the universe preferred generic rather than fine-tuned conditions; this is a philosophical rather than physical assumption. It may well be that, as regards the start of the universe, the options are that either an initial singularity occurred, or the initial conditions were very finely tuned and allowed an infinitely existing universe. Investigation of whether this conjecture is in fact valid, and if so which is the best option, are intriguing open topics.

# Cotangent Bundle Reduction

**J-P Ortega**, Université de Franche-Comté, Besançon, France
**T S Ratiu**, Ecole Polytechnique Fédérale de Lausanne, Lausanne, Switzerland

## Introduction

The general symplectic reduction theory (*see* Symmetry and Symplectic Reduction) becomes much richer and has many applications if the symplectic manifold is the cotangent bundle $(T^*Q, \Omega_Q = -\boldsymbol{d}\Theta_Q)$ of a manifold $Q$. The canonical 1-form $\Theta_Q$ on $T^*Q$ is given by $\Theta_Q(\alpha_q)(V_{\alpha_q}) = \alpha_q(T_{\alpha_q}\pi_Q(V_{\alpha_q}))$, for any $q \in Q$, $\alpha_q \in T_q^*Q$, and tangent vector $V_{\alpha_q} \in T_{\alpha_q}(T^*Q)$, where $\pi_Q : T^*Q \to Q$ is the cotangent bundle projection and $T_{\alpha_q}\pi_Q : T_{\alpha_q}(T^*Q) \to T_qQ$ is its tangent map (or derivative) at $q$. In natural cotangent bundle coordinates $(q^i, p_i)$, we have $\Theta_Q = p_i\boldsymbol{d}q^i$ and $\Omega_Q = \boldsymbol{d}q^i \wedge \boldsymbol{d}p_i$.

Let $\Phi : G \times Q \to Q$ be a left smooth action of the Lie group $G$ on the manifold and $Q$. Denote by $g \cdot q = \Phi(g, q)$ the action of $g \in G$ on the point $q \in Q$ and by $\Phi_g : Q \to Q$ the diffeomorphism of $Q$ induced by $g$. The lifted left action $G \times T^*Q \to T^*Q$, given by $g \cdot \alpha_q = T^*_{g\cdot q}\Phi_{g^{-1}}(\alpha_q)$ for $g \in G$ and $\alpha_q \in T_q^*Q$, preserves $\Theta_Q$, and admits the equivariant momentum map $\boldsymbol{J} : T^*Q \to \mathfrak{g}^*$ whose expression is $\langle \boldsymbol{J}(\alpha_q), \xi \rangle = \alpha_q((\xi_Q(q))$, where $\xi \in \mathfrak{g}$, the Lie algebra of $G$, $\langle\, , \rangle : \mathfrak{g}^* \times \mathfrak{g} \to \mathbb{R}$ is the duality pairing between the dual $\mathfrak{g}^*$ and $\mathfrak{g}$, and $\xi_Q(q) = \mathrm{d}\Phi(\exp t\xi, q)/\mathrm{d}t|_{t=0}$ is the value of the

infinitesimal generator vector field $\xi_Q$ of the $G$-action at $q \in Q$ (*see* Hamiltonian Group Actions and Symmetries and Conservation Laws). Throughout this article, it is assumed that the $G$-action on $Q$, and hence on $T^*Q$, is free and proper. Recall also that $((T^*Q)_\mu, (\Omega_Q)_\mu)$ denotes the reduced manifold at $\mu \in \mathfrak{g}^*$ (*see* Symmetry and Symplectic Reduction), where $(T^*Q)_\mu := \mathbf{J}^{-1}(\mu)/G_\mu$ is the orbit space of the $G_\mu$-action on the momentum level manifold $\mathbf{J}^{-1}(\mu)$ and $G_\mu := \{g \in G \mid \mathrm{Ad}_g^*\mu = \mu\}$ is the isotropy subgroup of the coadjoint representation of $G$ on $\mathfrak{g}^*$. The left-coadjoint representation of $g \in G$ on $\mu \in \mathfrak{g}^*$ is denoted by $\mathrm{Ad}_{g^{-1}}^*\mu$.

Cotangent bundle reduction at zero is already quite interesting and has many applications. Let $\rho: Q \to Q/G$ be the $G$-principal bundle projection defined by the proper free action of $G$ on $Q$, usually referred to as the shape space bundle. Zero is a regular value of $\mathbf{J}$ and the map $\varphi_0 : ((T^*Q)_0, (\Omega_Q)_0) \to (T^*(Q/G), \Omega_{Q/G})$ given by $\varphi_0([\alpha_q])(T_q\rho(v_q)) := \alpha_q(v_q)$, where $\alpha_q \in \mathbf{J}^{-1}(0)$, $[\alpha_q] \in (T^*Q)_0$, and $v_q \in T_qQ$, is a well-defined symplectic diffeomorphism.

This theorem generalizes in two nontrivial ways when one reduces at a nonzero value of $\mathbf{J}$: an embedding and a fibration theorem.

## Embedding Version of Cotangent Bundle Reduction

Let $\mu \in \mathfrak{g}^*, Q_\mu := Q/G_\mu, \rho_\mu : Q \to Q_\mu$ the projection onto the $G_\mu$-orbit space, $\mathfrak{g}_\mu := \{\xi \in \mathfrak{g} \mid \mathrm{ad}_\xi^*\mu = 0\}$ the Lie algebra of the coadjoint isotropy subgroup $G_\mu$, where $\mathrm{ad}_\xi\eta := [\xi, \eta]$ for any $\xi, \eta \in \mathfrak{g}$, $\mathrm{ad}_\xi^* : \mathfrak{g}^* \to \mathfrak{g}^*$ the dual map, $\mu' := \mu|_{\mathfrak{g}_\mu} \in \mathfrak{g}_\mu^*$ the restriction of $\mu$ to $\mathfrak{g}_\mu$, and $((T^*Q)_\mu, (\Omega_Q)_\mu)$ the reduced space at $\mu$. The induced $G_\mu$-action on $T^*Q$ admits the equivariant momentum map $\mathbf{J}^\mu : T^*Q \to \mathfrak{g}_\mu^*$ given by $\mathbf{J}^\mu(\alpha_q) = \mathbf{J}(\alpha_q)|_{\mathfrak{g}_\mu}$. Assume there is a $G_\mu$-invariant 1-form $\alpha_\mu$ on $Q$ with values in $(\mathbf{J}^\mu)^{-1}(\mu')$. Then there is a unique closed 2-form $\beta_\mu$ on $Q_\mu$ such that $\rho_\mu^*\beta_\mu = \mathbf{d}\alpha_\mu$. Define the magnetic term $B_\mu := \pi_{Q_\mu}^*\beta_\mu$, where $\pi_{Q_\mu}$ : $T^*Q_\mu \to Q_\mu$ is the cotangent bundle projection, which is a closed 2-form on $T^*Q_\mu$. Then the map $\varphi_\mu : ((T^*Q)_\mu, (\Omega_Q)_\mu) \to (T^*Q_\mu, \Omega_{Q_\mu} - B_\mu)$ given by $\varphi_\mu([\alpha_q])(T_q\rho_\mu(v_q)) := (\alpha_q - \alpha_\mu(q))(v_q)$, for $\alpha_q \in \mathbf{J}^{-1}(\mu)$, $[\alpha_q] \in (T^*Q)_\mu$, and $v_q \in T_qQ$, is a symplectic embedding onto a submanifold of $T^*Q_\mu$ covering the base $Q_\mu$. The embedding $\varphi_\mu$ is a diffeomorphism onto $T^*Q_\mu$ if and only if $\mathfrak{g} = \mathfrak{g}_\mu$. If the 1-form $\alpha_\mu$ takes values in the smaller set $\mathbf{J}^{-1}(\mu)$ then the image of $\varphi_\mu$ is the the vector sub-bundle $[T\rho_\mu(VQ)]^\circ$ of $T^*Q_\mu$, where $VQ \subset TQ$ is the vertical vector sub-bundle consisting of vectors tangent to the $G$-orbits, that is, its fiber at $q \in Q$ equals $V_qQ = \{\xi_Q(q) \mid \xi \in \mathfrak{g}\}$, and $^\circ$ denotes the annihilator relative to the natural duality pairing between $TQ_\mu$ and $T^*Q_\mu$. Note that if $\mathfrak{g}$ is abelian or $\mu = 0$, the embedding $\varphi_\mu$ is always onto and thus the reduced space is again, topologically, a cotangent bundle.

It should be noted that there is a choice in this theorem, namely the 1-form $\alpha_\mu$. Whereas the reduced symplectic space $((T^*Q)_\mu, (\Omega_Q)_\mu)$ is intrinsic, the symplectic structure on the space $T^*Q_\mu$ depends on $\alpha_\mu$. The theorem above states that no matter how $\alpha_\mu$ is chosen, there is a symplectic diffeomorphism, which also depends on $\alpha_\mu$, of the reduced space onto a submanifold of $T^*Q_\mu$.

## Connections

The 1-form $\alpha_\mu$ is usually obtained from a left connection on the principal bundle $\rho_\mu : Q \to Q/G_\mu$ or $\rho : Q \to Q/G$. A left connection 1-form $A \in \Omega^1(Q; \mathfrak{g})$ on the left principal $G$-bundle $\rho : Q \to Q/G$ is a Lie algebra-valued 1-form $A : TQ \to \mathfrak{g}$, where $\mathfrak{g}$ denotes the Lie algebra of $G$, satisfying the conditions $A(\xi_Q) = \xi$ for all $\xi \in \mathfrak{g}$ and $\mathcal{A}(T_q\Phi_g(v)) = \mathrm{Ad}_g(\mathcal{A}(v))$ for all $g \in G$ and $v \in T_qQ$, where $\mathrm{Ad}_g$ denotes the adjoint action of $G$ on $\mathfrak{g}$. The horizontal vector sub-bundle $HQ$ of the connection $A$ is defined as the kernel of $A$, that is, its fiber at $q \in Q$ is the subspace $H_q := \ker A(q)$. The map $v_q \mapsto \mathrm{ver}_q\ (v_q) := [A(q)(v_q)]_Q(q)$ is called the vertical projection, while the map $v_q \mapsto \mathrm{hor}_q(v_q) := v_q - \mathrm{ver}_q(v_q)$ is called the horizontal projection. Since for any vector $v_q \in T_qQ$ we have $v_q = \mathrm{ver}_q(v_q) + \mathrm{hor}_q(v_q)$, it follows that $TQ = HQ \oplus VQ$ and the maps $\mathrm{hor}_q : T_qQ \to H_qQ$ and $\mathrm{ver}_q : T_qQ \to V_qQ$ are projections onto the horizontal and vertical subspaces at every $q \in Q$.

Connections can be equivalently defined by the choice of a sub-bundle $HQ \subset TQ$ complementary to the vertical sub-bundle $VQ$ satisfying the following $G$-invariance property: $H_{g \cdot q}Q = T_q\Phi_g(H_qQ)$ for every $g \in G$ and $q \in Q$. The sub-bundle $HQ$ is called, as before, the horizontal sub-bundle and a connection 1-form $A$ is defined by setting $A(q)(\xi_Q(q) + u_q) = \xi$, for any $\xi \in \mathfrak{g}$ and $u_q \in H_qQ$.

The curvature of the connection $A$ is the Lie algebra-valued 2-form on $Q$ defined by $B(u_q, v_q) = \mathbf{d}A(\mathrm{hor}_q(u_q), \mathrm{hor}_q(v_q))$. When one replaces vectors in the exterior derivative with their horizontal projections, then the result is called the exterior covariant derivative and the preceding formula for $B$ is often written as $B = DA$. Curvature measures the lack of integrability of the horizontal distribution, namely $B(u, v) = -A([\mathrm{hor}(u), \mathrm{hor}(v)])$ for any two vector fields $u$ and $v$ on $Q$. The Cartan structure equations state that $B(u, v) = \mathbf{d}\mathcal{A}(u, v) - [\mathcal{A}(u), \mathcal{A}(v)]$, where the bracket on the right hand side is the Lie bracket in $\mathfrak{g}$.

Since the connection $A$ is a Lie algebra-valued 1-form, for each $\mu \in \mathfrak{g}^*$ the formula $\alpha_\mu(q) := A(q)^*(\mu)$, where $A(q)^* : \mathfrak{g}^* \to T_q^*Q$ is the dual of the linear map $A(q) : T_qQ \to \mathfrak{g}$, defines a usual 1-form on $Q$. This 1-form $\alpha_\mu$ takes values in $\boldsymbol{J}^{-1}(\mu)$ and is equivariant in the following sense: $\Phi_g^* \alpha_\mu = \alpha_{\mathrm{Ad}_g^* \mu}$ for any $g \in G$.

### Magnetic Terms and Curvature

There are two methods to construct the 1-form $\alpha_\mu$ from a connection. The first is to start with a connection 1-form $A^\mu \in \Omega^1(Q; \mathfrak{g}_\mu)$ on the principal $G_\mu$-bundle $\rho_\mu : Q \to Q/G_\mu$. Then the 1-form $\alpha_\mu := \langle \mu|_{\mathfrak{g}_\mu}, A^\mu \rangle \in \Omega^1(Q)$ is $G_\mu$-invariant and has values in $(\boldsymbol{J}^\mu)^{-1}(\mu|_{\mathfrak{g}_\mu})$. The magnetic term $B_\mu$ is the pullback to $T^*(Q/G_\mu)$ of the $\mu|_{\mathfrak{g}_\mu}$-component $\boldsymbol{d}\alpha_\mu$ of the curvature of $A^\mu$ thought of as a 2-form on the base $Q/G_\mu$.

The second method is to start with a connection $A \in \Omega^1(Q, \mathfrak{g})$ on the principal bundle $\rho : Q \to Q/G$, to define $\alpha_\mu := \langle \mu, A \rangle \in \Omega^1(Q)$, and to observe that this 1-form is $G_\mu$-invariant and has values in $\boldsymbol{J}^{-1}(\mu)$. The magnetic term $B_\mu$ is in this case the pullback to $T^*(Q/G_\mu)$ of the $\mu$-component $\boldsymbol{d}\alpha_\mu$ of the curvature of $A$ thought of as a 2-form on the base $Q/G_\mu$.

### The Mechanical Connection

If $(Q, \langle\langle \, , \rangle\rangle)$ is a Riemannian manifold and $G$ acts by isometries, there is a natural connection on the bundle $\rho : Q \to Q/G$, namely, define the horizontal space at a point to be the metric orthogonal to the vertical space. This connection is called the mechanical connection and its horizontal bundle consists of all vectors $v_q \in TQ$ such that $\boldsymbol{J}(\langle\langle v_q, \cdot \rangle\rangle) = 0$.

To determine the Lie algebra-valued 1-form $A$ of this connection, the notion of locked inertia tensor needs to be introduced. This is the linear map $\mathbb{I}(q) : \mathfrak{g} \to \mathfrak{g}^*$ depending smoothly on $q \in Q$ defined by the identity $\langle \mathbb{I}(q)\xi, \eta \rangle = \langle\langle \xi_Q(q), \eta_Q(q) \rangle\rangle$ for any $\xi, \eta \in \mathfrak{g}$. Since the $G$-action is free, each $\mathbb{I}(q)$ is invertible. The connection 1-form whose horizontal space was defined above is given by $A(q)(v_q) = \mathbb{I}(q)^{-1}(\boldsymbol{J}(\langle\langle v_q, \cdot \rangle\rangle))$.

Denote by $K : T^*Q \to \mathbb{R}$ the kinetic energy of the metric $\langle\langle , \rangle\rangle$ on the cotangent bundle, that is, $K(\langle\langle v_q, \cdot \rangle\rangle) := (1/2)\|v_q\|^2$. The 1-form $\alpha_\mu = A(\,\cdot\,)^*\mu$ is characterized for the mechanical connection $A$ by the condition $K(\alpha_\mu(q)) = \inf\{K(\beta_q) \mid \beta_q \in \boldsymbol{J}^{-1}(\mu) \cap T_q^*Q\}$.

### The Amended Potential

A simple mechanical system is a Hamiltonian system on a cotangent bundle $T^*Q$ whose Hamiltonian function is the the sum of the kinetic energy of a Riemannian metric on $Q$ and a potential function $V : Q \to \mathbb{R}$. If there is a Lie group $G$ acting on $Q$ by isometries and leaving the potential invariant, then we have a simple mechanical system with symmetry. The amended or effective potential $V_\mu : Q \to \mathbb{R}$ at $\mu \in \mathfrak{g}^*$ is defined by $V_\mu := H \circ \alpha_\mu$, where $\alpha_\mu$ is the 1-form associated to the mechanical connection. Its expression in terms of the locked moment of inertia tensor is given by $V_\mu(q) := V(q) + (1/2)\langle \mu, \mathbb{I}(q)^{-1}\mu \rangle$. The amended potential naturally induces a smooth function $\widehat{V}_\mu \in C^\infty(Q/G_\mu)$.

The fundamental result about simple mechanical systems with symmetry is the following. The push-forward by the embedding $\varphi_\mu : ((T^*Q)_\mu, (\Omega_Q)_\mu) \to (T^*Q_\mu, \Omega_{Q_\mu} - B_\mu)$ of the reduced Hamiltonian $H_\mu \in C^\infty((T^*Q)_\mu)$ of a simple mechanical system $H = K + V \circ \pi_Q \in C^\infty(T^*Q)$ is the restriction to the vector sub-bundle $\varphi_\mu((T^*Q)_\mu) \subset T^*(Q/G_\mu)$, which is also a symplectic submanifold of $(T^*(Q/G_\mu), \Omega_{Q/G_\mu} - B_\mu)$, of the simple mechanical system on $T^*(Q/G_\mu)$ whose kinetic energy is given by the quotient Riemannian metric on $Q/G_\mu$ and whose potential is $\widehat{V}_\mu$. However, Hamilton's equations on $T^*(Q/G_\mu)$ for this simple mechanical system are computed relative to the magnetic symplectic form $\Omega_{Q/G_\mu} - B_\mu$.

There is a wealth of applications starting from this classical theorem to mechanical systems, spanning such diverse areas as topological characterization of the level sets of the energy–momentum map to methods of proving nonlinear stability of relative equilibria (block-diagonalization of the stability form in the application of the energy–momentum method).

### Fibration Version of Cotangent Bundle Reduction

There is a second theorem that realizes the reduced space of a cotangent bundle as a locally trivial bundle over shape space $Q/G$. This version is particularly well suited in the study of quantization problems and in control theory. The result is the following. Assume that $G$ acts freely and properly on $Q$. Then the reduced symplectic manifold $(T^*Q)_\mu$ is a fiber bundle over $T^*(Q/G)$ with fiber the coadjoint orbit $\mathcal{O}_\mu$. How this is related to the Poisson structure of the quotient $(T^*Q)/G$ will be discussed later.

### The Kaluza–Klein Construction

The extra term in the symplectic form of the reduced space is called a magnetic term because it has this interpretation in electromagnetism. To understand why $B_\mu$ is called a magnetic term, consider the problem of a particle of mass $m$ and charge $e$ moving in $\mathbb{R}^3$ under the influence of a given

magnetic field $\boldsymbol{B} = B_x \boldsymbol{i} + B_y \boldsymbol{j} + B_z \boldsymbol{k}, \operatorname{div} \boldsymbol{B} = 0$. The Lorentz force law (written in the International System) gives the equations of motion

$$m \frac{\mathrm{d}\boldsymbol{v}}{\mathrm{d}t} = e\boldsymbol{v} \times \boldsymbol{B} \qquad [1]$$

where $e$ is the charge and $\boldsymbol{v} = (\dot{x}, \dot{y}, \dot{z}) = \dot{\boldsymbol{q}}$ is the velocity of the particle. What is the Hamiltonian description of these equations?

There are two possible answers to this question. To formulate them, associate to the divergence free vector field $\boldsymbol{B}$ the closed 2-form $B = B_x \boldsymbol{d}y \wedge \boldsymbol{d}z - B_y \boldsymbol{d}x \wedge \boldsymbol{d}z + B_z \boldsymbol{d}x \wedge \boldsymbol{d}y$. Also, write $\boldsymbol{B} = \operatorname{curl} \boldsymbol{A}$ for some other vector field $\boldsymbol{A} = (A_x, A_y, A_z)$ on $\mathbb{R}^3$, called the magnetic potential.

*Answer 1* Take on $T^*\mathbb{R}^3$ the symplectic form $\Omega_B = \boldsymbol{d}x \wedge \boldsymbol{d}p_x + \boldsymbol{d}y \wedge \boldsymbol{d}p_y + \boldsymbol{d}z \wedge \boldsymbol{d}p_z - eB$, where $(p_x, p_y, p_z) = \boldsymbol{p} := m\boldsymbol{v}$ is the momentum of the particle, and $h = m\|\boldsymbol{v}\|^2/2 = m(\dot{x}^2 + \dot{y}^2 + \dot{z}^2)/2$ is the Hamiltonian, the kinetic energy of the particle. A direct verification shows that $\boldsymbol{d}h = \Omega_B(X_h, \cdot\,)$, where

$$X_h = \dot{x}\frac{\partial}{\partial x} + \dot{y}\frac{\partial}{\partial y} + \dot{z}\frac{\partial}{\partial z} + e(B_z\dot{y} - B_y\dot{z})\frac{\partial}{\partial p_x} + e(B_x\dot{z} - B_z\dot{x})\frac{\partial}{\partial p_y} + e(B_y\dot{x} - B_z\dot{x})\frac{\partial}{\partial p_z} \qquad [2]$$

which gives the equations of motion [1].

*Answer 2* Take on $T^*\mathbb{R}^3$ the canonical symplectic form $\Omega = \boldsymbol{d}x \wedge \boldsymbol{d}p_x + \boldsymbol{d}y \wedge \boldsymbol{d}p_y + \boldsymbol{d}z \wedge \boldsymbol{d}p_z$ and the Hamiltonian $h_A = \|\boldsymbol{p} - e\boldsymbol{A}\|^2/2m$. A direct verification shows that $\boldsymbol{d}h_A = \Omega(X_{h_A}, \cdot\,)$, where $X_{h_A}$ has the same expression [2].

Next we show how the magnetic term in the symplectic form $\Omega_B$ is obtained by reduction from the Kaluza–Klein system. Let $Q = \mathbb{R}^3 \times S^1$ with the circle $G = S^1$ acting on $Q$, only on the second factor. Identify the Lie algebra $\mathfrak{g}$ of $S^1$ with $\mathbb{R}$. Since the infinitesimal generator of this action defined by $\xi \in \mathfrak{g} = \mathbb{R}$ has the expression $\xi_Q(\boldsymbol{q}, \theta) = (\boldsymbol{q}, \theta; \boldsymbol{0}, \xi)$, if $TS^1$ is trivialized as $S^1 \times \mathbb{R}$, a momentum map $\boldsymbol{J} : T^*Q = \mathbb{R}^3 \times S^1 \times \mathbb{R}^3 \times \mathbb{R} \to \mathfrak{g}^* = \mathbb{R}$ is given by $\boldsymbol{J}(\boldsymbol{q}, \theta; \boldsymbol{p}, p)\xi = (\boldsymbol{p}, p) \cdot (\boldsymbol{0}, \xi) = p\xi$, that is, $\boldsymbol{J}(\boldsymbol{q}, \theta; \boldsymbol{p}, p) = p$. In this case, the coadjoint action is trivial, so for any $\mu \in \mathfrak{g}^* = \mathbb{R}$, we have $G_\mu = S^1, \mathfrak{g}_\mu = \mathbb{R}$, and $\mu' = \mu$. The 1-form $\alpha_\mu = \mu(A_x\boldsymbol{d}x + A_y\boldsymbol{d}y + A_z\boldsymbol{d}z + \boldsymbol{d}\theta) \in \Omega^1(Q)$, where $\boldsymbol{d}\theta$ denotes the length 1-form on $S^1$, is clearly $G_\mu = S^1$-invariant, has values in $\boldsymbol{J}^{-1}(\mu) = \{(\boldsymbol{q}, \theta; \boldsymbol{p}, \mu) \mid \boldsymbol{q}, \boldsymbol{p} \in \mathbb{R}^3, \theta \in S^1\}$, and its exterior differential equals $\boldsymbol{d}\alpha_\mu = \mu B$. Thus, the closed 2-form $\beta_\mu$ on the base $Q_\mu = Q/G_\mu = Q/S^1 = \mathbb{R}^3$ equals $\mu B$ and hence the magnetic term, that is, the closed 2-form $B_\mu = \pi^*_{Q_\mu}\beta_\mu$ on $T^*Q_\mu = T^*\mathbb{R}^3$, is also $\mu B$ since $\pi_{Q_\mu} : Q = \mathbb{R}^3 \times S^1 \to Q/G_\mu = \mathbb{R}^3$ is the projection. Therefore, the reduced space $(T^*Q)_\mu$ is symplectically diffeomorphic to $(T^*\mathbb{R}^3, \boldsymbol{d}x \wedge \boldsymbol{d}p_x + \boldsymbol{d}y \wedge \boldsymbol{d}p_y + \boldsymbol{d}z \wedge \boldsymbol{d}p_z - \mu B)$, which coincides with the phase space in Answer 1 if we put $\mu = e$. This also gives the physical interpretation of the momentum map $\boldsymbol{J} : T^*Q = \mathbb{R}^3 \times S^1 \times \mathbb{R}^3 \times \mathbb{R} \to \mathfrak{g}^* = \mathbb{R}$, $\boldsymbol{J}(\boldsymbol{q}, \theta; \boldsymbol{p}, p) = p$ and hence of the variable conjugate to the circle variable $\theta$: $p$ represents the charge. Moreover, the magnetic term in the symplectic form is, up to a charge factor, the magnetic field.

The kinetic energy Hamiltonian

$$h(\boldsymbol{q}, \theta; \boldsymbol{p}, p) := \frac{1}{2m}\|\boldsymbol{p}\|^2 + \frac{1}{2}p^2$$

of the Kaluza–Klein metric, that is, the Riemannian metric obtained by keeping the standard metrics on each factor and declaring $\mathbb{R}^3$ and $S^1$ orthogonal, induces the reduced Hamiltonian

$$h_\mu(\boldsymbol{q}) = \frac{1}{2m}\|\boldsymbol{p}\|^2 + \frac{1}{2}\mu^2$$

which, up to the constant $\mu^2/2$, equals the kinetic energy Hamiltonian in Answer 1. Note that this reduced system is not the geodesic flow of the Euclidean metric because of the presence of the magnetic term in the symplectic form. However, the equations of motion of a charged particle in a magnetic field are obtained by reducing the geodesic flow of the Kaluza–Klein metric.

A similar construction is carried out in Yang–Mills theory where $A$ is a connection on a principal bundle and $B$ is its curvature. Magnetic terms also appear in classical mechanics. For example, in rotating systems the Coriolis force (up to a dimensional factor) plays the role of the magnetic term.

## Reconstruction of Dynamics for Cotangent Bundles

A general reconstruction method of the dynamics from the reduced dynamics was given in (*see* Symmetry and Symplectic Reduction). For cotangent bundles, using the mechanical connection, this method simplifies considerably.

Start with the following general situation. Let $G$ act freely on the configuration manifold $Q$; let $h : T^*Q \to \mathbb{R}$ be a $G$-invariant Hamiltonian, $\mu \in \mathfrak{g}^*$, $\alpha_q \in \boldsymbol{J}^{-1}(\mu)$, and $c_\mu(t)$ the integral curve of the reduced system with initial condition $[\alpha_q] \in (T^*Q)_\mu$ given by the reduced Hamiltonian function $h_\mu : (T^*Q)_\mu \to \mathbb{R}$. In terms of a connection $A \in \Omega^1(\boldsymbol{J}^{-1}(\mu); \mathfrak{g}_\mu)$ on the left $G_\mu$-principal bundle $\boldsymbol{J}^{-1}(\mu) \to (T^*Q)_\mu$ the reconstruction procedure proceeds in four steps:

- *Step 1*: Horizontally lift the curve $c_\mu(t) \in (T^*Q)_\mu$ to a curve $d(t) \in \boldsymbol{J}^{-1}(\mu)$ with $d(0) = \alpha_q$.
- *Step 2*: Set $\xi(t) = A(d(t))(X_h(d(t))) \in \mathfrak{g}_\mu$.

- *Step 3*: With $\xi(t) \in \mathfrak{g}_\mu$ determined in step 2, solve the nonautonomous differential equation $\dot{g}(t) = T_e L_{g(t)} \xi(t)$ with initial condition $g(0) = e$, where $L_g$ denotes left translation on $G$; this is the step that involves "quadratures" and is the main obstacle to finding explicit formulas.
- *Step 4*: The curve $c(t) = g(t) \cdot d(t)$, with $d(t)$ found in step 1 and $g(t)$ found in step 3 is the integral curve of $X_h$ with initial condition $c(0) = \alpha_q$.

This method depends on the choice of the connection $A \in \Omega^1(\mathbf{J}^{-1}(\mu); \mathfrak{g}_\mu)$. Here are several particular cases when this procedure simplifies.

(a) *One-dimensional coadjoint isotropy group*. If $G_\mu = S^1$ or $G_\mu = \mathbb{R}$, identify $\mathfrak{g}_\mu$ with $\mathbb{R}$ via the map $a \in \mathbb{R} \leftrightarrow a\zeta \in \mathfrak{g}_\mu$, where $\zeta \in \mathfrak{g}_\mu, \zeta \neq 0$, is a generator of $\mathfrak{g}_\mu$. Then a connection 1-form on the $S^1$ (or $\mathbb{R}$) principal bundle $\mathbf{J}^{-1}(\mu) \to (T^*Q)_\mu$ is the 1-form $A$ on $\mathbf{J}^{-1}(\mu)$ given by $A = (1/\langle \mu, \zeta \rangle)\theta_\mu$, where $\theta_\mu$ is the pullback of the canonical 1-form $\theta \in \Omega^1(T^*Q)$ to the submanifold $\mathbf{J}^{-1}(\mu)$. The curvature of this connection is the 2-form on $(T^*Q)_\mu$ given by $\operatorname{curv}(A) = -(1/\langle \mu, \zeta \rangle)\omega_\mu$, where $\omega_\mu$ is the reduced symplectic form on $(T^*Q)_\mu$. In this case, the curve $\xi(t) \in \mathfrak{g}_\mu$ in step 2 is given by $\xi(t) = \Lambda[h](d(t))$, where $\Lambda \in \mathfrak{X}(T^*Q)$ is the Liouville vector field characterized by the property of being the unique vector field on $T^*Q$ that satisfies the relation $\mathbf{d}\theta(\Lambda, \cdot) = \theta$. In canonical coordinates $(q^i, p_i)$ on $T^*Q, \Lambda = p_i \frac{\partial}{\partial p_i}$.

(b) *Induced connection*. Any connection $\mathcal{A} \in \Omega^1(Q; \mathfrak{g}_\mu)$ on the left principal bundle $Q \to Q/G_\mu$ induces a connection $A \in \Omega^1(\mathbf{J}^{-1}(\mu); \mathfrak{g}_\mu)$ by $A(\alpha_q) \times (V_{\alpha_q}) := \mathcal{A}(q)(T_{\alpha_q}\pi_Q(V_{\alpha_q}))$, where $q \in Q, \alpha_q \in T_q^*Q$, $V_{\alpha_q} \in T_{\alpha_q}(T^*Q)$, and $\pi_Q : T^*Q \to Q$ is the cotangent bundle projection. In this case, the curve $\xi(t) \in \mathfrak{g}_\mu$ in step 2 is given by $\xi(t) = \mathcal{A}(q(t))(\mathbb{F}h(d(t))$, where $q(t) := \pi_Q(d(t))$ is the base integral curve and the vector bundle morphism $\mathbb{F}h : T^*Q \to TQ$ is the fiber derivative of $h$ given by

$$\mathbb{F}h(\alpha_q)(\beta_q) := \left.\frac{\mathrm{d}}{\mathrm{d}t}\right|_{t=0} h(\alpha_q + t\beta_q)$$

for any $\alpha_q, \beta_q \in T_a^*Q$. Two particular instances of this situation are noteworthy.

(b1) Assume that the Hamiltonian $h$ is that of a simple mechanical system with symmetry. Choosing $A$ to be the mechanical connection $A_{\text{mech}}$, the curve $\xi(t) \in \mathfrak{g}_\mu$ in step 2 is given by $\xi(t) = A_{\text{mech}}(q(t))\,(\langle\langle d(t), \cdot \rangle\rangle)$.

(b2) If $Q = G$ is a Lie group, $\dim G_\mu = 1$, and $\zeta$ is a generator of $\mathfrak{g}_\mu$, then the connection $A \in \Omega^1(G)$ can be chosen to equal $\mathcal{A}(g) := (1/\langle \mu, \zeta \rangle)$ $T_g^* R_{g^{-1}}(\mu)$, where $\zeta$ is a generator of $\mathfrak{g}_\mu$ and $R_g$ is right translation on $G$.

(c) *Reconstruction of dynamics for simple mechanical systems with symmetry*. The case of simple mechanical systems with symmetry deserves special attention since several steps in the reconstruction method can be simplified. For simple mechanical systems, the knowledge of the base integral curve $q(t)$ suffices to determine the entire integral curve on $T^*Q$. Indeed, if $h = K + V \circ \pi_q$ is the Hamiltonian, the Legendre transformation $\mathbb{F}h : T^*Q \to TQ$ determines the Lagrangian system on $TQ$ given by $\ell(u_q) = (1/2)\|u_q\|^2 - V(u_q)$, for $u_q \in T_qQ$. Lagrange's equations are second-order and thus the evolution of the velocities is given by the time derivative $\dot{q}(t)$ of the base integral curve. Since $\mathbb{F}h = (\mathbb{F}\ell)^{-1}$, the solution of the Hamiltonian system is given by $\mathbb{F}\ell(\dot{q}(t))$. Using the explicit expression of the mechanical connection and the notation given in the general procedure, the method of reconstruction simplifies to the following steps. To find the integral curve $c(t)$ of the simple mechanical system with $G$-symmetry $h = K + V \circ \pi_Q$ on $T^*Q$ with initial condition $c(0) = \alpha_q \in T_q^*Q$, knowing the integral curve $c_\mu(t)$ of the reduced Hamiltonian system on $(T^*Q)_\mu$ given by the reduced Hamiltonian function $h_\mu : (T^*Q)_\mu \to \mathbb{R}$ with initial condition $c_\mu(0) = [\alpha_q]$ one proceeds in the following manner. Recall the symplectic embedding $\varphi_\mu : ((T^*Q)_\mu, (\Omega_Q)_\mu) \to (T^*(Q/G_\mu), \Omega_{Q/G_\mu} - B_\mu)$. The curve $\varphi_\mu(c_\mu(t)) \in T^*(Q/G_\mu)$ is an integral curve of the Hamiltonian system on $(T^*(Q/G_\mu), \Omega_{Q/G_\mu} - B_\mu)$ given by the function that is the sum of the kinetic energy of the quotient Riemannian metric and the quotient amended potential $\widehat{V}_\mu$. Let $q_\mu(t) := \pi_{Q/G_\mu}(c_\mu(t))$ be the base integral curve of this system, where $\pi_{Q/G_\mu} : T^*(Q/G_\mu) \to Q/G_\mu$ is the cotangent bundle projection.

- *Step 1*: Relative to the mechanical connection $A_{\text{mech}} \in \Omega^1(Q; \mathfrak{g}_\mu)$, horizontally lift $q_\mu(t) \in Q/G_\mu$ to a curve $q_h(t) \in Q$ passing through $q_h(0) = q$.
- *Step 2*: Determine $\xi(t) \in \mathfrak{g}_\mu$ from the algebraic system $\langle\langle \xi(t)_Q(q_h(t)), \eta_Q(q_h(t)) \rangle\rangle = \langle \mu, \eta \rangle$ for all $\eta \in \mathfrak{g}_\mu$, where $\langle\langle \cdot, \cdot \rangle\rangle$ is the $G$-invariant kinetic energy Riemannian metric on $Q$. This implies that $\dot{q}_h(0)$ and $\xi(0)_Q(q)$ are the horizontal and vertical components of the vector $\alpha_q^\sharp \in T_qQ$ which is associated by the metric $\langle\langle \cdot, \cdot \rangle\rangle$ to the initial condition $\alpha_q$.
- *Step 3*: Solve $\dot{g}(t) = T_e L_{g(t)} \xi(t)$ in $G_\mu$ with initial condition $g(0) = e$.
- *Step 4*: The curve $q(t) := g(t) \cdot q_h(t)$, with $q_h(t)$ and $g(t)$ determined in steps 2 and 4, respectively, is the base integral curve of the simple mechanical system with symmetry defined by the function $h$ satisfying $q(0) = 0$. The curve $(\mathbb{F}h)^{-1}(\dot{q}(t)) \in T^*Q$ is the integral curve of this system with initial

condition $c(0)=\alpha_q$. In addition, $q'(t)=g(t)\cdot(\dot{q}_h(t)+\xi(t)_Q(q_h(t)))$ is the horizontal plus vertical decomposition relative to the connection induced on $\boldsymbol{J}^{-1}(\mu)\to(T^*Q)_\mu$ by the mechanical connection $A_{\mathrm{mech}}\in\Omega^1(Q;\mathfrak{g}_\mu)$.

There are several important situations when step 3, the main obstruction to an explicit solution of the reconstruction problem, can be carried out. We shall review some of them below.

(c1) *The case* $G_\mu=S^1$. If $G_\mu$ is abelian, the equation in step 3 has the solution $g(t)=\exp\int_0^t\xi(s)\mathrm{d}s$. If, in addition, $G_\mu=S^1$, then $\xi(s)$ can be explicitly determined by step 2. Indeed, if $\zeta\in\mathfrak{g}_\mu$ is a generator of $\mathfrak{g}_\mu$, writing $\xi(s)=a(s)\zeta$ for some smooth real-valued function $a$ defined on some open interval around the origin, the algebraic equation in step 2 implies that $\langle\langle a(s)\xi(t)_Q(q_h(t)),\zeta_Q(q_h(t))\rangle\rangle=\langle\mu,\zeta\rangle$, which gives $a(s)=\langle\mu,\zeta\rangle/\|\zeta_Q(q_h(s))\|^2$. Therefore, the base integral curve of the solution of the simple mechanical system with symmetry on $T^*Q$ passing through $q$ is

$$q(t)=\exp\left(\langle\mu,\zeta\rangle\int_0^t\frac{\mathrm{d}s}{\|\zeta_Q(q_h(s))\|^2}\zeta\right)\cdot q_h(t)$$

and

$$\dot{q}(t)=\exp\left(\langle\mu,\zeta\rangle\int_0^t\frac{\mathrm{d}s}{\|\zeta_Q(q_h(s))\|^2}\zeta\right)\times\left(\dot{q}_h(t)+\frac{\langle\mu,\zeta\rangle}{\|\zeta_Q(q_h(s))\|^2}\zeta_Q(q_h(t))\right)$$

(c2) *The case of compact Lie groups*. An obvious situation when the differential equation in step 3 can be solved is if $\xi(t)=\xi$ for all $t$, where $\xi$ is a given element of $\mathfrak{g}_\mu$. Then the solution is $g(t)=\exp(t\xi)$. However, step 2 puts certain restrictions under this hypothesis, because it requires that $\langle\langle\xi(t)_Q(q_h(t)),\eta_Q(q_h(t))\rangle\rangle=\langle\mu,\eta\rangle$ for any $\eta\in\mathfrak{g}_\mu$. This is satisfied if there is a bilinear nondegenerate form $(\cdot,\cdot)$ on $\mathfrak{g}$ satisfying $(\zeta,\eta)=\langle\langle\zeta_Q(q),\eta_Q(q)\rangle\rangle$ for all $q\in Q$ and $\zeta,\eta\in\mathfrak{g}$. This implies that $(\cdot,\cdot)$ is positive definite and invariant under the adjoint action of $G$ on $\mathfrak{g}$, so semisimple Lie algebras of noncompact type are excluded. If $G$ is compact, which ensures the existence of a positive adjoint invariant inner product on $\mathfrak{g}$, and $Q=G$, this condition implies that the kinetic energy metric is invariant under the adjoint action. There are examples in which such conditions are natural, such as in Kaluza–Klein theories. Thus, if $G$ is a compact Lie group and $(\cdot,\cdot)$ is a positive-definite metric invariant under the adjoint action of $G$ on $\mathfrak{g}$ satisfying $(\zeta,\eta)=\langle\langle\zeta_Q(q),\eta_Q(q)\rangle\rangle$ for all $q\in Q$ and $\zeta,\eta\in\mathfrak{g}$, then the element $\xi(t)$ in step 2 can be chosen to be constant and is determined by the identity $(\xi,\cdot)=\mu|_{\mathfrak{g}_\mu}$ on $\mathfrak{g}_\mu$. The solution of the equation on step 3 is then $g(t)=\exp(t\xi)$.

(c3) *The case when* $\dot{\xi}(t)$ *is proportional to* $\xi(t)$. Try to find a real-valued function $f(t)$ such that $g(t)=\exp(f(t)\xi(t))$ is a solution of the equation $\dot{g}(t)=T_eL_{g(t)}\xi(t)$ with $f(0)=0$. This gives, for small $t$, the equation $\dot{f}(t)\xi(t)+f(t)\dot{\xi}(t)=\xi(t)$, that is, it is necessary that $\xi(t)$ and $\dot{\xi}(t)$ be proportional. So, if $\dot{\xi}(t)=\alpha(t)\xi(t)$ for some known smooth function $\alpha(t)$, then this gives $f(t)=\int_0^t\exp(\int_t^s\alpha(r)\mathrm{d}r)\,\mathrm{d}s$.

(c4) *The case of* $G_\mu$ *solvable*. Write $g(t)=\exp(f_1(t)\xi_1)\exp(f_2(t)\xi_2)\cdots\exp(f_n(t)\xi_n)$, for some basis $\{\xi_1,\xi_2,\ldots,\xi_n\}$ of $\mathfrak{g}_\mu$ and some smooth real-valued functions $f_i$, $i=1,2,\ldots,n$, defined around zero. It is known that if $G_\mu$ is solvable, the equation in step 3 can be solved by quadratures for the $f_i$.

### Reconstruction Phases for Simple Mechanical Systems with $S^1$ Symmetry

Consider a simple mechanical system with symmetry $G$ on the Riemannian manifold $(Q,\langle\langle\cdot,\cdot\rangle\rangle)$ with $G$-invariant potential $V\in C^\infty(Q)$. If $\mu\in\mathfrak{g}^*$, let $V_\mu$ be the amended potential and $\widehat{V}_\mu\in C^\infty(Q/G_\mu)$ the induced function on the base. Let $c:[0,T]\to T^*Q$ be an integral curve of the system with Hamiltonian $h=K+V\circ\pi_Q$ and suppose that its projection $c_\mu:[0,T]\to(T^*Q)_\mu$ to the reduced space is a closed integral curve of the reduced system with Hamiltonian $h_\mu$. The reconstruction phase associated to the loop $c_\mu(t)$ is the group element $g\in G_\mu$, satisfying the identity $c(T)=g\cdot c(0)$. We shall present two explicit formulas of the reconstruction phase for the case when $G_\mu=S^1$. Let $\zeta\in\mathfrak{g}_\mu=\mathbb{R}$ be a generator of the coadjoint isotropy algebra and write $c(T)=\exp(\varphi\zeta)\cdot c(0)$; in this case, $\varphi$ is identified with the reconstruction phase and, as we shall see in concrete mechanical examples, it truly represents an angle.

If $G_\mu=S^1$, the $G_\mu$-principal bundle $\pi_\mu:\boldsymbol{J}^{-1}(\mu)\to(T^*Q)_\mu:=\boldsymbol{J}^{-1}(\mu)/G_\mu$ admits two natural connections: $A=(1/\mu\zeta)\theta_\mu\in\Omega^1(\boldsymbol{J}^{-1}(\mu))$, where $\theta_\mu$ is the pullback of the canonical 1-form on the cotangent bundle to the momentum level submanifold $\boldsymbol{J}^{-1}(\mu)$, and $\pi_Q^*A_{\mathrm{mech}}\in\Omega^1(\boldsymbol{J}^{-1}(\mu))$. There is no reason to choose one connection over the other and thus there are two natural formulas for the reconstruction phase in this case. Let $c_\mu(t)$ be a periodic orbit of period $T$ of the reduced system and denote also by $h_\mu$ the value of the Hamiltonian function on it.

Assume that $D$ is a two-dimensional surface in $(T^*Q)_\mu$ whose boundary is the loop $c_\mu(t)$. Since the manifolds $(T^*Q)_\mu$ and $T^*(Q/S^1)$ are diffeomorphic (but not symplectomorphic), it makes sense to consider the base integral curve $q_\mu(t)$ obtained by projecting $c_\mu(t)$ to the base $Q/S^1$, which is a closed curve of period $T$. Denote by

$$\langle \widehat{V}_\mu \rangle := \frac{1}{T}\int_0^T \widehat{V}_\mu(q_\mu(t))\,\mathrm{d}t$$

the average of $\widehat{V}_\mu$ over the loop $q_\mu(t)$. Let $q_h(t)\in Q$ be the $A_{\mathrm{mech}}$-horizontal lift of $q_\mu(t)$ to $Q$ and let $\chi$ be the $A_{\mathrm{mech}}$-holonomy of the loop $q_\mu(t)$ measured from $q(0)$, the base point of $c(0)$; its expression is given by $\exp\chi = \exp(-\iint_D B)$, where $B$ is the curvature of the mechanical connection. Denote by $\omega_\mu$ the reduced symplectic form on $(T^*Q)_\mu$. With these notations the phase $\varphi$ is given by

$$\begin{aligned}\varphi &= \frac{1}{\mu\zeta}\iint_D \omega_\mu + \frac{2(h_\mu - \langle \widehat{V}_\mu\rangle)T}{\mu\zeta}\\ &= \chi + \mu\zeta\int_0^T \frac{\mathrm{d}s}{\|\zeta_Q(q_h(s))\|^2}\end{aligned} \qquad [3]$$

The first terms in both formulas are the so-called geometric phases because they carry only geometric information given by the connection, whereas the second terms are called the dynamic phases since they encapsulate information directly linked to the Hamiltonian. The expression of the total phase as a sum of a geometric and a dynamic phase is not intrinsic and is connection dependent. It can even happen that one of these summands vanishes. We shall consider now two concrete examples: the free rigid body and the heavy top.

#### Reconstruction Phases for the Free Rigid Body

The motion of the free rigid body is a geodesic with respect to a left-invariant Riemannian metric on SO(3) given by the moment of inertia of the body. The phase space of the free rigid body motion is $T^*\mathrm{SO}(3)$ and a momentum map $\boldsymbol{J}: T^*\mathrm{SO}(3)\to\mathbb{R}^3$ of the lift of left translation to the cotangent bundle is given by right translation to the identity element. We have identified here $\mathfrak{so}(3)$ with $\mathbb{R}^3$ by the Lie algebra isomorphism $\boldsymbol{x}\in(\mathbb{R}^3,\times)\mapsto\hat{\boldsymbol{x}}\in(\mathfrak{so}(3),[\cdot,\cdot])$, where $\hat{\boldsymbol{x}}(\boldsymbol{y}) = \boldsymbol{x}\times\boldsymbol{y}$, and $\mathfrak{so}(3)^*$ with $\mathbb{R}^3$ by the inner product on $\mathbb{R}^3$. The reduced manifold $\boldsymbol{J}^{-1}(\mu)/G_\mu$ is identified with the sphere $S^2_{\|\mu\|}$ in $\mathbb{R}^3$ of radius $\|\mu\|$ with the symplectic form $\omega_\mu = -\mathrm{d}S/\|\mu\|$, where $\mathrm{d}S$ is the standard area form on $S^2_{\|\mu\|}$ and $G_\mu \cong S^1$ is the group of rotations around the axis $\mu$. These concentric spheres are the coadjoint orbits of the Lie–Poisson space $\mathfrak{so}(3)^*$ and represent the level sets of the Casimir functions that are all smooth functions of $\|\Pi\|^2$, where $\Pi\in\mathbb{R}^3$ denotes the body angular momentum.

The Hamiltonian of the rigid body on the Lie–Poisson space $T^*\mathrm{SO}(3)/\mathrm{SO}(3)\cong\mathbb{R}^3$ is given by

$$h(\Pi) := \frac{1}{2}\left(\frac{\Pi_1^2}{I_1}+\frac{\Pi_2^2}{I_2}+\frac{\Pi_3^2}{I_3}\right)$$

where $I_1, I_2, I_3 > 0$ are the principal moments of inertia of the body. Let $\mathbb{I} := \mathrm{diag}(I_1, I_2, I_3)$ denote the moment of inertia tensor diagonalized in a principal-axis body frame. The Lie–Poisson bracket on $\mathbb{R}^3$ is given by $\{f,g\}(\Pi) = -\Pi\cdot(\nabla f(\Pi)\times\nabla g(\Pi))$ and the equation of motions are $\dot{\Pi} = \Pi\times\Omega$, where $\Omega\in\mathbb{R}^3$ is the body angular velocity given in terms of $\Pi$ by $\Omega_i := \Pi/I_i$, for $i = 1,2,3$, that is, $\Omega = \mathbb{I}^{-1}\Pi$. The trajectories of the these equations are found by intersecting a family of homothetic energy ellipsoids with the angular momentum concentric spheres. If $I_1 > I_2 > I_3$, one immediately sees that all orbits are periodic with the exception of four centers (the two possible rotations about the long and the short moment of inertia axis of the body), two saddles (the two rotations about the middle moment of inertia axis of the body), and four heteroclinic orbits connecting the two saddles.

Suppose that $\Pi(t)$ is a periodic orbit on the sphere $S^2_{\|\mu\|}$ with period $T$. After time $T$, by how much has the rigid body rotated in space? The answer to this question follows directly from [3]. Taking $\zeta = \mu/\|\mu\|$ and the potential $v\equiv 0$ we get

$$\begin{aligned}\varphi &= -\Lambda + \frac{2h_\mu T}{\|\mu\|}\\ &= \iint_D \frac{2\|\mathbb{I}\Pi(s)\|^2 - (\Pi(s)\cdot\mathbb{I}\Pi(s))(\mathrm{tr}\,\mathbb{I})}{(\Pi(s)\cdot\mathbb{I}\Pi(s))^2}\,\mathrm{d}s\\ &\quad + \|\mu\|^3\int_0^T \frac{\mathrm{d}s}{(\Pi(s)\cdot\mathbb{I}\Pi(s))}\end{aligned}$$

where $D$ is one of the two spherical caps on $S^2_{\|\mu\|}$ whose boundary is the periodic orbit $\Pi(t)$, $h_\mu$ is the value of the total energy on the solution $\Pi(t)$, and $\Lambda$ is the oriented solid angle, that is,

$$\Lambda := -\frac{1}{\|\mu\|}\iint_D \omega_\mu, \qquad |\Lambda| = \frac{\mathrm{area}D}{\|\mu\|^2}$$

#### Reconstruction Phases for the Heavy Top

The heavy top is a simple mechanical systems with symmetry $S^1$ on $T^*\mathrm{SO}(3)$ whose Hamiltonian function is given by $h(\alpha_h) := (1/2)\|\alpha_h^\sharp\|^2 + Mg\ell\boldsymbol{k}\cdot h\chi$, where $h\in\mathrm{SO}(3), \alpha_h\in T_h^*\mathrm{SO}(3), \boldsymbol{k}$ is the unit vector of the spatial $Oz$ axis (pointing in the direction opposite to

that of the gravity force), $M \in \mathbb{R}$ is the total mass of the body, $g \in \mathbb{R}$ is the value of the gravitational acceleration, the fixed point about which the body moves is the origin, and $\chi$ is the unit vector of the straight line segment of length $\ell$ connecting the origin to the center of mass of the body. This Hamiltonian is left invariant under rotations about the spatial $Oz$ axis. A momentum map induced by this $S^1$-action is given by $\boldsymbol{J} : T^*\mathrm{SO}(3) \to \mathbb{R}, \boldsymbol{J}(\alpha_h) = T_e^* L_h(\alpha_h) \cdot \boldsymbol{k}$; recall that $T_e^* L_h(\alpha_h) =: \Pi \in \mathbb{R}^3$ is the body angular momentum. The reduced space $\boldsymbol{J}^{-1}(\mu)/S^1$ is generically the cotangent bundle of the unit sphere endowed with the symplectic structure given by the sum of the canonical form plus a magnetic term; equivalently, this is the coadjoint orbit in the dual of the Euclidean Lie algebra $\mathfrak{se}(3)^* = \mathbb{R}^3 \times \mathbb{R}^3$ given by $\mathcal{O}_\mu = \{(\Pi, \Gamma) \mid \Pi \cdot \Gamma = \mu, \|\Gamma\|^2 = 1\}$. The projection map $\boldsymbol{J}^{-1}(\mu) \to \mathcal{O}_\mu$ implementing the symplectic diffeomorphism between the reduced space and the coadjoint orbit in $\mathfrak{se}(3)^*$ is given by $\alpha_h \mapsto (\Pi, \Gamma) := (T_e^* L_h(\alpha_h), h^{-1}\boldsymbol{k})$. The orbit symplectic form $\omega_\mu$ on $\mathcal{O}_\mu$ has the expression $\omega_\mu(\Pi, \Gamma)((\Pi \times \boldsymbol{x} + \Gamma \times \boldsymbol{y}, \Gamma \times \boldsymbol{x}), (\Pi \times \boldsymbol{x}' + \Gamma \times \boldsymbol{y}', \Gamma \times \boldsymbol{x}')) = -\Pi \cdot (\boldsymbol{x} \times \boldsymbol{x}') - \Gamma \cdot (\boldsymbol{x} \times \boldsymbol{y}' - \boldsymbol{x}' \times \boldsymbol{y})$ for any $\boldsymbol{x}, \boldsymbol{x}', \boldsymbol{y}, \boldsymbol{y}' \in \mathbb{R}^3$. The heavy-top equations $\dot{\Pi} = \Pi \times \Omega + Mg\ell\Gamma \times \chi, \dot{\Gamma} = \Gamma \times \Omega$ are Lie–Poisson equations on $\mathfrak{se}(3)^*$ for the Hamiltonian $h(\Pi, \Gamma) = (1/2)\Pi \cdot \Omega + Mg\ell\Gamma \cdot \chi$ and the Lie–Poisson bracket $\{f, g\}(\Pi, \Gamma) = -\Pi \cdot (\nabla_\Pi f \times \nabla_\Pi g) - \Gamma \cdot (\nabla_\Pi f \times \nabla_\Gamma g - \nabla_\Pi g \times \nabla_\Gamma f)$, where $\nabla_\Pi$ and $\nabla_\Gamma$ denote the partial gradients.

Let $(\Pi(t), \Gamma(t))$ be a periodic orbit of period $T$ of the heavy-top equations. After time $T$, by how much has the heavy top rotated in space? The answer is provided by [3]:

$$\begin{aligned}\varphi &= \frac{1}{\mu}\iint_{\mathcal{D}} \omega_\mu + \frac{1}{\mu}\left(2h_\mu T - 2Mg\ell \int_0^T \Gamma(s) \cdot \chi \mathrm{d}s\right) \\ &= \iint_D \frac{2\|\mathbb{I}\Gamma(s)\|^2 - (\Gamma(s) \cdot \mathbb{I}\Gamma(s))(\operatorname{tr} \mathbb{I})}{(\Gamma(s) \cdot \mathbb{I}\Gamma(s))^2} \mathrm{d}s \\ &\quad + \int_0^T \frac{\mathrm{d}s}{\Gamma(s) \cdot \mathbb{I}\Gamma(s)}\end{aligned}$$

where $D$ is the spherical cap on the unit sphere whose boundary is the closed curve $\Gamma(t)$ and $\mathcal{D}$ is a two-dimensional submanifold of the orbit $\mathcal{O}_\mu$ bounded by the closed integral curve $(\Pi(t), \Gamma(t))$. The first terms in each summand represent the geometric phase and the second terms the dynamic phase.

### Gauged Poisson Structures

If the Lie group $G$ acts freely and properly on a smooth manifold $Q$, then $(T^*Q)/G$ is a quotient Poisson manifold (*see* Poisson Reduction), where the quotient is taken relative to the (left) lifted cotangent action. The leaves of this Poisson manifold are the orbit reduced spaces $\boldsymbol{J}^{-1}(\mathcal{O}_\mu)/G$, where $\mathcal{O}_\mu \subset \mathfrak{g}^*$ is the coadjoint $G$-orbit through $\mu \in \mathfrak{g}^*$ (*see* Symmetry and Symplectic Reduction). Is there an explicit formula for this reduced Poisson bracket on a manifold diffeomorphic to $(T^*Q)/G$? It turns out that this question has two possible answers, once a connection on the principal bundle $\pi : Q \to Q/G$ is introduced. The discussion below will also link to the fibration version of cotangent bundle reduction.

In order to present these answers, we review two bundle constructions. Let $G$ act freely and properly on the manifold $P$ and consider the a (left) principal $G$-bundle $\rho : P \to P/G := M$. Let $\tau : N \to M$ be a surjective submersion. Then the pullback bundle $\tilde{\rho} : (n, p) \in \tilde{P} := \{(n, p) \in N \times P \mid \rho(p) = \tau(n)\} \mapsto n \in N$ over $N$ is also a principal (left) $G$-bundle relative to the action $g \cdot (n, p) := (n, g \cdot p)$.

If there is a (left) $G$-action a manifold $V$, then the diagonal $G$-action $g \cdot (p, v) = (g \cdot p, g \cdot v)$ on $P \times V$ is also free and proper and one can form the associated bundle $P \times_G V := (P \times V)/G$ which is a locally trivial fiber bundle $\rho_E : [p, v] \in E := P \times_G V \mapsto \rho(p) \in M$ over $M$ with fibers diffeomorphic to $V$. Analogously, one can form the associated fiber bundle $\rho_{\tilde{E}} : \tilde{E} := \tilde{P} \times_G V \to N$. Summarizing, the associated bundle $\tilde{E} = \tilde{P} \times_G V \to N$ is obtained from the principal bundle $\rho : P \to M$, the surjective submersion $\tau : N \to M$, and the $G$-manifold $V$ by pullback and association, in this order.

These operations can be reversed. First, form the associated bundle $\rho_E : E = P \times_G V \to M$ and then pull it back by the surjective submersion $\tau : N \to M$ to $N$ to get the pullback bundle $\tilde{\rho}_E : \tilde{E} \to N$. The map $\Phi : \tilde{P} \times_G V \to \tilde{E}$ defined by $\Phi([(n, p), v]) := (n, [p, v])$ is an isomorphism of locally trivial fiber bundles.

These general considerations will be used now to realize the quotient Poisson manifold $(T^*Q)/G$ in two different ways. Let $Q$ be a manifold and $G$ a Lie group (with Lie algebra $\mathfrak{g}$) acting freely and properly on it. Let $A \in \Omega^1(Q; \mathfrak{g})$ be a connection 1-form on the left $G$-principal bundle $\pi : Q \to Q/G$. Pull back the $G$-bundle $\pi : Q \to Q/G$ by the cotangent bundle projection $\pi_{Q/G} : T^*(Q/G) \to Q/G$ to $T^*(Q/G)$ to obtain the $G$-principal bundle $\tilde{\pi}_{Q/G} : (\alpha_{[q]}, q) \in \tilde{Q} := \{(\alpha_{[q]}, q) \mid [q] = \pi(q), q \in Q\} \mapsto \alpha_{[q]} \in T^*(Q/G)$. This bundle is isomorphic to the annihilator $(VQ)^\circ \subset T^*Q$ of the vertical bundle $VQ := \ker T\pi \subset TQ$. Next, form the coadjoint bundle $\rho_S : S := \tilde{Q} \times_G \mathfrak{g}^* \to T^*(Q/G)$ of $\tilde{Q}, \rho_S((\alpha_{[q]}, q), \mu) = \alpha_{[q]}$, that is, the associated vector bundle to the $G$-principal bundle $\tilde{Q} \to T^*(Q/G)$ given by the coadjoint representation of $G$ on $\mathfrak{g}^*$. The connection-dependent map $\Phi_A : S \to (T^*Q)/G$ defined by $\Phi_A([(\alpha_{[q]}, q), \mu]) := [T_q^*\pi(\alpha_{[q]}) + A(q)^*\mu]$, where $q \in Q, \alpha_q \in T_q^*Q$, and

$\mu \in \mathfrak{g}^*$, is a vector bundle isomorphism over $Q/G$. The Sternberg space is the Poisson manifold $(S, \{\cdot, \cdot\}_S)$, where $\{\cdot, \cdot\}_S$ is the pullback to $S$ by $\Phi_A$ of the quotient Poisson bracket on $(T^*Q)/G$.

Next, we proceed in the opposite order. Construct first the coadjoint bundle $\rho_{\tilde{\mathfrak{g}}^*} : [q, \mu] \in \tilde{\mathfrak{g}}^* := Q \times_G \mathfrak{g}^* \mapsto [q] \in Q/G$ associated to the principal bundle $\pi : Q \to Q/G$ and then pull it back by the cotangent bundle projection $\pi_{Q/G} : T^*(Q/G) \to Q/G$ to $T^*(Q/G)$ to obtain the vector bundle $\rho_W : W := \{(\alpha_{[q]}, [q, \mu]) \mid \pi_{Q/G}(\alpha_{[q]}) = \rho_{\tilde{\mathfrak{g}}^*}([q, \mu]) = [q]\}$, $\rho_W(\alpha_{[q]}, [q, \mu]) = \alpha_{[q]}$ over $T^*(Q/G)$. Note that $W = T^*(Q/G) \oplus \tilde{\mathfrak{g}}^*$ and hence $W$ is also a vector bundle over $Q/G$. Let $HQ$ be the horizontal sub-bundle defined by the connection $A$; thus, $TQ = HQ \oplus VQ$, where $H_qQ := \ker A(q)$. For each $q \in Q$, the linear map $T_q\pi|_{H_qQ} : H_qQ \to T_{[q]}(Q/G)$ is an isomorphism. Let $\mathrm{hor}_q := (T_q\pi|_{H_qQ})^{-1} : T_{[q]}(Q/G) \to H_qQ \subset T_qQ$ be the horizontal lift operator induced by the connection $A$. Thus, $\mathrm{hor}_q^* : T_q^*Q \to T_{[q]}^*(Q/G)$ is a linear surjective map whose kernel is the annihilator $(H_qQ)^\circ$ of the horizontal space. The connection-dependent map $\Psi_A : (T^*Q)/G \to W$ defined by $\Psi_A([\alpha_q]) := (\mathrm{hor}_q^*(\alpha_q), [q, \boldsymbol{J}(\alpha_q)])$, where $q \in Q$, $\alpha_q \in T_q^*Q$, and $\boldsymbol{J} : T^*Q \to \mathfrak{g}^*$ is the momentum map of the lifted action, $\langle \boldsymbol{J}(\alpha_q), \xi \rangle = \alpha_q((\xi_Q(q))$ for $\xi \in \mathfrak{g}$, is a vector bundle isomorphism over $Q/G$ and $\Psi_A \circ \Phi_A = \Phi$. The Weinstein space is the Poisson manifold $(W, \{\cdot, \cdot\}_W)$, where $\{\cdot, \cdot\}_W$ is the push-forward by $\Psi_A$ of the Poisson bracket of $(T^*Q)/G$. In particular, $\Phi : S \to W$ is a connection independent Poisson diffeomorphism. The Poisson brackets on $S$ and on $W$ are called gauged Poisson brackets. They are expressed explicitly in terms of various covariant derivatives induced on $S$ and on $W$ by the connection $A \in \Omega^1(Q; \mathfrak{g})$.

Recall that the connection $A$ on the principal bundle $\pi : Q \to Q/G$ naturally induces connections on pullback bundles and affine connections on associated vector bundles. Thus, both $S$ and $W$ carry covariant derivatives induced by $A$. They are given, according to general definitions, in the cases under consideration, by:

- If $f \in C^\infty(S)$, $s = [(\alpha_{[q]}, q), \mu] \in S$, and $v_{\alpha_{[q]}} \in T_{\alpha_{[q]}}T^*(Q/G)$, then $\boldsymbol{d}_{\tilde{A}}^S f(s) \in T_{\alpha_{[q]}}^* T^*(Q/G)$ is defined by $\boldsymbol{d}_{\tilde{A}}^S f(s)(v_{\alpha_{[q]}}) := \boldsymbol{d}f(s)(T_{((\alpha_{[q]}, q), \mu)}\pi_{\tilde{Q}\times\mathfrak{g}^*}((v_{\alpha_{[q]}}, \mathrm{hor}_q(T_{\alpha_{[q]}}\tau(v_{\alpha_{[q]}}))), 0))$ where $\pi_{\tilde{Q}\times\mathfrak{g}^*} : \tilde{Q} \times \mathfrak{g}^* \to \tilde{Q} \times_G \mathfrak{g}^* = S$ is the orbit map. The symbol $\boldsymbol{d}_{\tilde{A}}^S$ signifies that this is a covariant derivative on the associated bundle $S$ induced by the connection $\tilde{A}$ on the principal $G$-pullback bundle $\tilde{Q} \to T^*(Q/G)$. This connection $\tilde{A}$ is the pullback connection defined by $A$.
- If $f \in C^\infty(W)$, $w = (\alpha_{[q]}, [q, \mu]) \in W$, and $v_{\alpha_{[q]}} \in T_{\alpha_{[q]}}T^*(Q/G)$, then $\tilde{\nabla}_A^W f(w) \in T_{\alpha_{[q]}}^* T^*(Q/G)$ is defined by $\tilde{\nabla}_A^W f(w)(v_{\alpha_{[q]}}) = \boldsymbol{d}f(w)(v_{\alpha_{[q]}}, T_{(q,\mu)}\pi_{Q\times\mathfrak{g}^*}(\mathrm{hor}_q(T_{\alpha_{[q]}}\tau_{Q/G}(v_{\alpha_{[q]}})), 0))$ where $\pi_{Q\times\mathfrak{g}^*} : Q \times \mathfrak{g}^* \to Q \times_G \mathfrak{g}^* = \tilde{\mathfrak{g}}^*$ is the orbit map. The symbol $\tilde{\nabla}_A^W$ signifies that this is a covariant derivative on the pullback bundle $W$ induced by the covariant derivative $\nabla_A$ on the coadjoint bundle $\tilde{\mathfrak{g}}^*$. This covariant derivative $\nabla_A$ is induced on $\tilde{\mathfrak{g}}^*$ by the connection $A$.
- For $f \in C^\infty(W)$, we have $\boldsymbol{d}_{\tilde{A}}^S(f \circ \Phi) = (\tilde{\nabla}_A^W f) \circ \Phi$.

To write the two gauged Poisson brackets on $S$ and on $W$ explicitly, we denote by $\tilde{\mathfrak{g}} = Q \times_G \mathfrak{g}$ the adjoint bundle of $\pi : Q \to Q/G$, by $\Omega_{Q/G}$ the canonical symplectic structure on $T^*(Q/G)$, by $B \in \Omega^2(Q; \mathfrak{g})$ the curvature of $A$, and by $\mathcal{B}$ the $\tilde{\mathfrak{g}}$-valued 2-form $\mathcal{B} \in \Omega^2(Q/G; \tilde{\mathfrak{g}})$ on the base $Q/G$ defined by $\mathcal{B}([q])(u_{[q]}, v_{[q]}) = [q, B(q)(u_q, v_q)]$, for any $u_q, v_q \in T_qQ$ that satisfy $T_q\pi(u_q) = u_{[q]}$ and $T_q\pi(v_q) = v_{[q]}$. Note that both $S^*$ and $W^*$ are Lie algebra bundles, that is, their fibers are Lie algebras and the fiberwise Lie bracket operation depends smoothly on the base point. If $f \in C^\infty(S)$, denote by $\delta f/\delta s \in S^* = \tilde{Q} \times_G \mathfrak{g}$ the usual fiber derivative of $f$. Similarly, if $f \in C^\infty(W)$ denote by $\delta f/\delta w \in W^*$ the usual fiber derivative of $f$. Finally, $\sharp : T^*(T^*(Q/G)) \to T(T^*(Q/G))$ is the vector bundle isomorphism induced by $\Omega_{Q/G}$. The Poisson bracket of $f, g \in C^\infty(S)$ is given by

$$\begin{aligned}\{f, g\}_S(s) &= \Omega_{Q/G}(\alpha_{[q]})\left(\boldsymbol{d}_{\tilde{A}}^S f(s)^\sharp, \boldsymbol{d}_{\tilde{A}}^S g(s)^\sharp\right) \\ &\quad - \left\langle s, \left[\frac{\delta f}{\delta s}, \frac{\delta g}{\delta s}\right]\right\rangle \\ &\quad + \left\langle v, (\pi_{Q/G}^*\mathcal{B})(\alpha_{[q]})\left(\boldsymbol{d}_{\tilde{A}}^S f(s)^\sharp, \boldsymbol{d}_{\tilde{A}}^S g(s)^\sharp\right)\right\rangle\end{aligned}$$

where $v = [q, \mu] \in \tilde{\mathfrak{g}}^*$. The Poisson bracket $f, g \in C^\infty(W)$ is given by

$$\begin{aligned}\{f, g\}_W(w) &= \Omega_{Q/G}(\alpha_{[q]})\left(\tilde{\nabla}_A^W f(w)^\sharp, \tilde{\nabla}_A^W g(w)^\sharp\right) \\ &\quad - \left\langle w, \left[\frac{\delta f}{\delta w}, \frac{\delta g}{\delta w}\right]\right\rangle \\ &\quad + \left\langle v, (\pi_{Q/G}^*\mathcal{B})(\alpha_{[q]})\left(\tilde{\nabla}_A^W f(w)^\sharp, \tilde{\nabla}_A^W g(w)^\sharp\right)\right\rangle\end{aligned}$$

Note that their structure is of the form: "canonical" bracket plus a (left) "Lie–Poisson" bracket plus a curvature coupling term.

### The Symplectic Leaves of the Sternberg and Weinstein Spaces

The map $\varphi_A : \tilde{Q} \times \mathfrak{g}^* \to T^*Q$ given by $\varphi_A((\alpha_{[q]}, q), \mu) := T_q^*\pi(\alpha_{[q]}) + A(q)^*\mu$, where $((\alpha_{[q]}, q), \mu) \in \tilde{Q} \times \mathfrak{g}^*$, is a $G$-equivariant diffeomorphism; the $G$-action on $T^*Q$ is by cotangent lift and on $\tilde{Q} \times \mathfrak{g}^*$ is $g \cdot ((\alpha_{[q]}, q), \mu) = ((\alpha_{[q]}, g \cdot q), \mathrm{Ad}_{g^{-1}}^*\mu)$. The pullback $\boldsymbol{J}_A$

of the momentum map to $\tilde{Q}\times\mathfrak{g}^*$ has the expression $J_A((\alpha_{[q]},q),\mu)=\mu$, so if $\mathcal{O}\subset\mathfrak{g}^*$ is a coadjoint orbit we have $J_A^{-1}(\mathcal{O})=\tilde{Q}\times\mathcal{O}$, and hence the orbit reduced manifold $J_A^{-1}(\mathcal{O})/G$, whose connected components are the symplectic leaves of $S$, equals $\tilde{Q}\times_G\mathcal{O}$. Its symplectic form is the Sternberg minimal coupling form $\tilde{\omega}_{\mathcal{O}}^{-}+\rho_S^*\Omega_{Q/G}$.

In this formula, the 2-form $\tilde{\omega}_{\mathcal{O}}^{-}$ has not been defined yet. It is uniquely defined by the identity $\pi_{\tilde{Q}\times\mathfrak{g}^*}\tilde{\omega}_{\mathcal{O}}^{-}=\boldsymbol{d}\widehat{A}+\Pi_{\mathcal{O}}\omega_{\mathcal{O}}^{-}$, where $\omega_{\mathcal{O}}^{-}$ is the minus orbit symplectic form on $\mathcal{O}$ (*see* Symmetry and Symplectic Reduction), $\Pi_{\mathcal{O}}:\tilde{Q}\times\mathcal{O}\to\mathcal{O}$ is the projection on the second factor, and $\widehat{A}\in\Omega^2(\tilde{Q}\times\mathcal{O})$ is the 2-form given by $\widehat{A}((\alpha_{[q]},q),\mu)\quad((u_{\alpha_{[q]}},v_q),\nu)=-\langle\mu,A(q)(v_q)\rangle$ for $((\alpha_{[q]},q),\mu)\in\tilde{Q}\times\mathcal{O},(u_{\alpha_{[q]}},v_q)\in T_{(\alpha_{[q]},q)}\tilde{Q}$, and $\nu\in\mathfrak{g}^*$.

The symplectic leaves of the Weinstein space $W$ are obtained by pushing forward by $\Phi$ the symplectic leaves of the Sternberg space. They are the connected components of the symplectic manifolds $(T^*(Q/G)\oplus(Q\times_G\mathcal{O}),\Pi^*_{T^*(Q/G)}\Omega_{Q/G}+\Pi^*_{Q\times_G\mathcal{O}}\omega^{-}_{Q\times_G\mathcal{O}})$, where $\mathcal{O}$ is a coadjoint orbit in $\mathfrak{g}^*$, $\Omega_{Q/G}$ is the canonical symplectic form on $T^*(Q/G)$, $\omega^{-}_{Q\times_G\mathcal{O}}$ is a closed 2-form on $Q\times_G\mathcal{O}$ to be defined below, and $\Pi_{T^*(Q/G)}:T^*(Q/G)\oplus(Q\times_G\mathcal{O})\to T^*(Q/G),\Pi_{Q\times_G\mathcal{O}}:T^*(Q/G)\oplus(Q\times_G\mathcal{O})\to Q\times_G\mathcal{O}$ are the projections. The closed 2-form $\omega^{-}_{Q\times_G\mathcal{O}}\in\Omega^2(Q\times_G\mathcal{O})$ is uniquely determined by the identity $\pi^*_{Q\times\mathcal{O}}\omega^{-}_{Q\times_G\mathcal{O}}=\omega^{-}_{Q\times\mathcal{O}}$, where $\pi_{Q\times\mathcal{O}}:Q\times\mathcal{O}\to Q\times_G\mathcal{O}$ is the orbit space projection, $\omega^{-}_{Q\times\mathcal{O}}\in\Omega^2(Q\times\mathcal{O})$ is closed and given by $\omega^{-}_{Q\times\mathcal{O}}(q,\mu)((u_q,-\mathrm{ad}^*_\xi\mu),(v_q,-\mathrm{ad}^*_\eta\mu)):=-\boldsymbol{d}(\mathcal{A}\times\mathrm{id}_{\mathcal{O}})(q,\mu)((u_q,-\mathrm{ad}^*_\xi\mu),(v_q,-\mathrm{ad}^*_\eta\mu))+\omega^{-}_{\mathcal{O}}(\mu)(\mathrm{ad}^*_\xi\mu,\mathrm{ad}^*_\eta\mu)$, and $\mathcal{A}\times\mathrm{id}_{\mathcal{O}}\in\Omega^1(Q\times\mathfrak{g}^*)$ is given by $(\mathcal{A}\times\mathrm{id}_{\mathcal{O}})(q,\mu)(u_q,-\mathrm{ad}^*_\xi\mu)=\langle\mu,\mathcal{A}(q)(u_q)\rangle$, for $q\in Q,\mu\in\mathfrak{g}^*,u_q,v_q\in T_qQ,\xi,\eta\in\mathfrak{g}$.

Thus, on the Sternberg and Weinstein spaces, both the Poisson bracket as well as the symplectic form on the leaves have explicit connection dependent formulas (*see* Gauge Theory: Mathematical Applications for a general treatment of gauge theories).

# Critical Phenomena in Gravitational Collapse

**C Gundlach**, University of Southampton, Southampton, UK

## Introduction

Sufficiently dense concentrations of mass–energy in general relativity collapse irreversibly and form black holes. More precisely, the singularity theorems state that once a closed trapped surface has developed, some world lines will only extend to a finite length in the future – they end in a spacetime singularity. Furthermore, the cosmic censorship hypothesis states that this singularity is hidden away inside a black hole. One can, therefore, classify initial data in general relativity which describe an isolated system with no black hole present into those which remain regular, and those which form a black hole during their evolution.

Theorems on the stability of Minkowski spacetime, and similar results for some types of matter coupled to gravity, imply that sufficiently weak (in some technical sense) initial data will remain regular. On the other hand, no necessary or sufficient criterion for black hole formation is known. For very strong data the existence of a closed trapped surface implies black hole formation, but although the data themselves may be regular, the trapped surface must already be inside the black hole. Between the very weak and very strong regime, there is a middle regime of initial data for which one cannot decide if they will or will not form a black hole, other than evolving them in time.

The threshold between collapse and dispersion was first explored systematically by Choptuik (1992). He concentrated on the simple model of a spherically symmetric massless scalar (matter) field $\phi(r,t)$. In this model, the scalar-field matter must either form a black hole, or disperse to infinity – it cannot form stable stars. Choptuik explored the space of initial data by means of one-parameter families of initial data which interpolate between strong data (say with large parameter $p$) that form a black hole and weak data (with small $p$) that disperse. The critical value $p_*$ of the parameter $p$ can be found for each family by evolving many data sets from that family. Near the black hole threshold, Choptuik found the following phenomena:

1. *Mass scaling*. By fine-tuning the initial data to the threshold along any one-parameter family, one can make arbitrarily small black holes. Near the threshold, the black hole mass scales as
$$M \simeq C(p - p_*)^\gamma \quad \text{for } p \geq p_* \qquad [1]$$
for the black hole mass $M$ in the limit $p \to p_*$ from above.
2. *Universality*. While $p_*$ and $C$ depend on the particular one-parameter family of data, the critical exponent $\gamma$ has a universal value, $\gamma \simeq 0.374$, for all one-parameter families of scalar-field data. Furthermore, for a finite time in a finite region of space, the solutions generated by all near-critical data approach one and the same solution $\phi_*$, called the critical solution:
$$\phi(r, t) \simeq \phi_*\left(\frac{r}{L}, \frac{t - t_*}{L}\right) \qquad [2]$$
The constants $t_*$ and $L$ depend again on the family of initial data, but $\phi_*(r,t)$ is universal. This universal phase ends when the evolution decides between black hole formation and dispersion. The universal critical solution is approached by any initial data that are sufficiently close to the black hole threshold, on either side, and from any one-parameter family.
3. *Scale-echoing*. The critical solution $\phi_*(r,t)$ is unchanged when one rescales space and time by a factor $e^\Delta$:
$$\phi_*(r, t) = \phi_*\left(e^\Delta r, e^\Delta t\right) \qquad [3]$$
where $\Delta \simeq 3.44$ for the scalar field.

The same phenomena were quickly discovered in many other types of matter coupled to gravity, and even in vacuum gravity (where gravitational waves can form black holes). The echoing period $\Delta$ and critical exponent $\gamma$ depend on the type of matter, but the existence of the phenomena appears to be generic. For some types of matter (e.g., perfect fluid matter), the critical solution is continuously scale invariant (or continuously self-similar, CSS) in the sense that
$$\phi_*(r, t) = \phi_*(r/t) \qquad [4]$$
rather than scale-periodic (or discretely self-similar, DSS) as in [3]. (We use the notation $\phi_*(x)$ for the function of one variable $r/t$.) We have described scale invariance and scale-echoing here in terms of coordinates, but these do admit geometric, coordinate-invariant definitions, which are not restricted to spherical symmetry.

There is also another kind of critical behavior at the black hole threshold. Here, too, the evolution goes through a universal critical solution, but it is static, rather than scale invariant. As a consequence, the mass of black holes near the threshold takes a universal finite value (some fixed fraction of the mass of the critical solution), instead of showing power-law

scaling. In an analogy with first- and second-order phase transitions in statistical mechanics, the critical phenomena with a finite mass at the black hole threshold are called type I, and the critical phenomena with power-law scaling of the mass are called type II.

At this point, we characterize the degree of rigor of the various parts of the theory that is summarized in this article. Critical phenomena were discovered in the numerical time evolution of generic asymptotically flat initial data. Numerical evolution of many elements of a specific one-parameter family, and fine-tuning to the black hole threshold along that family showed self-similarity and mass scaling near the threshold. Doing this for a number of randomly chosen one-parameter families suggests that these phenomena, and in particular the echoing scale $\Delta$ and mass-scaling exponent $\gamma$, are universal between initial data within one model (e.g., the spherical scalar field). Numerical experiments, however, can only explore a finite-dimensional subspace of the infinite-dimensional space of initial data (phase space) of the field theory, and so cannot prove universality.

We go further by applying the theory of dynamical systems to general relativity. The arguments summarized in the next section would be difficult to make rigorous, as the dynamical system under consideration is infinite dimensional, but they suggest a focus on fixed points of the dynamical system and their linear perturbations. Even though the dynamical systems motivation is not mathematically rigorous, the linearized analysis itself is a well-defined problem that can be solved numerically to essentially arbitrary precision. This proves universality on a perturbative level, and provides numerical values of $\Delta$ and $\gamma$. A combination of the global dynamical systems analysis and perturbative analysis even predicts further critical exponents for black hole charge and angular momentum. Finally, critical phenomena have been discovered in a number of systems (different types of matter and symmetry restrictions), and this suggests that they may be generic for some large class of field theories (although details such as the numerical values of $\gamma$ and $\Delta$ do depend on the system), but there is no conclusive evidence for this at present.

## The Dynamical Systems Picture

When we consider general relativity as an infinite-dimensional dynamical system, a solution curve is a spacetime. Points along the curve are Cauchy surfaces in the spacetime, which can be thought of as moments of time. An important difference between general relativity and other field theories is that the same spacetime can be sliced in many different ways, none of which is preferred. Therefore, to turn general relativity into a dynamical system, one has to fix a slicing (and in practice also coordinates on each slice). In the example of the spherically symmetric massless scalar field, using polar slicing and an area radial coordinate $r$, a point in phase space can be characterized by the two functions

$$Z = \left\{ \phi(r),\ r\frac{\partial \phi}{\partial t}(r) \right\} \qquad [5]$$

In spherical symmetry, there are no degrees of freedom in the scalar field, and Cauchy data for the metric can be reconstructed from $Z$ using the Einstein constraints.

The phase space consists of two halves: initial data whose time evolution always remains regular, and data which contain a black hole or form one during time evolution. The numerical evidence collected from individual one-parameter families of data suggests that the black hole threshold that separates the two is a smooth hypersurface. The mass-scaling law [1] can, therefore, be restated without explicit reference to one-parameter families. Let $P$ be any function on phase space such that data sets with $P > 0$ form black holes, and data with $P < 0$ do not, and which is analytic in a neighborhood of the black hole threshold $P = 0$. The black hole mass as a function on phase space is then given by

$$M \simeq F(P)\ P^{\gamma} \qquad [6]$$

for $P > 0$, where $F(P) > 0$ is an analytic function.

Consider now the time evolution in this dynamical system, near the threshold ("critical surface") between black hole formation and dispersion. A phase-space trajectory that starts out in a critical surface by definition never leaves it. A critical surface is, therefore, a dynamical system in its own right, with one dimension fewer. If it has an attracting fixed point, such a point is called a critical point. It is an attractor of codimension 1, and the critical surface is its basin of attraction. The fact that the critical solution is an attractor of codimension 1 is visible in its linear perturbations: it has an infinite number of decaying perturbation modes tangential to (and spanning) the critical surface, and a single growing mode not tangential to the critical surface.

Any trajectory beginning near the critical surface, but not necessarily near the critical point, moves almost parallel to the critical surface toward the critical point. As the phase point approaches the critical point, its movement parallel to the surface

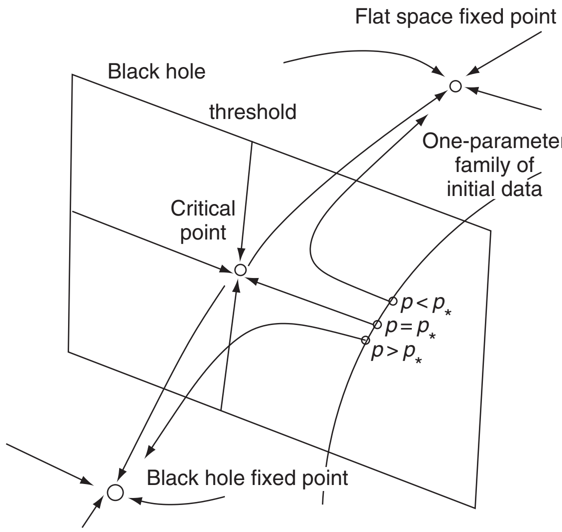

**Figure 1** The phase-space picture for the black hole threshold in the presence of a critical point. The arrow lines are time evolutions, corresponding to spacetimes. The line without an arrow is not a time evolution, but a one-parameter family of initial data that crosses the black hole threshold at $p = p_*$. (Reproduced with permission from Gundlach C (2003) Critical phenomena in gravitational collapse. *Physics Reports* 376: 339–405.)

slows down, while its distance and velocity out of the critical surface are still small. The phase point spends sometime moving slowly near the critical point. Eventually, it moves away from the critical point in the direction of the growing mode, and ends up on an attracting fixed point.

This is the origin of universality: any initial data set that is close to the black hole threshold (on either side) evolves to a spacetime that approximates the critical spacetime for sometime. When it finally approaches either the dispersion fixed point or the black hole fixed point, it does so on a trajectory that appears to be coming from the critical point itself. All near-critical solutions are passing through one of these two funnels. All details of the initial data have been forgotten, except for the distance from the black hole threshold: the closer the initial phase point is to the critical surface, the more the solution curve approaches the critical point, and the longer it will remain close to it.

In all systems that have been examined, the black hole threshold contains at least one critical point. A fixed point of the dynamical system represents a spacetime with an additional continuous symmetry that generic solutions do not have. If the critical spacetime is time independent in the usual sense, we have type I critical phenomena; if the symmetry is scale invariance, we have type II critical phenomena. The attractor within the critical surface may also be a limit cycle, rather than a fixed point. In spacetime terms this corresponds to a discrete symmetry (DSS rather than CSS in type II, or a pulsating critical solution, rather than a stationary one, in type I).

## Self-Similarity and Mass Scaling

Type II critical phenomena occur where the critical solution is scale invariant (self-similar, CSS or DSS). Using suitable spacetime coordinates, a CSS solution can be characterized as independent of a time coordinate $\tau$ which is also a logarithmic scale. Similarly, a DSS solution can be characterized as periodic in $\tau$. For example, starting from the scale periodicity [3] in polar-radial coordinates, we replace $r$ and $t$ by new coordinates

$$x \equiv -\frac{r}{t - t_*}, \qquad \tau \equiv -\ln\left(-\frac{t - t_*}{L}\right) \qquad [7]$$

where the accumulation time $t_*$ and scale $L$ must be matched to the one-parameter family under consideration. $\tau$ has been defined so that it increases as $t$ increases and approaches $t_*$ from below. It is useful to think of $r$, $t$, and $L$ as having dimension length in units $c = G = 1$, and of $x$ and $\tau$ as dimensionless. Choptuik's observation, expressed in these coordinates, is that in any near-critical solution there is a spacetime region where the fields $Z$ are well approximated by the critical solution, or

$$Z(x, \tau) \simeq Z_*(x, \tau) \qquad [8]$$

with

$$Z_*(x, \tau + \Delta) = Z_*(x, \tau) \qquad [9]$$

Note that the time parameter of the dynamical system must be chosen as $\tau$ if a CSS solution is to be a fixed point, or a DSS solution a cycle. More generally (going beyond spherical symmetry), on any self-similar spacetime one can introduce coordinates $x^\mu = (\tau, x^1, x^2, x^3)$ in which the metric is of the form

$$g_{\mu\nu} = \mathrm{e}^{-2\tau}\bar{g}_{\mu\nu} \qquad [10]$$

and where $\bar{g}_{\mu\nu}$ is independent of $\tau$ for a CSS spacetime, and periodic in $\tau$ for a DSS spacetime. These coordinates are not unique.

The critical exponent $\gamma$ can be calculated from the linear perturbations of the critical solution. In order to keep the notation simple, the discussion will be restricted to a critical solution that is spherically symmetric and CSS, which is correct, for example, for perfect-fluid matter.

Let us assume that we have fine-tuned initial data close to the black hole threshold so that in a region the resulting spacetime is well approximated by the CSS critical solution. This part of the spacetime

corresponds to the section of the phase-space trajectory that lingers near the critical point. In this region, we can linearize around $Z_*$. As $Z_*$ does not depend on $\tau$, its linear perturbations can depend on $\tau$ only exponentially. Labeling the perturbation modes by $i$, a single mode perturbation is of the form

$$\delta Z = C_i e^{\lambda_i \tau} Z_i(x) \qquad [11]$$

In the near-critical regime, we can therefore approximate the solution as

$$Z(x,\tau) \simeq Z_*(x) + \sum_{i=0}^{\infty} C_i(p)\, e^{\lambda_i \tau} Z_i(x) \qquad [12]$$

The notation $C_i(p)$ is used because the perturbation amplitudes $C_i$ depend on the initial data, and hence on the parameter $p$ that controls the initial data.

If $Z_*$ is a critical solution, by definition there is exactly one $\lambda_i$ with positive real part (in fact, it is purely real), say $\lambda_0$. As $t \to t_*$ from below, which corresponds to $\tau \to \infty$, all other perturbations decay and can be neglected. By definition, the critical solution corresponds to $p = p_*$, and so we must have $C_0(p_*) = 0$. Linearizing around $p_*$, we obtain

$$Z(x,\tau) \simeq Z_*(x) + \left.\frac{dC_0}{dp}\right|_{p_*} (p - p_*)\, e^{\lambda_0 \tau}\, Z_0(x) \qquad [13]$$

in a region of the spacetime.

Now we extract Cauchy data at one particular value of $\tau$ within that region, namely at $\tau_p$ defined by

$$\left.\frac{dC_0}{dp}\right|_{p_*} |p - p_*| e^{-\lambda_0 \tau_p} \equiv \epsilon \qquad [14]$$

where $\epsilon$ is an arbitrary small constant, so that

$$Z(x,\tau_p) \simeq Z_*(x) \pm \epsilon\, Z_0(x) \qquad [15]$$

where $\pm$ is the sign of $p - p_*$, left behind because by definition $\epsilon$ is positive. As $\tau$ increases from $\tau_p$, the growing perturbation becomes nonlinear and the approximation [13] breaks down. Then either a black hole forms (say for the positive sign), or the solution disperses (for the negative sign). We need not follow this nonlinear evolution in detail to find the black hole mass scaling in the former case: dimensional analysis is sufficient. Going back to coordinates $t$ and $r$, we have

$$Z(r, t_p) \simeq Z_*\left(\frac{r}{L_p}\right) \pm \epsilon\, Z_0\left(\frac{r}{L_p}\right) \qquad [16]$$

where

$$L_p \equiv L e^{-\tau_p} \qquad [17]$$

These Cauchy data at $t = t_p$ depend on the initial data at $t = 0$ only through the overall scale $L_p$, and through the sign in front of $\epsilon$. If the field equations themselves are scale invariant, or asymptotically scale invariant at scales $L_p$ and smaller, the black hole mass, which has dimensions of length in gravitational units, must be proportional to the initial data scale $L_p$, the only length scale that is present. Therefore,

$$M \propto L_p \propto (p - p_*)^{1/\lambda_0} \qquad [18]$$

and we have found the critical exponent to be $\gamma = 1/\lambda_0$.

## The Analogy with Statistical Mechanics

The existence of a threshold where a qualitative change takes place, universality, scale invariance, and critical exponents suggest that there is a mathematical analogy between type II critical phenomena and critical phase transitions in statistical mechanics.

In equilibrium statistical mechanics, observable macroscopic quantities, such as the magnetization of a ferromagnetic material, are derived as statistical averages over microstates of the system. The expected value of an observable is

$$\langle A \rangle = \sum_{\text{microstates}} A(\text{microstate})\, e^{-H(\text{microstate},\mu)} \qquad [19]$$

The Hamiltonian $H$ depends on the parameters $\mu$, which comprise the temperature, parameters characterizing the system such as interaction energies of the constituent molecules, and macroscopic forces such as the external magnetic field. The objective of statistical mechanics is to derive relations between the macroscopic quantities $A$ and parameters $\mu$.

Phase transitions in thermodynamics are thresholds in the space of external forces $\mu$ at which the macroscopic observables $A$, or one of their derivatives, change discontinuously. In a ferromagnetic material at high temperatures, the magnetization $\boldsymbol{m}$ of the material (alignment of atomic spins) is determined by the external magnetic field $\boldsymbol{B}$. At low temperatures, the material shows a spontaneous magnetization even at zero external field, which breaks rotational symmetry. With increasing temperature, the spontaneous magnetization $\boldsymbol{m}$ decreases and vanishes at the Curie temperature $T_*$ as

$$|\boldsymbol{m}| \sim (T_* - T)^{\gamma} \qquad [20]$$

In the presence of a very weak external field, the spontaneous magnetization aligns itself with the external field $\boldsymbol{B}$, while its strength is, to leading order, independent of $\boldsymbol{B}$. The function $\boldsymbol{m}(\boldsymbol{B}, T)$,

therefore, changes discontinuously at $\boldsymbol{B}=0$. The line $\boldsymbol{B}=0$ for $T < T_*$ is, therefore, a line of first-order phase transitions between the possible directions of the spontaneous magnetization (in a one-dimensional system, between $\boldsymbol{m}$ up and $\boldsymbol{m}$ down). This line ends at the critical point $(\boldsymbol{B}=0, T=T_*)$ where the order parameter $|\boldsymbol{m}|$ vanishes. The role of $\boldsymbol{B}=0$ as the critical value of $\boldsymbol{B}$ is obscured by the fact that $\boldsymbol{B}=0$ is singled out by symmetry.

A critical phase transition involves scale-invariant physics. One sign of this is that fluctuations appear on a large range of length scales between the underlying atomic scale and the scale of the sample. In particular, the atomic scale, and any dimensionful parameters associated with that scale, must become irrelevant at the critical point. This can be taken as the starting point for obtaining properties of the system at the critical point.

One first defines a semigroup acting on microstates: the renormalization group. Its action is to group together a small number of particles as a single particle of a fictitious new system, using some averaging procedure. Alternatively, this can also be done in Fourier space. One then defines a dual action of the renormalization group on the space of Hamiltonians by demanding that the partition function is invariant under the renormalization group action:

$$\sum_{\text{microstates}} \mathrm{e}^{-H} = \sum_{\text{microstates}'} \mathrm{e}^{-H'} \qquad [21]$$

The renormalized Hamiltonian $H'$ is in general more complicated than the original one, but it can be approximated by a fixed expression where only a finite number of parameters $\mu$ are adjusted. Fixed points of the renormalization group correspond to Hamiltonians with the parameters $\mu$ at their critical values. The critical value of any dimensional parameter $\mu$ must be zero (or infinity). Only dimensionless combinations can have nontrivial critical values.

The behavior of thermodynamical quantities at the critical point is in general not trivial to calculate. But the action of the renormalization group on length scales is given by its definition. The blowup of the correlation length $\xi$ at the critical point is, therefore, the easiest critical exponent to calculate. We make contact with critical phenomena in gravitational collapse by considering the time evolution in coordinates $(\tau, x)$ as a renormalization group action. The calculation of the critical exponent for the black hole mass $M$ is the precise analog of the calculation of the critical exponent for the correlation length $\xi$, substituting $T_* - T$ for $p - p_*$, and taking into account that the $\tau$-evolution in critical collapse is toward smaller scales, while the renormalization group flow goes toward larger scales: therefore, $\xi$ diverges at the critical point, while $M$ vanishes.

We have shown above that the black hole mass is controlled by one global function $P$ on phase space. Clearly, $P$ is the gravity equivalent of $T - T_*$ in the ferromagnet. But it is tempting to speculate (Gundlach 2002)that there is also a gravity equivalent of the external magnetic field $\boldsymbol{B}$, which gives rise to a second independent critical exponent. At least in some situations, the angular momentum of the initial data can play this role. Note that, like $\boldsymbol{B}$, angular momentum is a vector, with a critical value that is zero because all other values break rotational symmetry. Furthermore, the final black hole can have nonvanishing angular momentum, which must depend on the angular momentum of the initial data. The former is analogous to the magnetization $\boldsymbol{m}$, the latter to the external field $\boldsymbol{B}$. It can be shown that this analogy holds perturbatively for small angular momentum. Future numerical simulations will show if it goes further.

## Universality and Cosmic Censorship

Critical phenomena in gravitational collapse first generated interest because a complicated self-similar structure and dimensionless numbers $\gamma$ and $\Delta$ arise from generic initial data evolved by quite simple field equations. Another point of interest is the rather detailed analogy of phenomena in a deterministic field theory with critical phase transitions in statistical mechanics. But critical phenomena are important for general relativity mostly for a different reason.

Black holes are among the most important solutions of general relativity because of their universality: the black hole uniqueness theorems state that stable black holes are completely determined by their mass, angular momentum, and electric charge – the Kerr–Newman family of black holes. Perturbation theory shows that any perturbations of black holes from the Kerr–Newman solutions must be radiated away.

Critical solutions have a similar importance because they are generic intermediate states of the evolution that are also independent of the initial data. An important distinction is that critical solutions depend on the matter model, and are therefore less universal than black holes. However, critical phenomena in gravitational collapse seem to arise in axisymmetric vacuum spacetimes, and so are apparently not linked to the

presence of matter. Furthermore, they also arise in perfect-fluid matter with the equation of state $p = \rho/3$, which is that of an ultrarelativistic gas. This is a good approximation for matter at very high density, such as in the big bang. This is important because critical phenomena probe arbitrarily large matter densities or spacetime curvatures as the initial data are fine-tuned to the black hole threshold. At even higher densities, presumably on the Planck scale, scale invariance is again broken by quantum-gravity effects, and so critical phenomena will end there.

The cosmic censorship conjecture states that naked singularities do not arise from suitably generic initial data for suitably well-behaved matter. Critical phenomena in gravitational collapse have forced a tightening of this conjecture. Type II (self-similar) critical solutions contain a naked singularity, that is, a point of infinite spacetime curvature from which information can reach a distant observer. (By contrast, the singularity inside a black hole is hidden from distant observers.) On a kinematical level, this could be seen already from the form [10] of the metric. Because the critical solution is the end state for all initial data that are exactly on the black hole threshold, all initial data on the black hole threshold form a naked singularity. As type II critical phenomena appear to be generic at least in spherical symmetry, this means that in generic self-gravitating systems, the space of regular initial data that form naked singularities is larger than expected, namely of codimension 1. Excluding naked singularities from generic initial data may be the sharpest version of cosmic censorship one can now hope to prove.

Another point of interest in critical collapse is that it allows one to make a small region of arbitrarily high curvature from finite-curvature initial data. This may be a route for probing quantum-gravity effects. Similarly, one can make black holes that are much smaller than any length scale present in the initial data or the matter equation of state. An application has been suggested for this in cosmology, where primordial black holes could have masses much smaller than the Hubble scale at which they are created, rather than of the order of this scale.

## Outlook

Critical phenomena in gravitational collapse are now well understood in spherical symmetry, both theoretically and in numerical simulations. In some matter models, the phenomenology is quite complicated, but it still fits into the basic picture outlined here.

The crucial question as to what happens beyond spherical symmetry remains largely unanswered at the time of writing. Perturbation theory around spherical symmetry suggests that critical phenomena are not restricted to exactly spherical situations. This is also supported by simulations in axisymmetric (highly nonspherical) vacuum gravity. Other simulations of nonspherical gravitational collapse which cover the necessary range of spacetime scales required to see critical phenomena are only just becoming available, and the results are not yet clear-cut. For collapse with angular momentum, no high-resolution calculations have yet been carried out. As the necessary techniques become available, one should be prepared for numerical simulations to make dramatic extensions or corrections to the picture of critical collapse drawn up here.

# Current Algebra

**G A Goldin**, Rutgers University, Piscataway, NJ, USA

## Introduction

Certain commutation relations among the current density operators in quantum field theories define an infinite-dimensional Lie algebra. The original current algebra of Gell-Mann described weak and electromagnetic currents of the strongly interacting particles (hadrons), leading to the Adler–Weisberger formula and other important physical results. This helped inspire mathematical and quantum-theoretic developments such as the Sugawara model, light cone currents, Virasoro algebra, the mathematical theory of affine Kac–Moody algebras, and nonrelativistic current algebra in quantum and statistical physics. Lie algebras of local currents may be the infinitesimal representations of loop groups, local current groups or gauge groups, diffeomorphism groups, and their semidirect products or other extensions. Broadly construed, current algebra thus leads directly into the representation theory of infinite-dimensional groups and algebras. Applications have ranged across conformally invariant field theory, vertex operator algebras, exactly solvable lattice and continuum models in statistical physics, exotic particle statistics and $q$-commutation relations, hydrodynamics and quantized vortex motion. This brief survey describes but a few highlights.

## Relativistic Local Current Algebra for Hadrons

To model superfluidity, Landau had proposed in 1941 a quantum hydrodynamics fundamentally based on local fluid densities and currents as (operator) dynamical variables. However, current algebra came into its own in theoretical physics with the ideas of Gell-Mann in the early 1960s. The basic concept, in the era just preceding quantum chromodynamics (QCD), was that even without knowing the Lagrangian governing hadron dynamics in detail, exact kinematical information – the local symmetry – could still be encoded in an algebra of currents. The local (vector and axial vector) current density operators, expressed where possible in terms of underlying quantized field operators in Hilbert space, were to form two octets of Lorentz 4-vectors, with each octet corresponding to the eight generators of the compact Lie group SU(3).

More specifically (Adler and Dashen 1968), let $\mathcal{F}_a^{\mu}(x), a = 1, 2, \ldots, 8, \mu = 0, 1, 2, 3,$ be an octet of hadronic vector currents, where as usual $x = (x^{\nu}) = (x^0, \boldsymbol{x})$ denotes a point in four-dimensional spacetime. Likewise, introduce an axial vector octet $\mathcal{F}_a^{5\mu}(x)$. Unless otherwise specified, we use natural units, where $\hbar = 1$ and $c = 1$. Define the corresponding charges $F_a$ and $F_a^5$ to be the space integrals of the time components of these currents, that is,

$$F_a(x^0) = \int \mathrm{d}^3x \mathcal{F}_a^0(x^0, \boldsymbol{x})$$
$$F_a^5(x^0) = \int \mathrm{d}^3x \mathcal{F}_a^{50}(x^0, \boldsymbol{x}) \qquad [1]$$

where $\mathrm{d}^3x = \mathrm{d}x^1\,\mathrm{d}x^2\,\mathrm{d}x^3$. Then $F_1, F_2, F_3$ are the three components $I_1, I_2, I_3$ of the isotopic spin, and $Y = (2\sqrt{3}/3)F_8$ is the hypercharge. The usual electromagnetic current $J_{\mathrm{em}}^{\mu}(x^0, \boldsymbol{x})$ is given by

$$J_{\mathrm{em}}^{\mu} = q\left(\mathcal{F}_3^{\mu} + \frac{\sqrt{3}}{3}\mathcal{F}_8^{\mu}\right) \qquad [2]$$

where $q$ is the unit elementary charge, and the total charge is given by $Q = \int \mathrm{d}^3x\, J_{\mathrm{em}}^0(x^0, \boldsymbol{x}) = q(I_3 + Y/2)$. The hadronic part of the weak current entering an effective Lagrangian can be written as

$$J_{\mathrm{w}}^{\mu} = \left[\left(\mathcal{F}_1^{\mu} - \mathcal{F}_1^{5\mu}\right) + \mathrm{i}\left(\mathcal{F}_2^{\mu} - \mathcal{F}_2^{5\mu}\right)\right]\cos\theta_{\mathrm{C}}$$
$$+ \left[\left(\mathcal{F}_4^{\mu} - \mathcal{F}_4^{5\mu}\right) + \mathrm{i}\left(\mathcal{F}_5^{\mu} - \mathcal{F}_5^{5\mu}\right)\right]\sin\theta_{\mathrm{C}} \qquad [3]$$

where $\theta_{\mathrm{C}}$ is the Cabibbo angle (determined experimentally to be $\sim 0.27$ rad). The terms with $\mathcal{F}_1 - \mathcal{F}_1^5$ and $\mathcal{F}_2 - \mathcal{F}_2^5$ are strangeness conserving, those with $\mathcal{F}_4 - \mathcal{F}_4^5$ and $\mathcal{F}_5 - \mathcal{F}_5^5$ are not.

The main current algebra hypothesis is that the time components $\mathcal{F}^0$ and $\mathcal{F}^{50}$ of these octets satisfy the equal-time commutation relations:

$$[\mathcal{F}_a^0(x^0, \boldsymbol{x}), \mathcal{F}_b^0(y^0, \boldsymbol{y})]_{x^0=y^0} = \mathrm{i}\delta^{(3)}(\boldsymbol{x} - \boldsymbol{y})\sum_d c_{abd}\mathcal{F}_d^0(x^0, \boldsymbol{x})$$
$$[\mathcal{F}_a^0(x^0, \boldsymbol{x}), \mathcal{F}_b^{50}(y^0, \boldsymbol{y})]_{x^0=y^0} = \mathrm{i}\delta^{(3)}(\boldsymbol{x} - \boldsymbol{y})\sum_d c_{abd}\mathcal{F}_d^{50}(x^0, \boldsymbol{x}) \qquad [4]$$
$$[\mathcal{F}_a^{50}(x^0, \boldsymbol{x}), \mathcal{F}_b^{50}(y^0, \boldsymbol{y})]_{x^0=y^0} = \mathrm{i}\delta^{(3)}(\boldsymbol{x} - \boldsymbol{y})\sum_d c_{abd}\mathcal{F}_d^0(x^0, \boldsymbol{x})$$

where the $c_{abd}$ are structure constants of the Lie algebra of SU(3), antisymmetric in the indices. Since current commutators relate bilinear expressions to

linear ones, they fix the normalizations of the currents. The chiral currents $\mathcal{F}_a^{L\mu} = (1/2)(\mathcal{F}_a^\mu - \mathcal{F}_a^{5\mu})$ and $\mathcal{F}_a^{R\mu} = (1/2)(\mathcal{F}_a^\mu + \mathcal{F}_a^{5\mu})$ commute with each other, so that the local current algebra decomposes into two independent pieces.

The Dirac $\delta$-functions in eqns [4] require that $\mathcal{F}_a^0$ and $\mathcal{F}_a^{50}$ be interpreted as (unbounded) operator-valued distributions; while the fixed-time condition suggests these should make mathematical sense as three-dimensional distributions, with $x^0$ held constant. Such distributions may be modeled on the test-function space $\mathcal{D}$ of real-valued, compactly supported, $C^\infty$ functions on the spacelike hyperplane $\boldsymbol{R}^3$. For functions $f_a, f_a^5 \in \mathcal{D}$, one has formally the "smeared currents" that are expected to be bona fide (unbounded) operators in Hilbert space; suppressing $x^0$,

$$\begin{aligned} \mathcal{F}_a^0(f_a) &= \int_{\boldsymbol{R}^3} \mathrm{d}^3x f_a(\boldsymbol{x}) \mathcal{F}_a^0(x^0, \boldsymbol{x}) \\ \mathcal{F}_a^{50}(f_a^5) &= \int_{\boldsymbol{R}^3} \mathrm{d}^3x f_a^5(\boldsymbol{x}) \mathcal{F}_a^{50}(x^0, \boldsymbol{x}) \end{aligned} \qquad [5]$$

Equations [4] then become

$$\begin{aligned} [\mathcal{F}_a^0(f_a), \mathcal{F}_b^0(f_b)] &= [\mathcal{F}_a^{50}(f_a), \mathcal{F}_b^{50}(f_b)] \\ &= \mathrm{i} \sum_d \mathcal{F}_d^0(c_{abd} f_a f_b) \\ [\mathcal{F}_a^0(f_a), \mathcal{F}_b^{50}(f_b)] &= \mathrm{i} \sum_d \mathcal{F}_d^{50}(c_{abd} f_a f_b) \end{aligned} \qquad [6]$$

Let $g(\boldsymbol{x})$ be a $C^\infty$ map from $\boldsymbol{R}^3$ to the Lie algebra $\mathcal{G}$ of chiral $SU(3) \times SU(3)$, equal to zero outside a compact set. The set of all such $\mathcal{G}$-valued functions forms an infinite-dimensional Lie algebra under the pointwise bracket, $[g, g'](\boldsymbol{x}) = [g(\boldsymbol{x}), g'(\boldsymbol{x})]$. Let us call this Lie algebra $\mathrm{map}_0(\boldsymbol{R}^3, \mathcal{G})$, where the subscript 0 indicates the condition of compact support when that is applicable (on compact manifolds, we omit the subscript). Expanding $g(\boldsymbol{x})$ with respect to a fixed basis of $\mathcal{G}$, we straightforwardly identify the map $g$ with the two octets of test functions $f_a$ and $f_a^5$. Then, defining $\mathcal{F}(g) = \sum_a \mathcal{F}_a^0(f_a) + \sum_a \mathcal{F}_a^{50}(f_a^5)$, eqns [6] are interpreted (for fixed $x^0$) as a representation $\mathcal{F}$ of $\mathrm{map}_0(\boldsymbol{R}^3, \mathcal{G})$.

Integrating out the spatial variables entirely using eqns [1] leads to a representation at $x^0$ of $\mathcal{G}$ by the charges $F_a$ and $F_a^5$. The Adler–Weisberger sum rule was first derived (in 1965) from the commutation relations of these charges, together with the assumption of a partially conserved axial-vector current (PCAC). It connected nucleon $\beta$-decay coupling with pion–nucleon scattering cross sections, agreeing well with experiment. Various low-energy theorems followed, also in accord with experiment. Shortly thereafter, Adler was able to eliminate the PCAC assumption, and derived a further sum rule going beyond an experimental test of the algebra of charges to test the actual local current algebra. Here, the prediction pertained to structure functions in the deep inelastic scattering of neutrinos. This was elaborated by Bjorken to inelastic electron scattering. On the theoretical side, the study of the chiral current in perturbation theory led into the theory of anomalies. All these ideas were highly influential in subsequent theoretical work (Treiman *et al.* 1985, Mickelsson 1989).

It is a natural idea to try to extend eqns [4] or [6], which elegantly express the combined ideas of locality and symmetry, to an equal-time commutator algebra that would also include the space components of the local currents $\mathcal{F}_a^k, k = 1, 2, 3$. One may write without difficulty the commutators of the charges in [1] with these space components:

$$\begin{aligned} [F_a(x^0), \mathcal{F}_b^k(x^0, \boldsymbol{x})] &= [F_a^5(x^0), \mathcal{F}_b^{5k}(x^0, \boldsymbol{x})] \\ &= \mathrm{i} \sum_d c_{abd} \mathcal{F}_d^k(x^0, \boldsymbol{x}) \\ [F_a(x^0), \mathcal{F}_b^{5k}(x^0, \boldsymbol{x})] &= [F_a^5(x^0), \mathcal{F}_b^k(x^0, \boldsymbol{x})] \\ &= \mathrm{i} \sum_d c_{abd} \mathcal{F}_d^{5k}(x^0, \boldsymbol{x}) \end{aligned} \qquad [7]$$

But the commutator of the local time component with the local space component of the current cannot be merely the obvious extrapolation from eqns [4] and [7], that is, it cannot be

$$\begin{aligned} &[\mathcal{F}_a(x^0, \boldsymbol{x}), \mathcal{F}_b^k(y^0, \boldsymbol{y})]_{x^0 = y^0} \\ &\quad = \mathrm{i}\delta^{(3)}(\boldsymbol{x} - \boldsymbol{y}) \sum_d c_{abd} \mathcal{F}_d^k(x^0, \boldsymbol{x}) \end{aligned}$$

and so forth. Under very general conditions, for a relativistic theory based on local quantum fields or local observables, additional "Schwinger terms" are required on the right-hand sides of such commutators (Renner 1968).

Well-known difficulties in specifying the Schwinger terms are associated with the fact that operator-valued distributions are singular when regarded as if they were functions of spacetime points. Thus, the product of two distributions at a point is often singular or undefined. When the currents forming a local current algebra are written as normal-ordered products of field operator distributions and their derivatives, the Schwinger terms in their commutation relations may be calculated, for example, by "splitting points" in the arguments of the underlying fields, and subsequently letting the separation tend toward zero. The general form of a Schwinger term typically involves the derivative of a $\delta$-function times an operator. This may be a multiple of the identity (i.e., a $c$-number) or not, depending on the underlying

field-theoretic model. Furthermore, when the number of spacetime dimensions is greater than $1+1$, the $c$-number Schwinger terms turn out to be infinite. Hence, we do not obtain this way a bona- fide infinite-dimensional, equal-time commutator algebra comprising all the components of the local currents.

## Sugawara, Kac–Moody, and Virasoro Algebras

Since equations such as [4] and [6] are not explicitly dependent on how the currents are constructed from underlying canonical fields, one has the possibility of writing a theory entirely in terms of self-adjoint currents as the dynamical variables, bypassing the field operators entirely, and expressing a Hamiltonian operator directly in terms of such local currents. This is in the spirit of approaches to quantum field theory based on local algebras of observables. It suggests consideration of relativistic current algebras with finite c-number or operator Schwinger terms in $s+1$ dimensions, $s \geq 1$.

The Sugawara model, which is of this type, turned out to be one of the most influential of those proposed in the late 1960s and early 1970s. Henceforth, let $G$ be a compact Lie group, and $\mathcal{G}$ its Lie algebra; let $F_a, a=1,\ldots,\dim\mathcal{G}$, be a basis for $\mathcal{G}$, with $[F_a, F_b] = \mathrm{i}\Sigma_d c_{abd} F_d$. The Sugawara current algebra, at the fixed time $x^0 = y^0$ (which, from here on, we suppress in the notation), is given by

$$
\begin{aligned}
[J_a^0(\boldsymbol{x}), J_b^0(\boldsymbol{y})] &= \mathrm{i}\delta^{(3)}(\boldsymbol{x}-\boldsymbol{y})\sum_d c_{abd} J_d^0(\boldsymbol{x}) \\
[J_a^0(\boldsymbol{x}), J_b^k(\boldsymbol{y})] &= \mathrm{i}\delta^{(3)}(\boldsymbol{x}-\boldsymbol{y})\sum_d c_{abd} J_d^k(\boldsymbol{x}) \\
&\quad + \mathrm{i}c\delta_{ab}\frac{\partial}{\partial x^k}\delta^{(3)}(\boldsymbol{x}-\boldsymbol{y})I \\
[J_a^k(\boldsymbol{x}), J_b^\ell(\boldsymbol{y})] &= 0 \quad (k,\ell = 1,2,3)
\end{aligned}
\qquad [8]
$$

where $J_a^\mu = (J_a^0, J_a^k), k = 1,2,3$, is again a 4-vector, $c$ is a finite constant, and $I$ is the identity operator. The time components in eqns [8] behave like the local currents in eqns [4]. The Schwinger term is a $c$-number, while setting the commutators of the space components to zero is the simplest choice consistent with the Jacobi identity. The Sugawara Hamiltonian is given in terms of the local currents by the formal expression:

$$
H = \frac{1}{2c}\sum_a \int_{R^3} \mathrm{d}^3x \left[ J_a^0(\boldsymbol{x})^2 + \sum_{k=1}^3 J_a^k(\boldsymbol{x})^2 \right] \qquad [9]
$$

where the pointwise products of the currents require interpretation in the particular representation. This Hamiltonian leads to current conservation equations for the $J_a^\mu$.

Related to the Sugawara current algebra, with $s=1$ and the spatial dimension compactified, are affine Kac–Moody and Virasoro algebras (Goddard and Olive 1986, Kac 1990). Consider the infinite-dimensional Lie algebra map$(S^1, \mathcal{G})$ of smooth functions from the circle to $\mathcal{G}$ under the pointwise bracket. This is also called a loop algebra. Referring to the basis $F_a$, define $T_a^{(m)}$ for integer $m$ to be the Fourier function $\theta \to F_a \exp[-\mathrm{i}m\theta]$. The pointwise bracket in map$(S^1, \mathcal{G})$ gives $[T_a^{(m)}, T_b^{(n)}] = \mathrm{i}\Sigma_d c_{abd} T_d^{(m+n)}$ for these generators. The corresponding (untwisted) affine Kac–Moody algebra is a (uniquely defined, nontrivial) one-dimensional central extension of this loop algebra – that is, the new generator commutes with all elements of the Lie algebra and, in an irreducible representation, must be a multiple of the identity. In such a representation, the new bracket can be written as

$$
[T_a^{(m)}, T_b^{(n)}] = \mathrm{i}\sum_d c_{abd} T_d^{(m+n)} + km\delta_{ab}\delta_{m,-n}I \qquad [10]
$$

where $k$ is a constant. Here, $T_a^{(m=0)}$ is again a representation of $\mathcal{G}$. Self-adjointness of the local currents in the representation imposes the condition $T_a^{(m)^*} = T_a^{(-m)}$.

Now the compactly supported $C^\infty$ (tangent) vector fields on a $C^\infty$ manifold $M$ form a natural Lie algebra under the Lie bracket, denoted by vect$_0(M)$. In local Euclidean coordinates, for $\boldsymbol{g}_1, \boldsymbol{g}_2 \in$ vect$_0(M)$, one can write this bracket as

$$
[\boldsymbol{g}_1, \boldsymbol{g}_2] = \boldsymbol{g}_1 \cdot \nabla \boldsymbol{g}_2 - \boldsymbol{g}_2 \cdot \nabla \boldsymbol{g}_1 \qquad [11]
$$

As the affine Kac–Moody algebras are central extensions of the algebra of $\mathcal{G}$-valued functions on $S^1$, so are Virasoro algebras central extensions of the algebra of vector fields on $S^1$. Let $L^{(m)}$ denote the (complexified) vector field described by $\exp[-\mathrm{i}m\theta](1/\mathrm{i})\partial/\partial\theta$, for integer $m$. These generators then satisfy $[L^{(m)}, L^{(n)}] = (m-n)L^{(m+n)}$. Adjoining to the Lie algebra of vector fields a new central element (commuting with all the $L^{(m)}$), the Virasoro bracket in an irreducible representation is given by the formula

$$
\begin{aligned}
[L^{(m)}, L^{(n)}] &= (m-n)L^{(m+n)} \\
&\quad + c\frac{(m+1)m(m-1)}{12}\delta_{m,-n}I
\end{aligned}
\qquad [12]
$$

where the numerical coefficient $c$ is called the Virasoro central charge; self-adjointness of the currents imposes $L^{(m)^*} = L^{(-m)}$. It is straightforward to verify that eqn [12] satisfies the Jacobi identity. The special form of the central term in the Virasoro current algebra results from the Gelfand–Fuks cohomology on the algebra of vector fields.

The Kac–Moody and Virasoro algebras, both modeled on $S^1$, may be combined to form a natural semidirect sum of Lie algebras, with the additional bracket

$$[T_a^{(m)}, L^{(n)}] = mT_a^{(m+n)} \qquad [13]$$

Roughly speaking, the Kac–Moody generators correspond to Fourier transforms of charge densities on $S^1$, whereas the Virasoro generators correspond to Fourier transforms of infinitesimal motions in $S^1$. The central extensions provide the finite, $c$-number Schwinger terms. These structures have important application to light cone current algebra, conformally invariant quantum field theories in $(1+1)$-dimensional spacetime, the quantum theory of strings, exactly solvable models in statistical mechanics, and many other domains.

Of greatest physical importance, both in quantum field theory and statistical mechanics, are those irreducible, self-adjoint representations of the Virasoro algebra known as highest weight representations, where the spectrum of the operator $L^{(m=0)}$ is bounded below. In these applications, one represents a pair of Virasoro algebras by mutually commuting sets of operators $L^{(m)}$ and $\bar{L}^{(m)}$. In the quantum theory, for example, one takes the total energy $H \propto \bar{L}^{(0)} + L^{(0)}$, and the total momentum $P \propto \bar{L}^{(0)} - L^{(0)}$. In a highest weight representation, there is a unique eigenstate of $L^{(0)}$ having the lowest eigenvalue $h$; for this "vacuum" $|h\rangle, L^{(m)}|h\rangle = 0,\ m > 0$.

Friedan, Qiu, and Shenker showed in 1984 that highest weight representations are characterized by a class of specific, non-negative values of the central charge $c$ and, correspondingly, of $h$: either $c \geq 1$ (and $h \geq 0$) or $c = 1 - 6(\ell+2)^{-1}(\ell+3)^{-1}$, $\ell = 1, 2, 3, \ldots$ (and $h$ assumes a corresponding, specified set of values for each value of $\ell$). In a beautiful application to the study of the critical behavior of well-known statistical systems, in which the generator of dilations is proportional to $\bar{L}^{(0)} + L^{(0)}$, they discovered a direct correspondence with permitted values of the central charge; thus, $c = 1/2$ for the Ising model, $c = 7/10$ for the tricritical Ising model, $c = 4/5$ for the three-state Potts model, and $c = 6/7$ for the tricritical three-state Potts model.

## Current Algebras and Groups

Local current algebras may be exponentiated to obtain corresponding infinite-dimensional topological groups (Pressley and Segal 1986, Mickelsson 1989, Kac 1990). Let $G$ be a Lie group whose Lie algebra is $\mathcal{G}$. The algebra $\mathrm{map}_0(M, \mathcal{G})$, consisting of smooth, compactly supported $\mathcal{G}$-valued functions on $M$ under the pointwise bracket, exponentiates to the local current group $\mathrm{Map}_0(M, G)$, consisting of smooth maps from $M$ to $G$ that are the identity outside a compact set in $M$, under the pointwise group operation. When $M$ is taken to be the four-dimensional spacetime manifold (rather than a spacelike hyperplane), the local current group modeled on $M$ is mathematically a gauge group for nonabelian gauge field theory.

Likewise, the algebra $\mathrm{vect}_0(M)$ exponentiates to the group $\mathrm{Diff}_0(M)$ of compactly supported $C^\infty$ diffeomorphisms of $M$ (under composition). The Kac–Moody and Virasoro algebras exponentiate to central extensions of the loop group $\mathrm{Map}(S^1, G)$ and the diffeomorphism group $\mathrm{Diff}(S^1)$, respectively. The semidirect sums of the Lie algebras are the infinitesimal generators of semidirect products of the groups.

Under appropriate technical conditions, self-adjoint representations of current algebras generate (and may be obtained from) continuous unitary representations of the corresponding groups. The needed technical conditions have to do with the existence of a dense set of analytic vectors belonging to a common, dense invariant domain of essential self-adjointness for the currents.

## Nonrelativistic Current Algebra

In nonrelativistic local current algebra, Schwinger terms do not appear. In 1968, Dashen and Sharp defined (at fixed time $t$, suppressed in the present notation) a mass density $\rho(\boldsymbol{x}) = m\psi^*(\boldsymbol{x})\psi(\boldsymbol{x})$ and a momentum density $\boldsymbol{J}(\boldsymbol{x}) = (\hbar/2\mathrm{i})\{\psi^*(\boldsymbol{x})\nabla\psi(\boldsymbol{x}) - [\nabla\psi^*(\boldsymbol{x})]\psi(\boldsymbol{x})\}$, where $\psi$ is a second-quantized canonical field; here we keep $\hbar$ in the notation. The resulting equal-time algebra is the semidirect sum:

$$\begin{aligned}
&[\rho(\boldsymbol{x}), \rho(\boldsymbol{y})] = 0 \\
&[\rho(\boldsymbol{x}), J^k(\boldsymbol{y})] = -\mathrm{i}\hbar \frac{\partial}{\partial x^k}[\delta^{(3)}(\boldsymbol{x}-\boldsymbol{y})\rho(\boldsymbol{x})] \\
&[J^k(\boldsymbol{x}), J^\ell(\boldsymbol{y})] = \mathrm{i}\hbar\left\{\frac{\partial}{\partial y^k}[\delta^{(3)}(\boldsymbol{x}-\boldsymbol{y})J^\ell(\boldsymbol{y})] \right. \\
&\qquad\qquad \left. - \frac{\partial}{\partial x^\ell}[\delta^{(3)}(\boldsymbol{x}-\boldsymbol{y})J^k(\boldsymbol{x})]\right\}
\end{aligned} \qquad [14]$$

Since this current algebra is independent of whether $\psi$ obeys commutation or anticommutation relations, the information as to particle statistics (Bose or Fermi) is not encoded in the Lie algebra itself but in the choice of its representation (up to unitary equivalence). Again interpreting $\rho$ and $J^k$ as operator-valued distributions, define $\rho(f) = \int_{\boldsymbol{R}^3} \mathrm{d}^3x\, f(\boldsymbol{x})\rho(\boldsymbol{x})$ and $J(\boldsymbol{g}) = \int_{\boldsymbol{R}^3} \mathrm{d}^3x\, \Sigma_{k=1}^3 g^k(\boldsymbol{x})J^k(\boldsymbol{x})$, where $f$ and the

components $g^k$ of the vector field $\boldsymbol{g}$ belong to the function-space $\mathcal{D}$. Then the Lie algebra becomes

$$
\begin{aligned}
&[\rho(f_1), \rho(f_2)] = 0 \\
&[\rho(f), J(\boldsymbol{g})] = \mathrm{i}\hbar\rho(\boldsymbol{g}\cdot\nabla f) \\
&[J(\boldsymbol{g}_1), J(\boldsymbol{g}_2)] = -\mathrm{i}\hbar J([\boldsymbol{g}_1, \boldsymbol{g}_2])
\end{aligned} \qquad [15]
$$

Equations [15] are a representation by self-adjoint operators of the semidirect sum of the abelian Lie algebra $\mathcal{D}$ with $\mathrm{vect}_0(\boldsymbol{R}^3)$. The corresponding group is the natural semidirect product of the space $\mathcal{D}$ (regarded as an abelian topological group under addition) with $\mathrm{Diff}_0(\boldsymbol{R}^3)$.

The construction generalizes to a general manifold $M$ or manifold with boundary (in place of $\boldsymbol{R}^3$), and to a general set of charge densities that generate the local Lie algebra $\mathrm{map}_0(M, \mathcal{G})$. When $M = S^1$, we have the Kac–Moody and Virasoro algebras with central charge zero. However, $L^{(0)}$ in the nonrelativistic $(1+1)$-dimensional quantum theories is proportional to the total momentum $P$, and thus is unbounded above and below.

The continuous unitary representations of $\mathrm{Diff}_0(M)$, or its semidirect product with a local current group at fixed time, thus describe nonrelativistic quantum systems (Albeverio *et al.* 1999, Goldin 2004). The unitary representation $V(\phi), \phi \in \mathrm{Diff}_0(M)$, satisfies $V(\phi_r^{\boldsymbol{g}}) = \exp[\mathrm{i}(r/\hbar)J(\boldsymbol{g})]$, where $r \in \boldsymbol{R}$ and $\phi_r^{\boldsymbol{g}}$ is the one-parameter flow in $\mathrm{Diff}_0(M)$ generated by the vector field **g**. Such a representation may be described very generally by means of a measure $\mu$ on a configuration space $\Delta$, quasi-invariant under a group action of $\mathrm{Diff}_0(M)$ on $\Delta$, together with a unitary 1-cocycle $\chi$ on $\mathrm{Diff}_0(M) \times \Delta$. The Hilbert space for the representation is $\mathcal{H} = L^2_{\mathrm{d}\mu}(\Delta, \mathcal{W})$, which is the space of measurable functions $\Psi(\gamma), \gamma \in \Delta$, taking values in an inner product space $\mathcal{W}$, and square integrable with respect to $\mu$. The unitary representation $V$ is given by

$$
[V(\phi)\Psi](\gamma) = \chi_\phi(\gamma)\Psi(\phi\gamma)\sqrt{\frac{\mathrm{d}\mu_\phi}{\mathrm{d}\mu}(\gamma)} \qquad [16]
$$

where $\phi\gamma$ denotes the group action $\mathrm{Diff}_0(M) \times \Delta \to \Delta$; $\mu_\phi$ is the measure on $\Delta$ transformed by $\phi$ (which, by the quasi-invariance of $\mu$, is absolutely continuous with respect to $\mu$); $\mathrm{d}\mu_\phi/\mathrm{d}\mu$ is the Radon–Nikodym derivative; and $\chi_\phi(\gamma) : \mathcal{W} \to \mathcal{W}$ is a system of unitary operators in $\mathcal{W}$ obeying the cocycle equation

$$
\chi_{\phi_1\phi_2}(\gamma) = \chi_{\phi_1}(\gamma)\chi_{\phi_2}(\phi_1\gamma) \qquad [17]
$$

Equations [16] and [17] hold outside sets of $\mu$-measure zero in $\Delta$. Given the quasi-invariant measure $\mu$ on $\Delta$, one may always choose $\mathcal{W} = \mathbf{C}$ and $\chi_\phi(\gamma) \equiv 1$ to obtain a unitary group representation on complex-valued wave functions; but inequivalent cocycles describe unitarily inequivalent representations.

The configuration space $\Delta^{(N)}, N = 1, 2, 3, \ldots,$ consists of $N$-point subsets of $\boldsymbol{R}^s$, and $\mu^{(N)}$ is the (local) Lebesgue measure on $\Delta^{(N)}$. The corresponding diffeomorphism group and local current algebra representations describe $N$ identical quantum particles in $s$-dimensional space. When $\chi \equiv 1$, we have bosonic exchange symmetry. Inequivalent cocycles on $\Delta^{(N)}$ are obtained (for $s \geq 2$) by inducing (generalizing Mackey's method) from inequivalent unitary representations of the fundamental group $\pi_1[\Delta^{(N)}]$. For $s \geq 3$, this fundamental group is the symmetric group $S_N$ of particle permutations; the odd representation of $S_N, N \geq 2$, gives fermionic exchange symmetry, while the higher-dimensional representations are associated with particles satisfying the parastatistics of Greenberg and Messiah.

When $s = 2$, however, $\pi_1[\Delta^{(N)}]$ is the braid group $B_N$. Goldin, Menikoff, and Sharp obtained induced representations of the current algebra describing the intermediate statistics proposed by Leinaas and Myrheim for identical particles in 2-space. Such excitations, subsequently termed "anyons" by Wilczek and characterized as charge-flux tube composites, are important constructs in the theory of surface phenomena such as the quantum Hall effect, and anyonic statistics has also been applied to the study of high-$T_{\mathrm{c}}$ superconductivity. Current algebra representations induced by higher-dimensional representations of $B_N$ describe the statistics of "plektons." Similarly, current algebra in nonsimply connected space describes the Aharonov–Bohm effect.

Let $\psi^*(h) = \int_{\boldsymbol{R}^s} \mathrm{d}^s x\, h(\boldsymbol{x})\psi^*(\boldsymbol{x})$ denote the smeared creation field. Let the indexed set of representations $\rho_N, J_N, N = 0, 1, 2, \ldots,$ satisfying the current algebra [15], act in Hilbert spaces $\mathcal{H}_N$, where $\psi^*(h) : \mathcal{H}_N \to \mathcal{H}_{N+1}, \psi(h) : \mathcal{H}_{N+1} \to \mathcal{H}_N, \psi(h)|\mathcal{H}_0 = 0$, so that $\psi^*$ and $\psi$ intertwine the $N$-particle diffeomorphism group representations. Let $\rho(f)$ and $J(\boldsymbol{g})$ act on $\bigoplus_{N=0}^{\infty} \mathcal{H}_N$, so that $\rho(f)\Psi_N = \rho_N(f)\Psi_N, J(\boldsymbol{g})\Psi_N = J_N(\boldsymbol{g})\Psi_N$. Then conditions for a Fock space hierarchy are specified by commutator brackets of the fields with the currents:

$$
\begin{aligned}
&[\rho(f), \psi^*(h)] = \psi^*(\rho_{N=1}(f)h) \\
&[J(\boldsymbol{g}), \psi^*(h)] = \psi^*(J_{N=1}(\boldsymbol{g})h)
\end{aligned} \qquad [18]
$$

The local creation and annihilation fields for anyons in $\boldsymbol{R}^2$, obeying [18], satisfy $q$-commutation relations, where $q$ is the relative phase change associated with a single counterclockwise exchange of two anyons,

and the $q$-commutator $[A, B]_q = AB - qBA$. These relations generalize the canonical commutation ($q = 1$) and anticommutation ($q = -1$) relations of quantum field theory.

When $\Delta$ is the configuration space of infinite but locally finite subsets of $\boldsymbol{R}^s$, nonrelativistic current algebra describes the physics of infinite gases in continuum classical or quantum statistical mechanics. Here, the most important kinds of measures $\mu$ are Poisson measures (associated with gases of noninteracting particles at fixed average density) or Gibbsian measures (associated with translation-invariant two-body interactions). These measures describe equilibrium states and correlation functions in the classical case, and specify the current algebra representations in the quantum theory.

The group of volume-preserving diffeomorphisms was taken by Arnold as the symmetry group of an ideal, classical, incompressible fluid, and Marsden and Weinstein described the hydrodynamics of such a fluid using the Lie–Poisson bracket associated with the nonrelativistic current algebra of divergenceless vector fields. The idea of using this algebra to study quantized fluid motion, included in the program proposed by Rasetti and Regge, formed the basis of the subsequent study of quantized vortex structures in superfluids from the point of view of geometric quantization on coadjoint orbits of the diffeomorphism group. This leads to quantum configuration spaces whose elements are no longer sets of points – for example, spaces of vortex filaments in $\boldsymbol{R}^2$, or ribbons and tubes in $\boldsymbol{R}^3$.

## Deformation Quantization

**A C Hirshfeld**, Universität Dortmund, Dortmund, Germany

### Introduction

Deformation quantization is an alternative way of looking at quantum mechanics. Some of its techniques were introduced by the pioneers of quantum mechanics, but it was first proposed as an autonomous theory in a paper in *Annals of Physics* (Bayen *et al.* 1978). More recent reviews treat modern developments (HH I 2001, Dito and Sternheimer 2002, Zachos 2002).

Deformation quantization concentrates on the central physical concepts of quantum theory: the algebra of observables and their dynamical evolution. Because it deals exclusively with functions of phase-space variables, its conceptual break with classical mechanics is less severe than in other approaches. It formulates the correspondence principle very precisely which played such an important role in the historical development.

Although this article deals mainly with nonrelativistic bosonic systems, deformation quantization is much more general. For inclusion of fermions and the Dirac equation see (Hirshfeld *et al.* 2002b). The fermionic degrees of freedom may, in special cases, be obtained from the bosonic ones by supersymmetric extension (Hirshfeld *et al.* 2004). For applications to field theory, see Hirshfeld *et al.* (2002). For the relation to Hopf algebras see Hirshfeld *et al.* (2003), and to geometric algebra, see Hirshfeld *et al.* (2005).

The observables of a physical system, such as the Hamilton function, are smooth real-valued functions on phase space. Physical quantities of the system at some time, such as the energy, are calculated by evaluating the Hamilton function at the point $x_0 = (q_0, p_0)$ in phase space that characterizes the state of the system at this time (we assume for the moment, a one-particle system). The mathematical expression for this operation is

$$E = \int H(q,p)\delta^{(2)}(q - q_0, p - p_0)\, dq\, dp \quad [1]$$

where $\delta^{(2)}$ is the two-dimensional Dirac delta function. The observables of the dynamical system are functions on the phase space, the states of the system are positive functionals on the observables (here the Dirac delta functions), and we obtain the value of the observable in a definite state by the operation shown in eqn [1].

In general, functions on a manifold are multiplied by each other in a pointwise manner, that is, given two functions $f$ and $g$, their product $fg$ is the function

$$(fg)(x) = f(x)g(x) \quad [2]$$

In the context of classical mechanics, the observables build a commutative algebra, called the commutative "classical algebra of observables."

In Hamiltonian mechanics there is another way to combine two functions on phase space in such a way that the result is again a function on the phase space, namely by using the Poisson bracket

$$\begin{aligned} \{f,g\}(q,p) &= \sum_{i=1}^{n} \left( \frac{\partial f}{\partial q_i}\frac{\partial g}{\partial p_i} - \frac{\partial f}{\partial p_i}\frac{\partial g}{\partial q_i} \right)\bigg|_{q,p} \\ &= f\left( \overleftarrow{\partial}_q \overleftarrow{\partial}_p - \overleftarrow{\partial}_p \overrightarrow{\partial}_p \right) g \end{aligned} \quad [3]$$

in an abbreviated notation.

The notation can be further abbreviated by using $x$ to represent points of the phase-space manifold, $x = (x_1, \ldots, x_{2n})$, and introducing the Poisson tensor $\alpha^{ij}$, where the indices $i, j$ run from 1 to $2n$. In canonical coordinates $\alpha^{ij}$ is represented by the matrix

$$\alpha = \begin{pmatrix} 0 & -I_n \\ I_n & 0 \end{pmatrix} \quad [4]$$

where $I_n$ is the $n \times n$ identity matrix. Then eqn [3] becomes

$$\{f, g\}(x) = \alpha^{ij}\partial_i f(x)\, \partial_j g(x) \quad [5]$$

where $\partial_i = \partial/\partial x_i$.

For a general observable,

$$\dot{f} = \{f, H\} \quad [6]$$

Because $\alpha$ transforms like a tensor with respect to coordinate transformations, eqn [5] may also be written in noncanonical coordinates. In this case the components of $\alpha$ need not be constants, and may depend on the point of the manifold at which they are evaluated. But in Hamiltonian mechanics, $\alpha$ is still required to be invertible. A manifold equipped with a Poisson tensor of this kind is called a symplectic manifold. In general, the tensor $\alpha$ is no longer required to be invertible, but it nevertheless suffices to define Poisson brackets via eqn [5], and these brackets are required to have the properties

1. $\{f, g\} = -\{g, f\}$,
2. $\{f, gh\} = \{f, g\}h + g\{f, h\}$, and
3. $\{f, \{g, h\}\} + \{g, \{h, f\}\} + \{h, \{f, g\}\} = 0$.

Property (1) implies that the Poisson bracket is antisymmetric, property (2) is referred to as the Leibnitz rule, and property (3) is called the Jacobi identity. The Poisson bracket used in Hamiltonian mechanics satisfies all these properties, but we now abstract these properties from the concrete prescription of eqn [3], and a Poisson manifold $(M, \alpha)$ is defined as a smooth manifold $M$ equipped with a Poisson tensor $\alpha$, whose components are no longer necessarily constant, such that the bracket defined by eqn [5] has the above properties. It turns out that such manifolds provide a better context for treating dynamical systems with symmetries. In fact, they are essential for treating gauge-field theories, which govern the fundamental interactions of elementary particles.

## Quantum Mechanics and Star Products

The essential difference between classical and quantum mechanics is Heisenberg's uncertainty relation, which implies that in the latter, states can no longer be represented as points in phase space. The uncertainty is a consequence of the noncommutativity of the quantum mechanical observables. That is, the commutative classical algebra of observables must be replaced by a noncommutative quantum algebra of observables.

In the conventional approach to quantum mechanics, this noncommutativity is implemented by representing the quantum mechanical observables by linear operators in Hilbert space. Physical quantities are then represented by eigenvalues of these operators, and physical states are related to the operator eigenfunctions. Although these entities are somehow related to their classical counterparts, to which they are supposed to reduce in an appropriate limit, the precise relationship has remained obscure, one hundred years after the beginnings of quantum mechanics. Textbooks refer to the correspondence principle, which guided the pioneers of the subject. Attempts to give this idea a precise formulation by postulating a specific relation between the classical Poisson brackets of observables and the commutators of the corresponding quantum mechanical operators, as undertaken, for example, by Dirac and von Neumann, encountered insurmountable difficulties, as pointed out by Groenewold in 1946 in an unjustly neglected paper (Groenewold 1948). In the same paper Groenewold also wrote down the first explicit representation of a "star product" (see eqn [11]), without however realizing the potential of this concept for overcoming the difficulties that he wanted to resolve.

In the deformation quantization approach, there is no such break when going from the classical system to the corresponding quantum system; we describe the quantum system by using the same entities that are used to describe the classical system. The observables of the system are described by the same functions on phase space as their classical counterparts. Uncertainty is realized by describing physical states as distributions on phase space that are not sharply localized, in contrast to the Dirac delta functions which occur in the classical case. When we evaluate an observable in some definite state according to the quantum analog of eqn [1] (see eqn [24]), values of the observable in a whole region contribute to the number that is obtained, which is thus an average value of the observable in the given state. Noncommutativity is incorporated by introducing a noncommutative product for functions on phase space, so that we get a new noncommutative quantum algebra of observables. The systematic work on deformation quantization stems from Gerstenhaber's seminal paper, where he introduced the concept of a star product of smooth functions on a manifold (Gerstenhaber 1964).

For applications to quantum mechanics, we consider smooth complex-valued functions on a Poisson manifold. A star product $f * g$ of two such functions is a new smooth function, which, in general, is described by an infinite power series:

$$f * g = fg + (\mathrm{i}\hbar)C_1(f, g) + O(\hbar^2) = \sum_{n=0}^{\infty} (\mathrm{i}\hbar)^n C_n(f, g) \qquad [7]$$

The first term in the series is the pointwise product given in eqn [2], and $(\mathrm{i}\hbar)$ is the deformation parameter, which is assumed to be varying continuously. If $\hbar$ is identified with Planck's constant, then what varies is really the magnitude of the

action of the dynamical system considered in units of $\hbar$: the classical limit holds for systems with large action. In this limit, which we express here as $\hbar \to 0$, the star product reduces to the usual product. In general, the coefficients $C_n$ will be such that the new product is noncommutative, and we consider the noncommutative algebra formed from the functions with this new multiplication law as a deformation of the original commutative algebra, which uses pointwise multiplication of the functions.

The expressions $C_n(f, g)$ denote functions made up of the derivatives of the functions $f$ and $g$. It is obvious that without further restrictions of these coefficients, the star product is too arbitrary to be of any use. Gerstenhaber's discovery was that the simple requirement that the new product be associative imposes such strong requirements on the coefficients $C_n$ that they are essentially unique in the most important cases (up to an equivalence relation, as discussed below). Formally, Gerstenhaber required that the coefficients satisfy the following properties:

1. $\sum_{j+k=n} C_j(C_k(f,g),h) = \sum_{j+k=n} C_j(f, C_k(g,h))$,
2. $C_0(f,g) = fg$, and
3. $C_1(f,g) - C_1(g,f) = \{f,g\}$.

Property (1) guarantees that the star product is associative: $(f*g)*h = f*(g*h)$. Property (2) means that in the limit $\hbar \to 0$, the star product $f*g$ agrees with the pointwise product $fg$. Property (3) has at least two aspects: (i) mathematically, it anchors the new product to the given structure of the Poisson manifold and (ii) physically, it provides the connection between the classical and quantum behavior of the dynamical system. Define a commutator by using the new product:

$$[f,g]_* = f*g - g*f \tag{8}$$

Property (3) may then be written as

$$\lim_{\hbar\to 0} \frac{1}{i\hbar}[f,g]_* = \{f,g\} \tag{9}$$

Equation [9] is the correct form of the correspondence principle. In general, the quantity on the left-hand side of eqn [9] reduces to the Poisson bracket only in the classical limit. The source of the mathematical difficulties that previous attempts to formulate the correspondence principle encountered was related to trying to enforce equality between the Poisson bracket and the corresponding expression involving the quantum mechanical commutator. Equation [9] shows that such a relation in general only holds up to corrections of higher order in $\hbar$.

For physical applications we usually require the star product to be Hermitean: $\overline{f*g} = \bar{g}*\bar{f}$, where $\bar{f}$ denotes the complex conjugate of $f$. The star products considered in this article have this property.

For a given Poisson manifold, it is not clear *a priori* if a star product for the smooth functions on the manifold actually exists, that is, whether it is at all possible to find coefficients $C_n$ that satisfy the above list of properties. Even if we find such coefficients, it it still not clear that the series they define through eqn [7] yields a smooth function. Mathematicians have worked hard to answer these questions in the general case. For flat Euclidian spaces, $M = \mathbb{R}^{2n}$, a specific star product has long been known. In this case, the components of the Poisson tensor $\alpha^{ij}$ can be taken to be constants. The coefficient $C_1$ can then be chosen antisymmetric, so that

$$C_1(f,g) = \tfrac{1}{2}\alpha^{ij}(\partial_i f)(\partial_j g) = \tfrac{1}{2}\{f,g\} \tag{10}$$

by property (3) above. The higher-order coefficients may be obtained by exponentiation of $C_1$. This procedure yields the Moyal star product (Moyal 1949):

$$f *_M g = f \exp\left(\left(\frac{i\hbar}{2}\right)\alpha^{ij}\overleftarrow{\partial}_i\overrightarrow{\partial}_j\right) g \tag{11}$$

In canonical coordinates, eqn [11] becomes

$$(f *_M g)(q,p) = f(q,p)\exp\left(\frac{i\hbar}{2}(\overleftarrow{\partial}_q\overrightarrow{\partial}_p - \overleftarrow{\partial}_p\overrightarrow{\partial}_q)\right) g(q,p) \tag{12}$$

$$= \sum_{m,n=0}^{\infty}\left(\frac{i\hbar}{2}\right)^{m+n}\frac{(-1)^m}{m!n!}(\partial_p^m\partial_q^n f)(\partial_p^n\partial_q^m g) \tag{13}$$

We now come to the question of uniqueness of the star product on a given Poisson manifold. Two star products $*$ and $*'$ are said to be "$c$-equivalent" if there exists an invertible transition operator

$$T = 1 + \hbar T_1 + \cdots = \sum_{n=0}^{\infty}\hbar^n T_n \tag{14}$$

where the $T_n$ are differential operators that satisfy

$$f *' g = T^{-1}((Tf)*(Tg)) \tag{15}$$

It is known that for $M = \mathbb{R}^{2n}$ all admissible star products are $c$-equivalent to the Moyal product. The concept of $c$-equivalence is a mathematical one ($c$ stands for cohomology (Gerstenhaber 1964)); it does not by itself imply any kind of physical equivalence, as shown below.

Another expression for the Moyal product is a kind of Fourier representation:

$$(f *_M g)(q,p) = \frac{1}{\hbar^2\pi^2}\int \mathrm{d}q_1\,\mathrm{d}q_2\,\mathrm{d}p_1\,\mathrm{d}p_2 f(q_1,p_1)g(q_2,p_2) \times \exp\left[\frac{2}{\mathrm{i}\hbar}(p(q_1-q_2)+q(p_2-p_1) + (q_2p_1-q_1p_2)\right] \qquad [16]$$

Equation [16] has an interesting geometrical interpretation. Denote points in phase space by vectors, for example, in two dimensions:

$$\mathbf{r} = \begin{pmatrix} q \\ p \end{pmatrix}, \qquad \mathbf{r}_1 = \begin{pmatrix} q_1 \\ p_1 \end{pmatrix}, \qquad \mathbf{r}_2 = \begin{pmatrix} q_2 \\ p_2 \end{pmatrix} \qquad [17]$$

Now, consider the triangle in phase space spanned by the vectors $\mathbf{r}-\mathbf{r}_1$ and $\mathbf{r}-\mathbf{r}_2$. Its area (symplectic volume) is

$$\begin{aligned} A(\mathbf{r},\mathbf{r}_1,\mathbf{r}_2) &= \tfrac{1}{2}(\mathbf{r}-\mathbf{r}_1)\wedge(\mathbf{r}-\mathbf{r}_2) \\ &= \tfrac{1}{2}[p(q_2-q_1)+q(p_1-p_2)+(q_1p_2-q_2p_1)] \end{aligned} \qquad [18]$$

which is proportional to the exponent in eqn [16]. Hence, we may rewrite eqn [16] as

$$(f*g)(\mathbf{r}) = \int \mathrm{d}\mathbf{r}_1\,\mathrm{d}\mathbf{r}_2 f(\mathbf{r}_1)g(\mathbf{r}_2)\exp\left[\frac{4\mathrm{i}}{\hbar}A(\mathbf{r},\mathbf{r}_1,\mathbf{r}_2)\right] \qquad [19]$$

## Deformation Quantization

The properties of the star product are well adapted for describing the noncommutative quantum algebra of observables. We have already discussed the associativity and the incorporation of the classical and semiclassical limits. Note that the characteristic nonlocality feature of quantum mechanics is also explicit. In the expression for the Moyal product given in eqn [13], the star product of the functions $f$ and $g$ at the point $x=(q,p)$ involves not only the values of the functions $f$ and $g$ at this point, but also all higher derivatives of these functions at $x$. But for a smooth function, knowledge of all the derivatives at a given point is equivalent to the knowledge of the function on the entire space. In the integral expression of eqn [16], we also see that knowledge of the functions $f$ and $g$ on the whole phase space is necessary to determine the value of the star product at the point $x$.

The $c$-equivalent star products correspond to different quantization schemes. Having chosen a quantization scheme, the quantities of interest for the quantum system may be calculated. It turns out that different quantization schemes lead to different spectra for the observables. The choice of a specific quantization scheme can only be motivated by further physical requirements. In the simple example we discuss below, the classical system is completely specified by its Hamilton function. In more general cases, one may have to decide what constitutes a sufficiently large set of good observables for a complete specification of the system (Bayen *et al.* 1978).

A state is characterized by its energy $E$; the set of all possible values for the energy is called the spectrum of the system. The states are described by distributions on phase space called projectors. The state corresponding to the energy $E$ is denoted by $\pi_E(q,p)$. These distributions are normalized:

$$\frac{1}{2\pi\hbar}\int \pi_E(q,\,p)\mathrm{d}q\,\mathrm{d}p = 1 \qquad [20]$$

and idempotent:

$$(\pi_E * \pi_{E'})(q,\,p) = \delta_{E,E'}\pi_E(q,p) \qquad [21]$$

The fact that the Hamilton function takes the value $E$ when the system is in the state corresponding to this energy is expressed by the equation

$$(H*\pi_E)(q,\,p) = E\pi_E(q,\,p) \qquad [22]$$

Equation [22] corresponds to the time-independent Schrödinger equation, and is sometimes called the "$*$-genvalue equation." The spectral decomposition of the Hamilton function is given by

$$H(q,\,p) = \sum_E E\pi_E(q,\,p) \qquad [23]$$

where the summation sign may indicate an integration if the spectrum is continuous. The quantum mechanical version of eqn [1] is

$$\begin{aligned} E &= \frac{1}{2\pi\hbar}\int (H*\pi_E)(q,\,p)\mathrm{d}q\,\mathrm{d}p \\ &= \frac{1}{2\pi\hbar}\int H(q,p)\,\pi_E(q,\,p)\mathrm{d}q\,\mathrm{d}p \end{aligned} \qquad [24]$$

where the last expression may be obtained by using eqn [16] for the star product.

The time-evolution function for a time-independent Hamilton function is denoted by $\mathrm{Exp}(Ht)$, and the fact that the Hamilton function is the generator of the time evolution of the system is expressed by

$$\mathrm{i}\hbar\frac{\mathrm{d}}{\mathrm{d}t}\mathrm{Exp}(Ht) = H*\mathrm{Exp}(Ht) \qquad [25]$$

This equation corresponds to the time-dependent Schrödinger equation. It is solved by the star exponential:

$$\mathrm{Exp}(Ht) = \sum_{n=0}^{\infty} \frac{1}{n!} \left( \frac{-\mathrm{i}t}{\hbar} \right)^n (H*)^n \qquad [26]$$

where $(H*)^n = \underbrace{H*H*\cdots*H}_{n\,\mathrm{times}}$. Because each state of definite energy $E$ has a time evolution $\exp(\mathrm{i}Et/\hbar)$, the complete time-evolution function may be written in the form

$$\mathrm{Exp}(Ht) = \sum_E \pi_E \mathrm{e}^{-\mathrm{i}Et/\hbar} \qquad [27]$$

This expression is called the "Fourier–Dirichlet expansion" for the time-evolution function.

Questions concerning the existence and uniqueness of the star exponential as a $C^\infty$ function and the nature of the spectrum and the projectors again require careful mathematical analysis. The problem of finding general conditions on the Hamilton function $H$ which ensure a reasonable physical spectrum is analogous to the problem of showing, in the conventional approach, that the symmetric operator $\hat{H}$ is self-adjoint and finding its spectral projections.

## The Simple Harmonic Oscillator

As an example of the above procedure, we treat the simple one-dimensional harmonic oscillator characterized by the classical Hamilton function

$$H(q,p) = \frac{p^2}{2m} + \frac{m\omega^2}{2} q^2 \qquad [28]$$

In terms of the holomorphic variables

$$a = \sqrt{\frac{m\omega}{2}} \left( q + \mathrm{i}\frac{p}{m\omega} \right), \quad \bar{a} = \sqrt{\frac{m\omega}{2}} \left( q - \mathrm{i}\frac{p}{m\omega} \right) \qquad [29]$$

the Hamilton function becomes

$$H = \omega a \bar{a} \qquad [30]$$

Our aim is to calculate the time-evolution function. We first choose a quantization scheme characterized by the normal star product

$$f *_N g = f \mathrm{e}^{\hbar \overleftarrow{\partial}_a \overrightarrow{\partial}_{\bar{a}}} g \qquad [31]$$

we then have

$$\bar{a} *_N a = a\bar{a}, \qquad a *_N \bar{a} = a\bar{a} + \hbar \qquad [32]$$

so that

$$[a, \bar{a}]_{*_N} = \hbar \qquad [33]$$

Equation [25] for this case is

$$\mathrm{i}\hbar \frac{\mathrm{d}}{\mathrm{d}t} \mathrm{Exp}_N(Ht) = (H + \hbar\omega\bar{a}\partial_{\bar{a}}) \mathrm{Exp}_N(Ht) \qquad [34]$$

with the solution

$$\mathrm{Exp}_N(Ht) = \mathrm{e}^{-a\bar{a}/\hbar} \exp\left( \mathrm{e}^{-\mathrm{i}\omega t} a\bar{a}/\hbar \right) \qquad [35]$$

By expanding the last exponential in eqn [35], we obtain the Fourier–Dirichlet expansion

$$\mathrm{Exp}_N(Ht) = \mathrm{e}^{-a\bar{a}/\hbar} \sum_{n=0}^{\infty} \frac{1}{\hbar^n n!} \bar{a}^n a^n \, \mathrm{e}^{-\mathrm{i}n\omega t} \qquad [36]$$

From here, we can read off the energy eigenvalues and the projectors describing the states by comparing coefficients in eqns [27] and [36]:

$$\pi_0^{(N)} = \mathrm{e}^{-a\bar{a}/\hbar} \qquad [37]$$

$$\pi_n^{(N)} = \frac{1}{\hbar^n n!} \pi_0 \bar{a}^n a^n = \frac{1}{\hbar^n n} \bar{a}^n *_N \pi_0^{(N)} *_N a^n \qquad [38]$$

$$E_n = n\hbar\omega \qquad [39]$$

Note that the spectrum obtained in eqn [39] does not include the zero-point energy. The projector onto the ground state $\pi_0^{(N)}$ satisfies

$$a *_N \pi_0^{(N)} = 0 \qquad [40]$$

The spectral decomposition of the Hamilton function (eqn [23]) is in this case

$$H = \sum_{n=0}^{\infty} n\hbar\omega \left( \frac{1}{\hbar^n n!} \mathrm{e}^{-a\bar{a}/\hbar} \bar{a}^n a^n \right) = \omega a \bar{a} \qquad [41]$$

We now consider the Moyal quantization scheme. If we write eqn [12] in terms of holomorphic coordinates, we obtain

$$f *_M g = f \exp\left( \frac{\hbar}{2} (\overleftarrow{\partial}_a \overrightarrow{\partial}_{\bar{a}} - \overleftarrow{\partial}_{\bar{a}} \overrightarrow{\partial}_a) \right) g \qquad [42]$$

Here, we have

$$a *_M \bar{a} = a\bar{a} + \frac{\hbar}{2}, \qquad \bar{a} *_M a = a\bar{a} - \frac{\hbar}{2} \qquad [43]$$

and again

$$[a, \bar{a}]_{*_M} = \hbar \qquad [44]$$

The value of the commutator of two phase-space variables is fixed by property (3) of the star product,

and cannot change when one goes to a $c$-equivalent star product. The Moyal star product is $c$-equivalent to the normal star product with the transition operator

$$T = \mathrm{e}^{-(\hbar/2)\vec{\partial}_a \vec{\partial}_{\bar{a}}} \quad [45]$$

We can use this operator to transform the normal product version of the $*$-genvalue equation, eqn [22], into the corresponding Moyal product version according to eqn [15]. The result is

$$\begin{aligned} H *_{M} \pi_n^{(M)} &= \omega\left(\bar{a} *_{M} a + \frac{\hbar}{2}\right) *_{M} \pi_n^{(M)} \\ &= \hbar\omega\left(n + \tfrac{1}{2}\right)\pi_n^{(M)} \end{aligned} \quad [46]$$

with

$$\pi_0^{(M)} = T\pi_0^{(N)} = 2\mathrm{e}^{-2a\bar{a}/\hbar} \quad [47]$$

$$\pi_n^{(M)} = T\pi_n^{(N)} = \frac{1}{\hbar^n n}\bar{a}^n *_{M} \pi_0^{(M)} *_{M} a^n \quad [48]$$

The projector onto the ground state $\pi_0^{(M)}$ satisfies

$$a *_{M} \pi_0^{(M)} = 0 \quad [49]$$

We now have, for the spectrum,

$$E_n = \left(n + \tfrac{1}{2}\right)\hbar\omega \quad [50]$$

which is the textbook result. We conclude that for this problem, the Moyal quantization scheme is the correct one.

The use of the Moyal product in eqn [25] for the star exponential of the harmonic oscillator leads to the following differential equation for the time evolution function:

$$\begin{aligned} &\mathrm{i}\hbar\frac{\mathrm{d}}{\mathrm{d}t}\mathrm{Exp}_M(Ht) \\ &= \left(H - \frac{(\hbar\omega)^2}{4}\partial_H - \frac{(\hbar\omega)^2}{4}H\partial_H^2\right)\mathrm{Exp}_M(Ht) \end{aligned} \quad [51]$$

The solution is

$$\mathrm{Exp}_M(Ht) = \frac{1}{\cos(\omega t/2)}\exp\left[\left(\frac{2H}{\mathrm{i}\hbar\omega}\right)\tan\left(\frac{\omega t}{2}\right)\right] \quad [52]$$

This expression can be brought into the form of the Fourier–Dirichlet expansion of eqn [27] by using the generating function for the Laguerre polynomials:

$$\frac{1}{1+s}\exp\left[\frac{zs}{1+s}\right] = \sum_{n=0}^{\infty} s^n(-1)^n L_n(z) \quad [53]$$

with $s = \mathrm{e}^{-\mathrm{i}\omega t}$. The projectors then become

$$\pi_n^{(M)} = 2(-1)^n \mathrm{e}^{-2H/\hbar\omega} L_n\left(\frac{4H}{\hbar\omega}\right) \quad [54]$$

which is equivalent to the expression already found in eqn [48].

## Conventional Quantization

One usually finds the observables characterizing some quantum mechanical system by starting from the corresponding classical system, and then, either by guessing or by using some more or less systematic method, and finding the corresponding representations of the classical quantities in the quantum system. The guiding principle is the correspondence principle: the quantum mechanical relations are supposed to reduce somehow to the classical relations in an appropriate limit. Early attempts to systematize this procedure involved finding an assignment rule $\Theta$ that associates to each phase-space function $f$ a linear operator in Hilbert space $\hat{f} = \Theta(f)$ in such a way that in the limit $\hbar \to 0$, the quantum mechanical equations of motion go over to the classical equations. Such an assignment cannot be unique, because even though an operator that is a function of the basic operators $\hat{Q}$ and $\hat{P}$ reduces to a unique phase-space function in the limit $\hbar \to 0$, there are many ways to assign an operator to a given phase-space function, due to the different orderings of the operators $\hat{Q}$ and $\hat{P}$ that all reduce to the original phase-space function. Different ordering procedures correspond to different quantization schemes. It turns out that there is no quantization scheme for systems with observables that depend on the coordinates or the momenta to a higher power than quadratic which leads to a correspondence between the quantum mechanical and the classical equations of motion, and which simultaneously strictly maintains the Dirac–von Neumann requirement that $(1/\mathrm{i}\hbar)[\hat{f}, \hat{g}] \leftrightarrow \{f, g\}$. Only within the framework of deformation quantization does the correspondence principle acquire a precise meaning.

A general scheme for associating phase-space functions and Hilbert space operators, which includes all of the usual orderings, is given as follows: the operator $\Theta_\lambda(f)$ corresponding to a given phase-space function $f$ is

$$\Theta_\lambda(f) = \int \tilde{f}(\xi, \eta)\mathrm{e}^{-\mathrm{i}(\xi\hat{Q} + \eta\hat{P})}\mathrm{e}^{\lambda(\xi,\eta)}\mathrm{d}\xi\,\mathrm{d}\eta \quad [55]$$

where $\tilde{f}$ is the Fourier transform of $f$, and $(\hat{Q}, \hat{P})$ are the Schrödinger operators that correspond to the phase-space variables $(q, p)$; $\lambda(\xi, \eta)$ is a quadratic form:

$$\lambda(\xi, \eta) = \frac{\hbar}{4}(\alpha\eta^2 + \beta\xi^2 + 2\mathrm{i}\gamma\xi\eta) \quad [56]$$

Different choices for the constants $(\alpha, \beta, \gamma)$ yield different operator ordering schemes.

The relation between operator algebras and star products is given by

$$\Theta(f)\Theta(g) = \Theta(f * g) \qquad [57]$$

where $\Theta$ is a linear assignment of the kind discussed above. Different assignments, which correspond to different operator orderings, correspond to $c$-equivalent star products. It demonstrates that the quantum mechanical algebra of observables is a representation of the star product algebra. Because in the algebraic approach to quantum theory all the information concerning the quantum system may be extracted from the algebra of observables, specifying the star product completely determines the quantum system.

The inverse procedure of finding the phase-space function that corresponds to a given operator $\hat{f}$ is, for the special case of Weyl ordering, given by

$$f(q,p) = \int \langle q + \tfrac{1}{2}\xi|\hat{f}|q - \tfrac{1}{2}\xi\rangle \mathrm{e}^{-\mathrm{i}\xi p/\hbar}\,\mathrm{d}\xi \qquad [58]$$

When using holonomic coordinates, it is convenient to work with the coherent states

$$\hat{a}|a\rangle = a|a\rangle, \quad \langle\bar{a}|\hat{a}^\dagger = \langle\bar{a}|\bar{a} \qquad [59]$$

These states are related to the energy eigenstates of the harmonic oscillator

$$|n\rangle = \frac{1}{\sqrt{n!}}\hat{a}^{\dagger^n}|0\rangle \qquad [60]$$

by

$$|a\rangle = e^{-\frac{1}{2}a\bar{a}/\hbar}\sum_{n=0}^{\infty}\frac{a^n}{\sqrt{n!}}|n\rangle,$$
$$\langle\bar{a}| = e^{-\frac{1}{2}a\bar{a}/\hbar}\sum_{n=0}^{\infty}\frac{\bar{a}^n}{\sqrt{n!}}\langle n| \qquad [61]$$

In normal ordering, we obtain the phase space function $f(a,\bar{a})$ corresponding to the operator $\hat{f}$ by just taking the matrix element between coherent states:

$$f(a,\bar{a}) = \langle\bar{a}|f(\hat{a},\hat{a}^\dagger)|a\rangle \qquad [62]$$

For holomorphic coordinates, it is easy to show

$$\pi_n^{(N)}(a,\bar{a}) = \frac{1}{\hbar^n}\langle\bar{a}|n\rangle\langle n|a\rangle = \frac{1}{\hbar^n n!}(\bar{a}a)^n \mathrm{e}^{-\bar{a}a/\hbar} \qquad [63]$$

in agreement with eqn [38] for the normal star product projectors.

The star exponential $\mathrm{Exp}(Ht)$ and the projectors $\pi_n$ are the phase-space representations of the time-evolution operator $\exp(-\mathrm{i}\hat{H}t/\hbar)$ and the projection operators $\hat{\rho}_n = |n\rangle\langle n|$, respectively. Weyl ordering corresponds to the use of the Moyal star product for quantization and normal ordering to the use of the normal star product. In the density matrix formalism, we say that the projection operator is that of a pure state, which is characterized by the property of being idempotent: $\hat{\rho}_n^2 = \hat{\rho}_n$ (compare eqn [21]). The integral of the projector over the momentum gives the probability distribution in position space:

$$\begin{aligned}\frac{1}{2\pi\hbar}&\int \pi_n^{(M)}(q,p)\mathrm{d}p \\ &= \frac{1}{2\pi\hbar}\int \langle q+\xi/2|n\rangle\langle n|q-\xi/2\rangle \mathrm{e}^{-\mathrm{i}\xi p/\hbar}\mathrm{d}\xi\,\mathrm{d}p \\ &= \langle q|n\rangle\langle n|q\rangle = |\psi_n(q)|^2\end{aligned} \qquad [64]$$

and the integral over the position gives the probability distribution in momentum space:

$$\frac{1}{2\pi\hbar}\int \pi_n^{(M)}(q,p)\mathrm{d}q = \langle p|n\rangle\langle n|p\rangle = |\tilde{\psi}_n(p)|^2 \qquad [65]$$

The normalization is

$$\frac{1}{2\pi\hbar}\int \pi_n^{(M)}(q,p)\mathrm{d}q\,\mathrm{d}p = 1 \qquad [66]$$

which is the same as eqn [20]. Applying these relations to the ground-state projector of the harmonic oscillator, eqn [47] shows that this is a minimum-uncertainty state. In the classical limit $\hbar \to 0$, it goes to a Dirac $\delta$-function. The expectation value of the Hamiltonian operator is

$$\begin{aligned}\frac{1}{2\pi\hbar}\int (H *_M \pi_n^{(M)})(q,p)\mathrm{d}q\,\mathrm{d}p &= \int \langle q|\hat{H}\hat{\rho}_n|q\rangle \mathrm{d}q \\ &= \mathrm{tr}(\hat{H}\hat{\rho}_n)\end{aligned} \qquad [67]$$

which should be compared to eqn [24].

## Quantum Field Theory

A real scalar field is given in terms of the coefficients $a(\mathbf{k}), \bar{a}(\mathbf{k})$ by

$$\phi(x) = \int \frac{\mathrm{d}^3 k}{(2\pi)^{3/2}\sqrt{2\omega_\mathbf{k}}}\left[a(\mathbf{k})\mathrm{e}^{-ikx} + \bar{a}(\mathbf{k})\mathrm{e}^{ikx}\right] \qquad [68]$$

where $\hbar\omega_\mathbf{k} = \sqrt{\hbar^2 k^2 + m^2}$ is the energy of a single-quantum of the field. The corresponding quantum field operator is

$$\Phi(x) = \int \frac{\mathrm{d}^3 k}{(2\pi)^{3/2}\sqrt{2\omega_\mathbf{k}}}\left[\hat{a}(\mathbf{k})\mathrm{e}^{-\mathrm{i}kx} + \hat{a}^\dagger(\mathbf{k})\mathrm{e}^{ikx}\right] \qquad [69]$$

where $\hat{a}(\mathbf{k}), \hat{a}^\dagger(\mathbf{k})$ are the annihilation and creation operators for a quantum of the field with momentum $\hbar\mathbf{k}$. The Hamiltonian is

$$H = \int \mathrm{d}^3 k \hbar\omega_\mathbf{k}\hat{a}^\dagger(\mathbf{k})\hat{a}(\mathbf{k}) \qquad [70]$$

$N(\mathbf{k}) = \hat{a}^\dagger(\mathbf{k})\hat{a}(\mathbf{k})$ is interpreted as the number operator, and eqn [70] is then just the generalization of eqn [39], the expression for the energy of the harmonic oscillator in the normal ordering scheme, for an infinite number of degrees of freedom. Had we chosen the Weyl-ordering scheme, it would have resulted in (by the generalization of eqn [50]) an infinite vacuum energy. Hence, requiring the vacuum energy to vanish implies the choice of the normal ordering scheme in free field theory. In the framework of deformation quantization, this requirement leads to the choice of the normal star product for treating free scalar fields: only for this choice is the star product well defined.

Currently, in realistic physical field theories involving interacting relativistic fields we are limited to perturbative calculations. The objects of interest are products of the fields. The analog of the Moyal product of eqn [11] for systems with an infinite number of degrees of freedom is

$$\phi(x_1) * \phi(x_2) * \cdots * \phi(x_n) = \exp\left[\frac{1}{2}\sum_{i<j}\int \mathrm{d}^4x\,\mathrm{d}^4y \frac{\delta}{\delta\phi_i(x)}\Delta(x-y)\frac{\delta}{\delta\phi_j(y)}\right] \times \phi_1(x_1), \ldots, \phi_n(x_n)|_{\phi_i=\phi} \qquad [71]$$

where the expressions $\delta/\delta\phi(x)$ indicate functional derivatives. Here, we have used the antisymmetric Schwinger function:

$$\Delta(x-y) = [\Phi(x), \Phi(y)] \qquad [72]$$

The Schwinger function is uniquely determined by relativistic invariance and causality from the equal-time commutator

$$\left[\Phi(x), \dot{\Phi}(y)\right]\big|_{x^0=y^0} = \mathrm{i}\hbar\delta^{(3)}(\mathbf{x}-\mathbf{y}) \qquad [73]$$

which is the characterization of the canonical structure in the field theoretic framework.

The Moyal product is, however, not the suitable star product to use in this context. In relativistic quantum field theory, it is necessary to incorporate causality in the form advocated by Feynman: positive frequencies propagate forward in time, whereas negative frequencies propagate backwards in time. This property is achieved by using the Feynman propagator:

$$\Delta_F(x) = \begin{cases} \Delta^+(x) & \text{for } x^0 > 0 \\ -\Delta^-(x) & \text{for } x^0 < 0 \end{cases} \qquad [74]$$

where $\Delta^+(x), \Delta^-(x)$ are the propagators for the positive and negative frequency components of the field, respectively. In operator language

$$\Delta_F(x-y) = \mathcal{T}(\Phi(x)\Phi(y)) - \mathcal{N}(\Phi(x)\Phi(y)) \qquad [75]$$

where $\mathcal{T}$ indicates the time-ordered product of the fields and $\mathcal{N}$ the normal-ordered product. Because the second term in eqn [75] is a normal-ordered product with vanishing vacuum expectation value, the Feynman propagator may be simply characterized as the vacuum expectation value of the time-ordered product of the fields. The antisymmetric part of the positive frequency propagator is the Schwinger function:

$$\Delta^+(x) - \Delta^+(-x) = \Delta^+(x) + \Delta^-(x) = \Delta(x) \qquad [76]$$

The fact that going over to a $c$-equivalent product leaves the antisymmetric part of the differential operator in the exponent of eqn [71] invariant suggests that the use of the positive frequency propagator instead of the Schwinger function merely involves the passage to a $c$-equivalent star product. This is indeed easy to verify. The time-ordered product of the operators is obtained by replacing the Schwinger function $\Delta(x-y)$ in eqn [72] by the $c$-equivalent positive frequency propagator $\Delta^+(x-y)$, restricting the time integration to $x^0 > y^0$, as in eqn [74], and symmetrizing the integral in the variables $x$ and $y$, which brings in the negative frequency propagator $\Delta^-(x-y)$ for times $x^0 < y^0$. Then eqn [71] becomes Wick's theorem, which is the basic tool of relativistic perturbation theory. In operator language

$$\mathcal{T}(\Phi(x_1), \ldots, \Phi(x_n)) = \exp\left[\frac{1}{2}\int \mathrm{d}^4x\,\mathrm{d}^4y \frac{\delta}{\delta\Phi(x)}\Delta_F(x-y)\frac{\delta}{\delta\Phi(y)}\right] \times \mathcal{N}(\Phi(x_1), \ldots, \Phi(x_n)) \qquad [77]$$

Another interesting relation between deformation quantization and quantum field theory has been uncovered by studies of the Poisson–Sigma model. This model involves a set of scalar fields $X^i$ which map a two-dimensional manifold $\Sigma_2$ onto a Poisson space $M$, as well as generalized gauge fields $A_i$, which are 1-forms on $\Sigma_2$ mapping to 1-forms on $M$. The action is given by

$$S_{PS} = \int_{\Sigma_2} (A_i dX^i + \alpha^{ij} A_i A_j) \qquad [78]$$

where $\alpha^{ij}$ is the Poisson structure of $M$. A remarkable formula was found (Cattaneo and Felder 2000):

$$(f * g)(x) = \int DXDA f(X(1))g(X(2))\mathrm{e}^{\mathrm{i}S_{PS}/\hbar} \qquad [79]$$

where $f$, $g$ are functions on $M$, $*$ is Kontsevich's star product (Kontsevich 1997), and the functional integration is over all fields $X$ that satisfy the boundary condition $X(\infty) = x$. Here $\Sigma_2$ is taken to be a disk in $\mathbb{R}^2$; 1, 2, and $\infty$ are three points on its circumference. By expanding the functional integral in eqn [79] according to the usual rules of perturbation theory, one finds that the coefficients of the powers of $\hbar$ reproduce the graphs

and weights that characterize Kontsevich's star product. For the case in which the Poisson tensor is invertible, we can perform the Gaussian integration in eqn [79] involving the fields $A_i$. The result is

$$(f * g)(x) = \int DXf(X(1))g(X(2)) \exp\left[\frac{i}{\hbar}\int \Omega_{ij} dX^i dX^j\right] \quad [80]$$

Equation [80] is formally similar to eqn [16] for the Moyal product, to which the Kontsevich product reduces in the symplectic case. Here $\Omega_{ij} = (\alpha^{ij})^{-1}$ is the symplectic 2-form, and $\int \Omega_{ij} dX^i\, dX^j$ is the symplectic volume of the manifold $M$. To make this relationship exact, one must integrate out the gauge degrees of freedom in the functional integral in eqn [79]. Since the Poisson-sigma model represents a topological field theory there remains only a finite-dimensional integral, which coincides with the integral in eqn [80].

## The Quantization Problem

Though quantum theory for the classical phase space $\mathbb{R}^{2n}$ is well established by means of what usually is called canonical quantization, physics demands to go beyond $\mathbb{R}^{2n}$: On the one hand, systems with constraints lead by phase-space reduction to classical phase spaces different from $\mathbb{R}^{2n}$; in general one ends up with a symplectic or even Poisson manifold. Thus, one needs to quantize geometrically nontrivial phase spaces. On the other hand, field theories and thermodynamical systems require to pass from $\mathbb{R}^{2n}$ to infinitely many degrees of freedom, where one faces additional analytical difficulties. Both types of difficulties combine for gauge field theories and gravity, whence it is clear that quantization is still one of the most important issues in mathematical physics.

One possibility (among many others) is to use the structural similarity between the classical and quantum observable algebras. In both cases the observables constitute a complex $*$-algebra: in the classical case it is commutative with the additional structure of a Poisson bracket, whereas in the quantum case the algebra is noncommutative. In deformation quantization, one tries to pass from the classical observables to the quantum observables by a deformation of the algebraic structures.

## From Canonical Quantization to Star Products

Let us briefly recall canonical quantization and the ordering problem. In order to "quantize" classical

observables like the polynomials on $\mathbb{R}^{2n}$ to $q^k, p_l$, one assigns the operators

$$q^k \mapsto \varrho(q^k) = Q^k = (q \mapsto q^k \psi(q)) \qquad [1]$$

$$p_l \mapsto \varrho(p_l) = P_l = \left(q \mapsto \frac{\hbar}{\mathrm{i}} \frac{\partial \psi}{\partial q^l}(q)\right) \qquad [2]$$

for $k, l = 1, \ldots, n$, defined on a suitable domain in $L^2(\mathbb{R}^n, \mathrm{d}^n q)$. For simplicity, we choose $C_0^\infty(\mathbb{R}^n)$ as domain. The well-known ordering problem is encountered if one wants to also quantize higher polynomials. One convenient (although not the only) possibility is Weyl's total symmetrization rule, that is, for a monomial like $q^2 p$ we take the quantization

$$\begin{aligned} \varrho_{\mathrm{Weyl}}(q^2 p) &= \tfrac{1}{3}(Q^2 P + QPQ + PQ^2) \\ &= -\mathrm{i}\hbar q^2 \frac{\partial}{\partial q} - \mathrm{i}\hbar q \end{aligned} \qquad [3]$$

This can be written in the more explicit form:

$$\varrho_{\mathrm{Weyl}}(f) = \sum_{r=0}^{\infty} \frac{1}{r!} \left(\frac{\hbar}{\mathrm{i}}\right)^r \frac{\partial^r (Nf)}{\partial p_{i_1} \cdots \partial p_{i_r}}\bigg|_{p=0} \frac{\partial^r}{\partial q^{i_1} \cdots \partial q^{i_r}} \qquad [4]$$

with

$$N = \exp\left(\frac{\hbar}{2\mathrm{i}} \Delta\right) \quad \text{and} \quad \Delta = \frac{\partial^2}{\partial q^i \partial p_i}$$

Using [4] one can easily extend $\varrho_{\mathrm{Weyl}}$ to all functions $f \in C^\infty(\mathbb{R}^{2n})$ which are polynomial in the momentum variables only and have an arbitrary smooth dependence on the position variables. This Poisson subalgebra of $C^\infty(\mathbb{R}^{2n})$ certainly covers all classical observables of physical interest. Denoting these observables by $\mathrm{Pol}(T^*\mathbb{R}^n)$, one obtains a linear isomorphism

$$\varrho_{\mathrm{Weyl}} : \mathrm{Pol}(T^*\mathbb{R}^n) \xrightarrow{\cong} \mathrm{Diffop}(\mathbb{R}^n) \qquad [5]$$

into the differential operators with smooth coefficients, called Weyl symbol calculus. Other orderings would result in a different linear isomorphism like [5], for example, the standard ordering is obtained by simply omitting the operator $N$ in [4].

Using [5], one can pull back the operator product of $\mathrm{Diffop}(\mathbb{R}^n)$ to obtain a new product $\star_{\mathrm{Weyl}}$ for $\mathrm{Pol}(T^*\mathbb{R}^n)$, that is

$$f \star_{\mathrm{Weyl}} g = \varrho_{\mathrm{Weyl}}{}^{-1}(\varrho_{\mathrm{Weyl}}(f)\varrho_{\mathrm{Weyl}}(g)) \qquad [6]$$

which is called the Weyl–Moyal star product. Explicitly, one has

$$f \star_{\mathrm{Weyl}} g = \mu \circ \exp\left(\frac{\mathrm{i}\hbar}{2}\left(\frac{\partial}{\partial q^k} \otimes \frac{\partial}{\partial p_k} - \frac{\partial}{\partial p_k} \otimes \frac{\partial}{\partial q^k}\right)\right) f \otimes g \qquad [7]$$

where $\mu(f \otimes g) = fg$ is the commutative product. Clearly, for $f, g \in \mathrm{Pol}(T^*\mathbb{R}^n)$ the exponential series terminates after finitely many terms. If one now wants to extend further to all smooth functions, then [7] is only a formal power series in $\hbar$. Since on a manifold one does not have *a priori* a nice distinguished class of functions like $\mathrm{Pol}(T^*\mathbb{R}^n)$, one indeed has to generalize in this direction if a geometric framework is desired. This observation and the simple fact, that $\star_{\mathrm{Weyl}}$ satisfies all the following properties, lead to the definition of a formal star product by Bayen *et al.* (1978):

**Definition 1** A formal star product on a Poisson manifold $(M, \pi)$ is an associative $\mathbb{C}[[\lambda]]$-bilinear product

$$f \star g = \sum_{r=0}^{\infty} \lambda^r C_r(f, g) \qquad [8]$$

for $f, g \in C^\infty(M)[[\lambda]]$ such that

1. $C_0(f, g) = fg$ and $C_1(f, g) - C_1(g, f) = \mathrm{i}\{f, g\}$,
2. $1 \star f = f = f \star 1$, and
3. $C_r$ is a bidifferential operator.

If in addition $\overline{f \star g} = \bar{g} \star \bar{f}$, then $\star$ is called Hermitian.

Clearly, $\star_{\mathrm{Weyl}}$ defines a Hermitian star product for $\mathbb{R}^{2n}$. The first condition is called the correspondence principle in deformation quantization and the formal parameter $\lambda = \bar{\lambda}$ corresponds to Planck's constant $\hbar$ once a convergence scheme is established.

If $S = \mathsf{id} + \sum_{r=1}^{\infty} \lambda^r S_r$ is a formal series of differential operators with $S_r 1 = 0$ for $r \geq 1$, then it is easy to see that

$$f \star' g = S^{-1}(Sf \star Sg) \qquad [9]$$

defines again a star product which is Hermitian if $\star$ is Hermitian and if in addition $\overline{Sf} = S\bar{f}$. In particular, the operator $N$, as before, serves for the transition from $\star_{\mathrm{Weyl}}$ to the standard-ordered star product $\star_{\mathrm{Std}}$ obtained the same way from the standard-ordered quantization. Thus, [9] can be seen as the abstract notion of changing the ordering prescription, even if no operator representation has been specified. Two star products related by such an equivalence transformation are called equivalent and $*$-equivalent in the Hermitian case.

One main advantage of formal deformation quantization is that one has very strong existence and classification results:

**Theorem 2** *On every Poisson manifold there exists a star product.*

The above theorem was first shown by deWilde and Lecomte (1983) for the symplectic case and

independently by Fedosov (1985) and Omori, Maeda, and Yoshioka (1991). In 1997, Kontsevich was able to prove the general Poisson case by showing his profound formality theorem. The full classification of star products up to equivalence was first obtained for the symplectic case by Nest and Tsygan (1995) and independently by Deligne (1995), Bertelson, Cahen, and Gutt (1997), and Weinstein and Xu (1997). The general Poisson case again follows from Kontsevich's formality. In particular, in the symplectic case, star products are classified by their characteristic class

$$c : \star \mapsto c(\star) \in \frac{[\omega]}{\mathrm{i}\lambda} + \mathrm{H}^2_{\mathrm{deRham}}(M, \mathbb{C})[[\lambda]] \qquad [10]$$

As conclusion one can state that for the price of formal power series in $\hbar$ one obtains in formal deformation quantization a very general and well-understood picture of the observable algebra for the quantum version of any classical system described kinematically by a Poisson manifold. It turns out that already in this framework one can discuss dynamics as well by use of a Heisenberg equation formulated with $\star$. Moreover, the quantization of symmetries described by Hamiltonian Lie group or Lie algebra actions has been extensively studied.

For a physical theory of quantization, however, there are still at least two ingredients missing. On the one hand, one has to overcome the formal power series expansion in $\hbar$. This problem is, in principle, on the same footing as any perturbative approach to quantum theory and thus no easy answer can be expected to hold in general. In particular examples, however, such as the Weyl–Moyal star product, it can easily be solved. These issues together with the corresponding questions about a spectral calculus are best studied in the framework of Rieffel's strict deformation quantization based on a more $C^*$-algebraic formulation of the deformation problem. On the other hand, the observable algebra is not enough to describe a quantum system: one also needs to have a notion for the states. It turns out that already in the formal framework one has a physically reasonable notion of states as discussed by Bordemann and Waldmann (1998).

## States and Representations

The notion of states in deformation quantization is adapted from the $C^*$-algebraic world and based on the notion of positive functionals. Recall that for a $*$-algebra $\mathcal{A}$ over $\mathbb{C}$ a linear functional $\omega : \mathcal{A} \to \mathbb{C}$ is called positive if $\omega(a^*a) \geq 0$. For formal deformation quantization, things are slightly more subtle as now one has to consider $\mathbb{C}[[\lambda]]$-linear functionals

$$\omega : (C^\infty(M)[[\lambda]], \star) \longrightarrow \mathbb{C}[[\lambda]] \qquad [11]$$

where $\star$ is assumed to be a Hermitian star product in the following. Then the positivity is understood in the sense of formal power series where $a \in \mathbb{R}[[\lambda]]$ is called positive if $a = \sum_{r=r_0}^{\infty} \lambda^r a_r$ with $a_{r_0} > 0$. Thus, we can make sense out of the following requirement:

**Definition 3** Let $\star$ be a Hermitian star product on $M$. A $\mathbb{C}[[\lambda]]$-linear functional $\omega : C^\infty(M)[[\lambda]] \to \mathbb{C}[[\lambda]]$ is called positive with respect to $\star$ if

$$\omega(\overline{f} \star f) \geq 0 \qquad [12]$$

and it is called a state if, in addition, $\omega(1) = 1$.

In fact, $\omega(f)$ is interpreted as the expectation value of the observable $f$ in the state $\omega$. The positivity [12] ensures that the usual uncertainty relations between expectation values hold.

Sometimes it is convenient to consider positive functionals only defined on a (proper) $*$-ideal in $C^\infty(M)[[\lambda]]$, for instance, $C_0^\infty(M)[[\lambda]]$.

Since in some situations one wants more general formal series than just power series, it is convenient to embed the above definition of states into a larger and more algebraic context: consider an ordered ring $\mathsf{R}$, that is, a commutative, associative, unital ring $\mathsf{R}$ together with a distinguished subset $\mathsf{P} \subset \mathsf{R}$ (the positive elements) such that $\mathsf{R}$ is the disjoint union $-\mathsf{P} \dot{\cup} \{0\} \dot{\cup} \mathsf{P}$, and we have $\mathsf{P} \cdot \mathsf{P} \subseteq \mathsf{P}$ and $\mathsf{P} + \mathsf{P} \subseteq \mathsf{P}$. Then $\mathsf{C} = \mathsf{R}(\mathrm{i})$ denotes the ring extension by a square root i of –1 and consider $*$-algebras $\mathcal{A}$ over $\mathsf{C}$. Clearly, this generalizes the cases $\mathsf{R} = \mathbb{R}$, where $\mathsf{C} = \mathbb{C}$, as well as $\mathsf{R} = \mathbb{R}[[\lambda]]$, where $\mathsf{C} = \mathbb{C}[[\lambda]]$. In this way, one provides a framework where $C^*$-algebras, $*$-algebras over $\mathbb{C}$, and formal Hermitian star products can be treated on the same footing. It is clear that the definition of a positive functional immediately extends to $\omega : \mathcal{A} \to \mathsf{C}$ for such a ring $\mathsf{C}$.

**Example 4**

(i) For the Wick star product on $\mathbb{R}^{2n} \cong \mathbb{C}^n$, defined by

$$f \star_{\mathrm{Wick}} g = \sum_{r=0}^{\infty} \frac{(2\lambda)^r}{r!} \frac{\partial^r f}{\partial z^{i_1} \cdots \partial z^{i_r}} \frac{\partial^r g}{\partial \overline{z}^{i_1} \cdots \partial \overline{z}^{i_r}} \qquad [13]$$

the $\delta$-functional $\delta : f \mapsto f(0)$ is positive. Note, however, that $\delta$ is not positive for $\star_{\mathrm{Weyl}}$.

(ii) For the Weyl–Moyal star product $\star_{\mathrm{Weyl}}$ the Schrödinger functional

$$\omega(f) = \int_{\mathbb{R}^n} f(q, p = 0)\mathrm{d}^n q \qquad [14]$$

defined on the $*$-ideal $C_0^\infty(\mathbb{R}^{2n})[[\lambda]]$, is positive.

(iii) For any connected symplectic manifold $(M, \omega)$ and any Hermitian star product $\star$, there exists a unique normalized trace functional

$$\begin{aligned} \mathsf{tr} : C_0^\infty(M)[[\lambda]] &\longrightarrow \mathbb{C}[[\lambda]] \\ \mathsf{tr}(f \star g) &= \mathsf{tr}(g \star f) \end{aligned} \qquad [15]$$

with zeroth order equal to the integration over $M$ with respect to the Liouville measure $\Omega = \omega^n$. Then this trace is positive as well, $\mathsf{tr}(\bar{f} \star f) \geq 0$.

Having a notion for states as expectation-value functionals is still not enough to formulate quantum theory. One main feature of quantum states, the superposition principle, is not yet implemented. In particular, forming convex combinations like $\omega = c_1\omega_1 + c_2\omega_2$, with $c_1, c_2 \geq 0$ and $c_1 + c_2 = 1$, does not give a superposition of $\omega_1$ and $\omega_2$ but a mixed stated. Hence, one needs an additional linear structure on the states whence we look for a $*$-representation $\pi$ of the observable algebra $\mathcal{A}$ on a pre-Hilbert space $\mathcal{H}$ over $\mathsf{C}$ such that the states $\omega_1, \omega_2$ can be written as vector states $\omega_i(a) = \langle \phi_i, \pi(a)\phi_i \rangle$ for some unit vectors $\phi_1, \phi_2 \in \mathcal{H}$. Then one can build superpositions of the vectors $\phi_1, \phi_2$ in the usual way. While this is the well-known argument in any quantum theory based on the observable algebras, for deformation quantization one first has to make sense out of the above notions, since now $\mathsf{R} = \mathbb{R}[[\lambda]]$ is only an ordered ring. This can actually be done in a consistent way as demonstrated and exemplified by Bordemann, Bursztyn, Waldmann, and others.

We recall the basic results: A pre-Hilbert space $\mathcal{H}$ over $\mathsf{C}$ is a $\mathsf{C}$-module with a $\mathsf{C}$-sesquilinear inner product $\langle \cdot, \cdot \rangle : \mathcal{H} \times \mathcal{H} \to \mathsf{C}$ such that $\langle \phi, \psi \rangle = \overline{\langle \psi, \phi \rangle}$ and $\langle \phi, \phi \rangle > 0$ for $\phi \neq 0$. This makes sense since $\mathsf{R}$ is ordered. An operator $A : \mathcal{H}_1 \to \mathcal{H}_2$ is called adjointable if there exists an operator $A^* : \mathcal{H}_2 \to \mathcal{H}_1$ such that $\langle A\phi, \psi \rangle_2 = \langle \phi, A^*\psi \rangle_1$ for all $\phi \in \mathcal{H}_1$, $\psi \in \mathcal{H}_2$. The set of adjointable operators is denoted by $\mathfrak{B}(\mathcal{H}_1, \mathcal{H}_2)$, and $\mathfrak{B}(\mathcal{H}) = \mathfrak{B}(\mathcal{H}, \mathcal{H})$ turns out to be a $*$-algebra over $\mathsf{C}$. This allows one to define a $*$-representation $\pi$ of $\mathcal{A}$ on $\mathcal{H}$ to be a $*$-homomorphism $\pi : \mathcal{A} \to \mathfrak{B}(\mathcal{H})$. An intertwiner $T$ between two $*$-representations $(\mathcal{H}_1, \pi_1)$ and $(\mathcal{H}_2, \pi_2)$ is an operator $T \in \mathfrak{B}(\mathcal{H}_1, \mathcal{H}_2)$ with $T\pi_1(a) = \pi_2(a)T$ for all $a \in \mathcal{A}$. This defines the category $*$-$\mathsf{Rep}(\mathcal{A})$ of $*$-representations of $\mathcal{A}$.

Let us now recall that a positive linear functional $\omega$ can be written as an expectation value for a vector state in some representation. This is the well-known Gelfand–Naimark–Segal (GNS) construction from operator algebra theory which can be transferred to this purely algebraic context (Bordemann and Waldmann 1998). First recall that any positive linear functional $\omega : \mathcal{A} \to \mathsf{C}$ satisfies the Cauchy–Schwarz inequality

$$\omega(a^*b)\,\overline{\omega(a^*b)} \leq \omega(a^*a)\omega(b^*b) \qquad [16]$$

and $\omega(a^*b) = \overline{\omega(b^*a)}$. If $\mathcal{A}$ is unital, which will always be assumed for simplicity, then $\omega(a^*) = \overline{\omega(a)}$ follows. Then

$$\mathcal{J}_\omega = \{a \in \mathcal{A} \mid \omega(a^*a) = 0\} \qquad [17]$$

is a left ideal in $\mathcal{A}$, the so-called Gel'fand ideal, and hence $\mathcal{H}_\omega = \mathcal{A}/\mathcal{J}_\omega$ is a left $\mathcal{A}$-module with module structure denoted by $\pi_\omega(a)\psi_b = \psi_{ab}$, where $\psi_b \in \mathcal{H}_\omega$ denotes the equivalence class of $b \in \mathcal{A}$. Finally, $\langle \psi_b, \psi_c \rangle = \omega(b^*c)$ turns $\mathcal{H}_\omega$ into a pre-Hilbert space and $\pi_\omega$ becomes a $*$-representation, the GNS representation with respect to $\omega$. Moreover, $\psi_1 \in \mathcal{H}_\omega$ is a cyclic vector, $\psi_b = \pi_\omega(b)\psi_1$, with the property

$$\omega(a) = \langle \psi_1, \pi_\omega(a)\psi_1 \rangle \qquad [18]$$

These properties characterize the GNS representation $(\mathcal{H}_\omega, \pi_\omega, \psi_1)$ up to unitary equivalence.

**Example 5** We can now apply this construction to the three basic examples and obtain the following well-known representations as GNS representations:

(i) The GNS representation corresponding to the $\delta$-functional and the Wick star product is (unitarily equivalent to) the formal Bargmann–Fock representation. Here $\mathcal{H}_\delta = \mathbb{C}[[\bar{y}^1, \ldots, \bar{y}^n]][[\lambda]]$ with inner product

$$\begin{aligned} \langle \phi, \psi \rangle = \sum_{r=0}^{\infty} \frac{(2\lambda)^r}{r!} &\overline{\frac{\partial^r \phi}{\partial \bar{y}^{i_1} \cdots \partial \bar{y}^{i_r}}(0)} \\ &\times \frac{\partial^r \psi}{\partial \bar{y}^{i_1} \cdots \partial \bar{y}^{i_r}}(0) \end{aligned} \qquad [19]$$

and $\pi_\delta$ is explicitly given by

$$\begin{aligned} \pi_\delta(f) = \sum_{r,s=0}^{\infty} \frac{(2\lambda)^r}{r!s!} &\frac{\partial^{r+s} f}{\partial z^{i_1} \cdots \partial z^{i_r} \partial \bar{z}^{j_1} \cdots \partial \bar{z}^{j_s}}(0) \\ &\times \bar{y}^{j_1} \cdots \bar{y}^{j_s} \frac{\partial^r}{\partial \bar{y}^{i_1} \cdots \partial \bar{y}^{i_r}} \end{aligned} \qquad [20]$$

In particular, $\pi_\delta(z^i) = 2\lambda\partial/\partial\bar{y}^i$ and $\pi_\delta(\bar{z}^i) = \bar{y}^i$ are the annihilation and creation operators and [20] gives the Wick (or normal) ordering. This basic example has been extended to arbitrary Kähler manifolds by Bordemann and Waldmann (1998).

(ii) The Weyl–Moyal star product $\star_{\text{Weyl}}$ and the Schrödinger functional $\omega$ as in [14] give the usual Schrödinger representation as GNS representation. We obtain $\mathcal{H}_\omega = C_0^\infty(\mathbb{R}^n)[[\lambda]]$ with inner product

$$\langle \phi, \psi \rangle = \int_{\mathbb{R}^n} \overline{\phi(q)} \psi(q) \, \mathrm{d}^n q \qquad [21]$$

and $\pi_\omega(f) = \varrho_{\text{Weyl}}(f)$ as in [4] with $\hbar$ replaced by $\lambda$. The Schrödinger representation as a particular case of a GNS representation has been generalized to arbitrary cotangent bundles including representations on sections of line bundles over the configuration space (Dirac's representation for magnetic monopoles) by Bordemann, Neumaier, Pflaum, and Waldmann (1999, 2003). In this context, the WKB expansion can also be formulated.

(iii) For the positive trace $\mathsf{tr}$, the GNS pre-Hilbert is simply the space $\mathcal{H}_{\mathsf{tr}} = C_0^\infty(M)[[\lambda]]$ with inner product $\langle f, g \rangle = \mathsf{tr}(\overline{f} \star g)$. The corresponding GNS representation is the left regular representation $\pi_{\mathsf{tr}}(f)g = f \star g$. Note that in this case the commutant of the representation is (anti-)isomorphic to the observable algebra and given by all the right multiplications. Thus, $\pi_{\mathsf{tr}}$ is highly reducible and the size of the commutant indicates a "thermodynamical" interpretation of this representation. Indeed, one can take this GNS representation, and more general for arbitrary KMS functionals, as a starting point of a preliminary version of a Tomita–Takesaki theory for deformation quantization as shown by Waldmann (1999).

After these fundamental examples, we now reconsider the question of superpositions: in general, two (pure) states $\omega_1, \omega_2$ cannot be realized as vector states inside a single irreducible representation. One encounters superselection rules. Usually, for instance, in algebraic quantum field theory, the existence of superselection rules indicates the presence of charges. In particular, it is not sufficient to consider one single representation of the observable algebra $\mathcal{A}$. Instead, one has to investigate (as good as possible) all superselection sectors of the representation theory $*\text{-}\mathsf{Rep}(\mathcal{A})$ of $\mathcal{A}$ and find physically motivated criteria to select distinguished representations. In usual quantum mechanics on $\mathbb{R}^{2n}$, this turns out to be rather simple, thanks to the (nontrivial) uniqueness theorem of von Neumann: one has a unique irreducible representation of the Weyl algebra up to unitary equivalence. In infinite dimensions or in topologically nontrivial situations, however, von Neumann's theorem does not apply and one indeed has superselection rules.

In deformation quantization, some parts of these superselection rules have been understood well: again, for cotangent bundles $T^*Q$, one can classify the unitary equivalence classes of Schrödinger-like representations on $C_0^\infty(Q)[[\lambda]]$ by topological classes of nontrivial vector potentials. Thus, one arrives at the interpretation of the Aharonov–Bohm effect as superselection rule where the classification is essentially given by $\mathrm{H}^1_{\text{deRham}}(Q, \mathbb{C})/2\pi\mathrm{i}\ \mathrm{H}^1_{\text{deRham}}(Q, \mathbb{Z})$.

## General Representation Theory

Although it is very much desirable to determine the structure and the superselection sectors in $*\text{-}\mathsf{Rep}(\mathcal{A})$ completely, this is only achievable in the very simplest examples. Moreover, for formal star products, many artifacts due to the purely algebraic nature have to be expected: the Bargmann–Fock and Schrödinger representation in Example 5 are unitarily inequivalent and thus define a superselection rule, even the pre-Hilbert spaces are nonisomorphic. However, these artifacts vanish immediately when one imposes the suitable convergence conditions together with appropriate topological completions (von Neumanns's theorem). Given such problems, it is very difficult to find "hard" superselection rules which indeed have physical significance already at the formal level. Nevertheless, the example of the Aharonov–Bohm effect shows that this is possible. In any case, new techniques for investigating $*\text{-}\mathsf{Rep}(\mathcal{A})$ have to be developed. It turns out that comparing $*\text{-}\mathsf{Rep}(\mathcal{A})$ with some other $*\text{-}\mathsf{Rep}(\mathcal{B})$ is much simpler but still gives some nontrivial insight in the structure of the representation theory. Here the Morita theory provides a highly sophisticated tool.

The classical notion of Morita equivalence as well as Rieffel's more specialized strong Morita equivalence for $C^*$-algebras have been transferred to deformation quantization and, more generally, to $*$-algebras $\mathcal{A}$ over $\mathsf{C} = \mathsf{R}(\mathrm{i})$ by Bursztyn and Waldmann (2001). The aim is to construct functors

$$\mathsf{F} : *\text{-}\mathsf{Rep}(\mathcal{A}) \longrightarrow *\text{-}\mathsf{Rep}(\mathcal{B}) \qquad [22]$$

which allow us to compare these categories and determine whether they are equivalent. But even if they are not equivalent, functors such as [22] are interesting. As example, one considers the situation of classical phase space reduction $M \rightsquigarrow M_{\text{red}}$ as it is present in every constraint system or gauge theory. Suppose one succeeded with the (highly nontrivial) problem of quantizing both classical phase spaces in a reasonable way whence one has quantum observable algebras $\mathcal{A}$ and $\mathcal{A}_{\text{red}}$. Then, of course, a relation between $*\text{-}\mathsf{Rep}(\mathcal{A})$ and $*\text{-}\mathsf{Rep}(\mathcal{A}_{\text{red}})$ is of

particular physical interest although one cannot expect both representation theories to be equivalent: $\mathcal{A}$ contains additional but physically irrelevant structure leading to possibly "more" representations.

To get a clear picture of the Morita theory, one has to extend the notion of $*$-representations to the following framework: for an auxiliary $*$-algebra $\mathcal{D}$ over $\mathsf{C}$, one defines a pre-Hilbert right $\mathcal{D}$-module to be a right $\mathcal{D}$-module $\mathcal{H}$ together with a $\mathsf{C}$-sesquilinear $\mathcal{D}$-valued inner product $\langle \cdot , \cdot \rangle : \mathcal{H} \times \mathcal{H} \to \mathcal{D}$ such that $\langle \phi, \psi \rangle^*$ and $\langle \phi, \psi \cdot d \rangle = \langle \phi, \psi \rangle d$ for $d \in \mathcal{D}$ and such that $\langle \cdot , \cdot \rangle$ is completely positive. This means $(\langle \phi_i, \phi_j \rangle) \in M_n(\mathcal{D})^+$ for all $\phi_1, \ldots, \phi_n$, where, in general, an algebra element $a \in \mathcal{A}$ is called positive, $a \in \mathcal{A}^+$, if $\omega(a) \geq 0$ for all positive linear functionals $\omega : \mathcal{A} \to \mathsf{C}$.

Then one defines $\mathfrak{B}(\mathcal{H})$ analogously as for pre-Hilbert spaces leading to a definition of a $*$-representation $\pi$ of $\mathcal{A}$ on a pre-Hilbert right $\mathcal{D}$-module $\mathcal{H}$. The corresponding category of $*$-representations is denoted by $*\text{-}\mathsf{Rep}_{\mathcal{D}}(\mathcal{A})$. Clearly, elements in $*\text{-}\mathsf{Rep}_{\mathcal{D}}(\mathcal{A})$ are in particular $(\mathcal{A}, \mathcal{D})$-bimodules.

The advantage is that now one has a tensor product $\hat{\otimes}$ taking care of the inner products as well. For $*$-algebras $\mathcal{A}, \mathcal{B}, \mathcal{C}$, one has a functor

$$\hat{\otimes} : *\text{-}\mathsf{Rep}_{\mathcal{B}}(\mathcal{C}) \times *\text{-}\mathsf{Rep}_{\mathcal{A}}(\mathcal{B}) \longrightarrow *\text{-}\mathsf{Rep}_{\mathcal{A}}(\mathcal{C}) \quad [23]$$

which, on objects, is essentially given by $\otimes_{\mathcal{B}}$. In fact, for $\mathcal{F} \in *\text{-}\mathsf{Rep}_{\mathcal{B}}(\mathcal{C})$ and $\mathcal{E} \in *\text{-}\mathsf{Rep}_{\mathcal{A}}(\mathcal{B})$, one defines on the $(\mathcal{C}, \mathcal{A})$-bimodule $\mathcal{F} \otimes_{\mathcal{B}} \mathcal{E}$ an $\mathcal{A}$-valued inner product by $\langle x \otimes \phi, y \otimes \psi \rangle = \langle \phi, \langle x, y \rangle \cdot \psi \rangle$, which turns out to be well defined and completely positive again. Then $\mathcal{F} \hat{\otimes} \mathcal{E}$ is $\mathcal{F} \otimes_{\mathcal{B}} \mathcal{E}$ equipped with this inner product modulo its possibly nonempty degeneracy space.

By fixing one of the arguments of $\hat{\otimes}$, one obtains the functor of Rieffel induction of $*$-representations

$$\mathsf{R}_{\mathcal{E}} : *\text{-}\mathsf{Rep}_{\mathcal{D}}(\mathcal{A}) \longrightarrow *\text{-}\mathsf{Rep}_{\mathcal{D}}(\mathcal{B}) \quad [24]$$

where $\mathcal{E} \in *\text{-}\mathsf{Rep}_{\mathcal{A}}(\mathcal{B})$ is fixed and $\mathsf{R}_{\mathcal{E}}(\mathcal{H}) = \mathcal{E} \hat{\otimes} \mathcal{H}$ for $\mathcal{H} \in *\text{-}\mathsf{Rep}_{\mathcal{D}}(\mathcal{A})$.

The idea of strong Morita equivalence is then to search for such bimodules $\mathcal{E}$ where $\mathsf{R}_{\mathcal{E}}$ gives an equivalence of categories. In detail, this is accomplished by the following definition, where, for simplicity, only unital $*$-algebras are considered.

**Definition 6** A $(\mathcal{B}, \mathcal{A})$-bimodule $\mathcal{E}$ is called a strong Morita equivalence bimodule if it is equipped with completely positive inner products $\langle \cdot , \cdot \rangle_{\mathcal{A}}$ and $\langle \cdot , \cdot \rangle_{\mathcal{B}}$ such that both inner products are full, in the sense that

$$\mathsf{C}\text{-span}\{\langle x, y \rangle_{\mathcal{A}} | x, y \in \mathcal{E}\} = \mathcal{A} \quad [25]$$

and analogously for $\langle \cdot , \cdot \rangle_{\mathcal{B}}$, and compatible, in the sense that

$$\langle b \cdot x, y \rangle_{\mathcal{A}} = \langle x, b^* \cdot y \rangle_{\mathcal{A}}, \quad \langle x \cdot a, y \rangle_{\mathcal{B}} = \langle x, y \cdot a^* \rangle_{\mathcal{B}} \quad [26]$$

$$\langle x, y \rangle_{\mathcal{B}} \cdot z = x \cdot \langle y, z \rangle_{\mathcal{A}} \quad [27]$$

In this case, $\mathcal{A}$ and $\mathcal{B}$ are called strongly Morita equivalent.

It turns out that this is indeed an equivalence relation and that strong Morita equivalence implies the equivalence of the representation theories:

**Theorem 7** *For unital $*$-algebras over $\mathsf{C}$, strong Morita equivalence is an equivalence relation.*

**Theorem 8** *If $\mathcal{E}$ is a strong Morita equivalence bimodule, then $\mathsf{R}_{\mathcal{E}}$ as in [24] is an equivalence of categories.*

**Example 9** The fundamental example in Morita theory is that a unital $*$-algebra $\mathcal{A}$ is strongly Morita equivalent to the matrices $M_n(\mathcal{A})$ via the $(M_n(\mathcal{A}), \mathcal{A})$-bimodule $\mathcal{A}^n$ where the inner product is $\langle x, y \rangle_{\mathcal{A}} = \sum_{i=1}^n x_i^* y_i$ and $\langle \cdot , \cdot \rangle_{M_n(\mathcal{A})}$ is uniquely determined by the compatibility condition [27].

An efficient way to encode the whole Morita theory of unital $*$-algebras over $\mathsf{C}$ is to collect all strong Morita equivalence bimodules modulo isometric isomorphisms of bimodules. Then the tensor product $\hat{\otimes}$ makes this into a "large" groupoid whose units are the $*$-algebras themselves. This so-called Picard groupoid $\mathsf{Pic}$ then encodes everything one can say about strong Morita equivalence. In particular, the orbits of this groupoid are precisely the strong Morita equivalence classes of $*$-algebras. The isotropy groups are the Picard groups $\mathsf{Pic}(\mathcal{A})$ which generalize the (outer) automorphism groups.

## Strong Morita Equivalence of Star Products

This section considers star products from the viewpoint of the Morita equivalence. Here one can show that for $\mathcal{A} = (C^\infty(M)[[\lambda]], \star)$, the possible candidates of equivalence bimodules are formal power series of sections $\Gamma^\infty(E)[[\lambda]]$ of vector bundles $E \to M$. This follows as, on the one hand, strong Morita equivalence is compatible with the classical limit $\lambda = 0$ in the sense that it implies strong Morita equivalence of the classical limits. On the other hand, any (classical or quantum) equivalence bimodule is finitely generated and projective as right $\mathcal{A}$-module. Thus, by the Serre–Swan theorem one obtains the sections of a vector bundle in the

classical limit. Now one can show that every vector bundle can uniquely (up to equivalence) be deformed such that $\Gamma^\infty(E)[[\lambda]]$ becomes a right $\mathcal{A}$-module. Thus, the only thing to be computed is which deformation $\star'$ is induced by this deformation of $E$ for the endomorphisms $\Gamma^\infty(\mathsf{End}(E))[[\lambda]]$, since one can show that then the result will always be a strong Morita equivalence bimodule. The inner products come from deformations of a Hermitian fiber metric on $E$.

Since every vector bundle $E \to M$ can be deformed in this manner in an essentially unique way, we arrive at a general global construction of a noncommutative field theory where the fields are sections of $E$ endowed with a deformed bimodule structure. In the case where $M$ is even a symplectic manifold, a simple extension of Fedosov's construction of a star product $\star$ gives a rather explicit formula for the deformed bimodule structure of $\Gamma^\infty(E)[[\lambda]]$ including a construction of the deformation $(\Gamma^\infty(\mathsf{End}(E))[[\lambda]], \star')$ which acts from the left. As usual in Fedosov's approach, the construction depends functorially on the choice of a connection $\nabla^E$ for $E$.

Returning to the question of strong Morita equivalence of star products, we see that the vector bundle $E$ has to be a line bundle $L$ since only in this case we have $\Gamma^\infty(\mathsf{End}(E)) \cong C^\infty(M)$. Since the deformation of the Hermitian fiber metric is always possible and since two equivalent Hermitian star products are always $*$-equivalent, one can show that strong Morita equivalence is already implied by ring-theoretic Morita equivalence (the converse is true in general).

**Theorem 10** *Star products are strongly Morita equivalent if and only if they are Morita equivalent.*

An analogous statement holds for $C^*$-algebras, known as Beer's theorem (1982).

In the symplectic case, the characteristic class $c(\star')$ of the induced star product $\star'$ can be computed explicitly leading to the following classification by Bursztyn and Waldmann (2002):

**Theorem 11** *Let $\star, \star'$ be star products on a symplectic manifold $M$. Then $\star'$ is (strongly) Morita equivalent to $\star$ if and only if there exists a symplectomorphism $\psi$ such that*

$$\psi^* c(\star') - c(\star) \in 2\pi \mathrm{i} \mathrm{H}^2_{\mathrm{deRham}}(M, \mathbb{Z}) \qquad [28]$$

A similar result in the general Poisson case was given by Jurčo, Schupp, and Wess (2002) based on Kontsevich's formality theorem. This approach is motivated by a careful investigation of noncommutative (scalar) field theories.

Finally, it is worth mentioning that [28] has a very simple physical interpretation. Consider again a cotangent bundle $T^*Q$ with a topologically nontrivial configuration space $Q$, for example, $\mathbb{R}^3 \setminus \{0\}$. Then there is a canonical Weyl-type star product $\star_{\mathrm{Weyl}}$ depending on the choice of a connection $\nabla$ and an integration density $\mu > 0$, generalizing [7] to a curved situation. Now let $B$ be a magnetic field, modeled as a closed 2-form on $Q$. Minimal coupling leads to a new star product $\star^B_{\mathrm{Weyl}}$ describing an electrically charged particle moving in $Q$ in the external field $B$. Then the two star products $\star_{\mathrm{Weyl}}$ and $\star^B_{\mathrm{Weyl}}$ are (strongly) Morita equivalent if and only if the magnetic field satisfies Dirac's integrality condition for the (possibly nontrivial) magnetic charges described by $B$. Thus, Dirac's condition is responsible for the very strong statement that the quantizations with and without magnetic field are Morita equivalent. In particular, the $*$-representation theories of $\star_{\mathrm{Weyl}}$ and $\star^B_{\mathrm{Weyl}}$ are equivalent. Even more specifically, using $B$ to construct a line bundle $L \to Q$ one obtains the result that Dirac's $*$-representation of $\star^B_{\mathrm{Weyl}}$ on $\Gamma^\infty_0(L)[[\lambda]]$ is precisely the Rieffel induction of the Schrödinger representation of $\star_{\mathrm{Weyl}}$ on $C^\infty_0(Q)[[\lambda]]$.

# Deformation Theory

**M J Pflaum**, Johann Wolfgang Goethe-Universität, Frankfurt, Germany

## Introduction and Historical Remarks

In mathematical deformation theory one studies how an object in a certain category of spaces can be varied as a function of the points of a parameter space. In other words, deformation theory thus deals with the structure of families of objects like varieties, singularities, vector bundles, coherent sheaves, algebras, or differentiable maps. Deformation problems appear in various areas of mathematics, in particular in algebra, algebraic and analytic geometry, and mathematical physics. According to Deligne, there is a common philosophy behind all deformation problems in characteristic zero. It is the goal of this survey to explain this point of view. Moreover, we will provide several examples with relevance for mathematical physics.

Historically, modern deformation theory has its roots in the work of Grothendieck, Artin, Quillen, Schlessinger, Kodaira–Spencer, Kuranishi, Deligne, Grauert, Gerstenhaber, and Arnol'd. The application of deformation methods to quantization theory goes back to Bayen–Flato–Fronsdal–Lichnerowicz–Sternheimer, and has led to the concept of a star product on symplectic and Poisson manifolds. The existence of such star products has been proved by de Wilde–Lecomte and Fedosov for symplectic and by Kontsevich for Poisson manifolds.

Recently, Fukaya and Kontsevich have found a far-reaching connection between general deformation theory, the theory of moduli, and mirror symmetry. Thus, deformation theory comes back to its origins, which lie in the desire to construct moduli spaces. Briefly, a moduli problem can be described as the attempt to collect all isomorphism classes of spaces of a certain type into one single object, the moduli space, and then to study its geometric and analytic properties. The observations by Fukaya and Kontsevich have led to new insight into the algebraic geometry of mirror varieties and their application to string theory.

## Basic Definitions and Examples

Deformation theory is based on the notion of a ringed space, so we briefly recall its definition.

**Definition 1** Let $\Bbbk$ be a field. By a $\Bbbk$-ringed space one understands a topological space $X$ together with a sheaf $\mathcal{A}$ of unital $\Bbbk$-algebras on $X$. The sheaf $\mathcal{A}$ will be called the structure sheaf of the ringed space. In case each of the stalks $\mathcal{A}_x, x \in X$, is a local algebra, that is, has a unique maximal ideal $\mathfrak{m}_x$, one calls $(X, \mathcal{A})$ a locally $\Bbbk$-ringed space. Likewise, one defines a commutative $\Bbbk$-ringed space as a ringed space such that the stalks of the structure sheaf are all commutative.

Given two $\Bbbk$-ringed spaces $(X, \mathcal{A})$ and $(Y, \mathcal{B})$, a morphism from $(X, \mathcal{A})$ to $(Y, \mathcal{B})$ is a pair $(f, \varphi)$, where

$f: X \to Y$ is a continuous mapping and $\varphi: f^{-1}\mathcal{B} \to \mathcal{A}$ a morphism of sheaves of algebras. This means in particular that for every point $x \in X$ there is a homomorphism of algebras $\varphi_x: \mathcal{B}_{f(x)} \to \mathcal{A}_x$ induced by $\varphi$. Under the assumption that both ringed spaces are local, $(f, \varphi)$ is called a morphism of locally ringed spaces, if each $\varphi_x$ is a homomorphism of local $\Bbbk$-algebras, that is, maps the maximal ideal of $\mathcal{B}_{f(x)}$ to the one of $\mathcal{A}_x$.

Clearly, $\Bbbk$-ringed spaces (resp. locally or commutative $\Bbbk$-ringed spaces) together with their morphisms form a category. The following is a list of examples of ringed spaces, in particular of those which will be needed later.

**Example 2**

(i) Denote by $\mathcal{C}^\infty$ the sheaf of smooth functions on $\mathbb{R}^n$, by $\mathcal{C}^\omega$ the sheaf of real analytic functions, and let $\mathcal{O}$ be the sheaf of holomorphic functions on $\mathbb{C}^n$. Then $(\mathbb{R}^n, \mathcal{C}^\infty)$, $(\mathbb{R}^n, \mathcal{C}^\omega)$, and $(\mathbb{C}^n, \mathcal{O})$ are ringed spaces over $\mathbb{R}$ resp. $\mathbb{C}$.

(ii) A differentiable manifold of dimension $n$ can be understood as a locally $\mathbb{R}$-ringed space $(M, \mathcal{C}^\infty_M)$ which locally is isomorphic to $(\mathbb{R}^n, \mathcal{C}^\infty)$. Likewise, a real analytic manifold is a ringed space $(M, \mathcal{C}^\omega_M)$ which locally can be modeled by $(\mathbb{R}^n, \mathcal{C}^\omega)$, and a complex manifold is an $(M, \mathcal{O}_M)$ which locally looks like $(\mathbb{C}^n, \mathcal{O})$.

(iii) Let $D$ be a domain in $\mathbb{C}^n$, and $\mathcal{J}$ an ideal sheaf in $\mathcal{O}_D$ of finite type, which means that $\mathcal{J}$ is locally finitely generated over $\mathcal{O}_D$. Let $Y$ be the support of the quotient sheaf $\mathcal{O}_D/\mathcal{J}$. The pair $(Y, \mathcal{O}_Y)$, where $\mathcal{O}_Y$ denotes the restriction of $\mathcal{O}_D/\mathcal{J}$ to $Y$, then is a ringed space, called a complex model space. A complex space now is a ringed space $(X, \mathcal{O}_X)$ which locally looks like a complex model space (cf. Grauert and Remmert 1984).

(iv) Let $\Bbbk$ be an algebraically closed field, and $\mathbb{A}^n$ the affine space over $\Bbbk$ of dimension $n$. Then $\mathbb{A}^n$, together with the sheaf of regular functions, is a ringed space.

(v) Given a ring $A$, its spectrum Spec $A$ together with the sheaf of regular functions $\mathcal{O}_A$ forms a ringed space (cf. (Hartshorne (1997), section II.2)). One calls (Spec $A, \mathcal{O}_A$) an affine scheme. More generally, a scheme is a ringed space $(X, \mathcal{O}_X)$ which locally can be modeled by affine schemes.

(vi) Finally, if $A$ is a local $\Bbbk$-algebra, the pair $(*, A)$ can be understood as a locally ringed space. With $A$ the algebra of formal power series $\Bbbk[[t]]$ over one variable $t$, this example plays an important role in the theory of formal deformations of algebras.

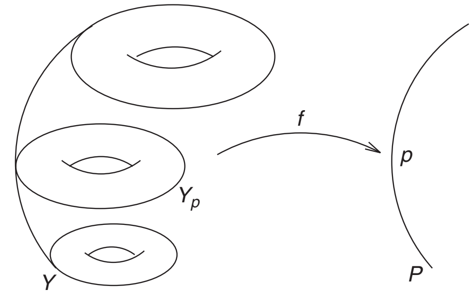

**Figure 1** A fibered space.

**Definition 3** A morphism $(f, \varphi): (Y, \mathcal{B}) \to (P, \mathcal{S})$ of ringed spaces is called fibered, if the following conditions are fulfilled:

(i) $(P, \mathcal{S})$ is a commutative locally ringed space;
(ii) $f: Y \to P$ is surjective; and
(iii) $\varphi_y: \mathcal{S}_{f(y)} \to \mathcal{B}_y$ maps $\mathcal{S}_{f(y)}$ into the center of $\mathcal{B}_y$ for each $y \in Y$.

The *fiber* of $(f, \varphi)$ over a point $p \in P$ then is the ringed space $(Y_p, \mathcal{B}_p)$ defined by

$$Y_p = f^{-1}(p), \qquad \mathcal{B}_p = \mathcal{B}_{|f^{-1}(p)}/\mathfrak{m}_p\mathcal{B}_{|f^{-1}(p)}$$

where $\mathfrak{m}_p$ is the maximal ideal of $\mathcal{S}_p$ which acts on $\mathcal{B}_{|f^{-1}(p)}$ via $\varphi$.

A fibered morphism of ringed spaces can be pictured in Figure 1.

Additionally to this intuitive picture, conditions (i)–(iii) imply that the stalks $\mathcal{B}_y$ are central extensions of $\mathcal{B}_y/\mathfrak{m}_{f(y)}\mathcal{B}_y$ by $\mathcal{S}_{f(y)}$.

**Definition 4** Let $(P, \mathcal{S})$ be a commutative locally ringed space over a field $\Bbbk$ with $P$ connected, let $*$ be a fixed point in $P$, and $(X, \mathcal{A})$ a $\Bbbk$-ringed space. A deformation of $(X, \mathcal{A})$ over the parameter space $(P, \mathcal{S})$ with distinguished point $*$ then is a fibered morphism $(f, \varphi): (Y, \mathcal{B}) \to (P, \mathcal{S})$ over $\Bbbk$ together with an isomorphism $(i, \iota): (X, \mathcal{A}) \to (Y_*, \mathcal{B}_*)$ such that for all $p \in P$ and $y \in f^{-1}(p)$ the homomorphism $\varphi_y: \mathcal{S}_p \to \mathcal{B}_y$ is flat.

The condition of flatness in the definition of a deformation serves as a substitute for "local triviality" and works also in the presence of singularities. (see Palamodov (1990), section 3) for a discussion of this point.

In the remainder of this section, we provide a list of some of the most important deformation problems in mathematics, and show how these can be formulated within the above language.

### Products of $\Bbbk$-Ringed Spaces

Let $(X, \mathcal{A})$ be any $\Bbbk$-ringed space and $(P, \mathcal{S})$ a $\Bbbk$-scheme. For any closed point $* \in P$, the product

$(X \times P, \mathcal{B}) = (X, \mathcal{A}) \times_{\Bbbk} (P, \mathcal{S})$ then is a flat deformation of $(X, \mathcal{A})$ with distinguished point $*$. This can be seen easily from the fact that $\mathcal{B}_{(x,p)} = \mathcal{A}_x \otimes_{\Bbbk} \mathcal{S}_p$ for every $x \in X$ and $p \in P$.

### Families of Matrices as Deformations

Let $(P, \mathcal{O}_P)$ be a complex space with distinguished point $*$ and $A_P : P \to \mathrm{Mat}(n \times n, \mathbb{C})$ a holomorphic family of complex $n \times n$ matrices over $P$. By the following construction, $A_P$ can be understood as a deformation, more precisely as a deformation of the matrix $A := A_P(*)$. Let $Y$ be the graph of $A_P$ in the product space $P \times \mathrm{Mat}(n \times n, \mathbb{C})$ and $f : Y \to P$ be the restriction of the projection onto the first coordinate. Define the sheaf $\mathcal{B}$ as the inverse image sheaf $f^{-1}\mathcal{S}$, and let $\varphi$ be the sheaf morphism which for every $y \in Y$ is induced by the identity map $\varphi_y : \mathcal{S}_{f(y)} \to \mathcal{B}_y := \mathcal{S}_{f(y)}$. It is then immediately clear that $(f, \varphi)$ is a deformation of the fiber $f^{-1}(*)$ and that this fiber coincides with the matrix $A$.

Now let $A$ be an arbitrary complex $n \times n$-matrix, and choose a $\mathrm{GL}(n, \mathbb{C})$-slice through $A$, that is, a submanifold $P$ containing $A$ which is transversal to the $\mathrm{GL}(n, \mathbb{C})$-orbit through $A$. Hereby, it is assumed that $\mathrm{GL}(n, \mathbb{C})$ acts by the adjoint action on $\mathrm{Mat}(n \times n, \mathbb{C})$. The family $A_P$ given by the canonical embedding $P \hookrightarrow \mathrm{Mat}(n \times n, \mathbb{C})$ now is a deformation of $A$. The germ of this deformation at $*$ is versal in the sense defined in the next section.

### Deformation of a Scheme à la Grothendieck

Assume that $(P, \mathcal{S})$ is a connected scheme over $\Bbbk$. A deformation of a scheme $(X, \mathcal{A})$ then is a deformation $(f, \varphi) : (Y, \mathcal{B}) \to (P, \mathcal{S})$ in the sense defined above, together with the requirement that $f : Y \to P$ is a proper map, that is, $f^{-1}(K)$ is compact for every compact $K \subset P$. As a particular example, consider the $\Bbbk$-scheme $Y = \mathrm{Spec}\, \Bbbk[x, y, t]/(xy - t)$. It gives rise to a fibration $Y \to \mathrm{Spec}\, \Bbbk[t]$, whose fibers $Y_a$ with $a \in \Bbbk$ are hyperbolas $xy = a$, when $a \neq 0$, and consist of the two axes $x = 0$ and $y = 0$, when $a = 0$. For $\Bbbk = \mathbb{R}$, this deformation can be illustrated as in Figure 2.

For further information on this and similar examples, see Hartshorne (1977), in particular example 3.3.2.

### Deformation of a Complex Space

According to Grothendieck, one understands by a deformation of a complex space $(X, \mathcal{A})$ a morphism of complex spaces $(f, \varphi) : (Y, \mathcal{B}) \to (P, \mathcal{S})$ which is both a proper flat morphism of complex spaces and a deformation of $(X, \mathcal{A})$ as a ringed space. In case $(X, \mathcal{A})$ and $(P, \mathcal{S})$ are complex manifolds and if $P$ is

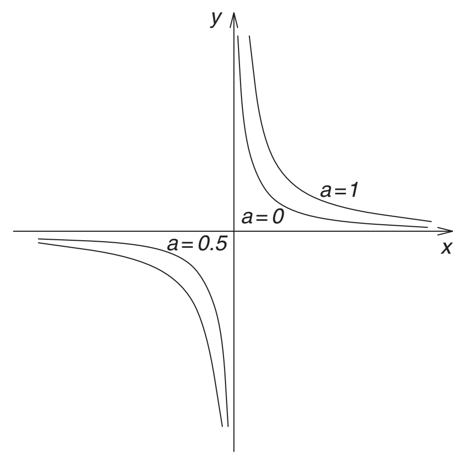

**Figure 2** Deformation of the coordinate axes.

connected, each of the fibers $Y_p$ is a compact complex manifold. Moreover, the family $(Y_p)_{p \in P}$ then is a family of compact complex manifolds in the sense of Kodaira–Spencer (cf. Palamodov (1990)).

### Deformation of Singularities

Let $p$ be a point of some $\mathbb{C}^n$. Two complex spaces $(X, \mathcal{O}_X) \subset (\mathbb{C}^n, \mathcal{O})$ and $(X', \mathcal{O}_{X'}) \subset (\mathbb{C}^n, \mathcal{O})$ with $x \in X \cap X'$ are then called germ equivalent at $x$ if there exists an open neighborhood $U \in \mathbb{C}^n$ of $x$ such that $X \cap U = X' \cap U$. Obviously, germ equivalence at $x$ is an equivalence relation indeed. We denote the equivalence class of $X$ by $[X]_x$. Clearly, if $[X]_x = [X']_x$, then one has $\mathcal{O}_{X,x} = \mathcal{O}_{X',x}$ for the stalks at $x$. By a singularity one understands a pair $([X]_x, \mathcal{O}_{X,x})$. In the literature, such a singularity is often denoted by $(X, x)$. The singularity $(X, x)$ is called nonsingular or regular if $\mathcal{O}_{X,x}$ is isomorphic to an algebra of convergent power series $\mathbb{C}\{z_1, \ldots, z_d\}$. A deformation of a complex singularity $(X, x)$ over a complex germ $(P, *)$ is a morphism of ringed spaces $([Y]_x, \mathcal{O}_{Y,x}) \to ([P]_*, \mathcal{O}_{P,*})$ which is induced by a holomorphic map and which is a deformation of $([X]_x, \mathcal{O}_{X,x})$ as a ringed space. See Artin (1976) and the overview article by Greuel (1992) for further details and a variety of examples.

### First-Order Deformation of Algebras

Consider a $\Bbbk$-algebra $A$ and the truncated polynomial algebra $S = \Bbbk[\varepsilon]/\varepsilon^2\Bbbk[\varepsilon]$. Furthermore, let $\alpha : A \times A \to A$ be a Hochschild 2-cocycle of $A$; in other words, assume that the relation

$$a_1\alpha(a_2, a_3) - \alpha(a_1a_2, a_3) + \alpha(a_1, a_2a_3) - \alpha(a_1, a_2)a_3 = 0 \qquad [1]$$

holds for all $a_1, a_2, a_3 \in A$. Then one can define a new $k$-algebra $B$, whose underlying linear structure

is isomorphic to $A \otimes_{\mathbb{k}} S$ and whose product is given by the following construction: any element $b \in B$ can be written uniquely in the form $b = a_0 + a_1\varepsilon$, with $a_0, a_1 \in A$. Then the product of $b = a_0 + a_1\varepsilon \in B$ and $b' = a_0' + a_1'\varepsilon \in B$ is given by

$$b \cdot b' = a_0 a_0' + \left[\alpha(a_0, a_0') + a_0 a_1' + a_1 a_0'\right]\varepsilon \qquad [2]$$

By condition [1], this product is associative. One thus obtains a flat deformation $\Delta: S \to B$ of the algebra $A$ and calls it the first-order or infinitesimal deformation of $A$ along the Hochschild cocycle $\alpha$. For further information on this and the connection between deformation theory and Hochschild cohomology, see the overview article by Gerstenhaber and Schack (1986).

### Formal Deformation of an Algebra

Let us generalize the preceding example and explain the concept of a formal deformation of an algebra by Gerstenhaber. Assume again $A$ to be an arbitrary $\mathbb{k}$-algebra and choose bilinear maps $\alpha_n : A \times A \to A$ for $n \in \mathbb{N}$ such that $\alpha_0$ is the product on $A$ and $\alpha_1$ is a Hochschild cocycle. Furthermore, let $S$ be the algebra $\mathbb{k}[[t]]$ of formal power series in one variable over $\mathbb{k}$. Then define on the linear space $B = A[[t]]$ of formal power series in one variable with coefficients in $A$ the following bilinear map:

$$\star : B \times B \to B$$
$$\left(\sum_{n\in\mathbb{N}} a_n t^n, \sum_{n\in\mathbb{N}} b_n t^n\right) \mapsto \sum_{n\in\mathbb{N}} \sum_{\substack{k,l,m\in\mathbb{N}\\ k+l+m=n}} \alpha_m(a_k, b_l) t^n \qquad [3]$$

If $B$ together with $\star$ becomes a $\mathbb{k}$-algebra or, in other words, if $\star$ is associative, one can easily see that it gives a flat deformation of $A$ over $S = \mathbb{k}[[t]]$. In that case, one says that $B$ is a formal deformation of $A$ by the family $(\alpha_n)_{n\in\mathbb{N}}$. Contrarily to the preceding example, there might not exist for every Hochschild cocycle $\alpha$ on $A$ a formal deformation $B$ of $A$ defined by a family $(\alpha_n)_{n\in\mathbb{N}}$ such that $\alpha_1 = \alpha$. In case it exists, we will say that the deformation $B$ of $A$ is in the direction of $\alpha$. If the third Hochschild cohomology group $\mathrm{H}^3(A, A)$ vanishes, there exists for every Hochschild cocycle $\alpha$ on $A$ a deformation $B$ of $A$ in the direction of $\alpha$ (see again Gerstenhaber and Schack (1986) for further details).

### Formal Deformation Quantization of Symplectic and Poisson Manifolds

Let us consider the last two examples for the case where $A$ is the algebra $\mathcal{C}^\infty(M)$ of smooth functions on a symplectic or Poisson manifold $M$. Then the Poisson bracket $\{,\}$ gives a Hochschild cocycle on $\mathcal{C}^\infty(M)$. There exists a first-order deformation of $\mathcal{C}^\infty(M)$ along $(1/2\mathrm{i})\{,\}$ and, even though $\mathrm{HH}^3(A, A)$ might not always vanish, a deformation quantization of $M$, that means a formal deformation of $\mathcal{C}^\infty(M)$ in the direction of the Poisson bracket $(1/2\mathrm{i})\{,\}$. For the symplectic case, this fact has been proved first by deWilde–Lecomte using methods from Hochschild cohomology theory. A more geometric and intuitive proof has been given by Fedosov (1996). The Poisson case has been settled in the work of Kontsevich (2003) (see also the section "Deformation quantization of Poisson manifolds").

### Quantized Universal Enveloping Algebras According to Drinfeld

A quantized universal enveloping algebra for a complex Lie algebra $\mathfrak{g}$ is a Hopf algebra $A$ over $\mathbb{C}[[t]]$ such that $A$ is a topologically free $\mathbb{C}[[t]]$-module (i.e., $A = (A/tA)[[t]]$ as left $\mathbb{C}[[t]]$-module) and $A/tA$ is the universal enveloping algebra $U\mathfrak{g}$ of $\mathfrak{g}$. Because $A$ is a topologically free $\mathbb{C}[[t]]$-module, $A$ is a flat $\mathbb{C}[[t]]$-module and thus a deformation of $U\mathfrak{g}$ over $\mathbb{C}[[t]]$. See Drinfel'd (1986) and the monograph by Kassel (1995) for further details and examples of quantized universal enveloping algebras.

### Quantum Plane

Consider the tensor algebra $T = \bigoplus_{n\in\mathbb{N}} (\mathbb{R}^2)^{\otimes n}$ of the two-dimensional real vector space $\mathbb{R}^2$, and let $(x, y)$ be the canonical basis of $\mathbb{R}^2$. Then form the tensor product sheaf $\mathcal{T}_{\mathbb{C}^*} = T \otimes_{\mathbb{R}} \mathcal{O}_{\mathbb{C}^*}$ and let $\mathcal{I}_{\mathbb{C}^*}$ be the ideal sheaf in $\mathcal{T}_{\mathbb{C}^*}$ generated by the relation

$$x \otimes y - zy \otimes x = 0 \qquad [4]$$

where $z : \mathbb{C}^* \to \mathbb{C}$ is the identity function. The quotient sheaf $\mathcal{B} = \mathcal{B}_{\mathbb{C}^*} = \mathcal{T}_{\mathbb{C}^*}/\mathcal{I}_{\mathbb{C}^*}$ then is a sheaf of $\mathbb{C}$-algebras and an $\mathcal{O}_{\mathbb{C}^*}$-module. Using eqn [4] now move all occurrences of $x$ in an element of $\mathcal{B}_{\mathbb{C}^*}$ to the right of all $y$'s. Since $1/z$ is an element of $\mathcal{O}(\mathbb{C}^*)$, one can thus show that $\mathcal{B}_{\mathbb{C}^*}$ is a free $\mathcal{O}_{\mathbb{C}^*}$-module. Hence, $\mathcal{B}_{\mathbb{C}^*}$ is flat over $\mathcal{O}_{\mathbb{C}^*}$. Further, it is easy to see that for every $q \in \mathbb{C}^*$ the $\mathbb{C}$-algebra $A_q = \mathcal{B}_q/\mathfrak{m}_q\mathcal{B}_q$ is freely generated by elements $x$, $y$ with relations

$$x \otimes y - qy \otimes x = 0 \qquad [5]$$

We call $A_q$ the q-deformed quantum plane and $B = \mathcal{B}(\mathbb{C}^*)$ the over $\mathbb{C}^*$ universally deformed quantum plane. Altogether, one can interpret $B$ as a deformation of $A_q$ over $\mathbb{C}^*$, in particular as a deformation of $A_1 = T \otimes_{\mathbb{R}} \mathbb{C} = \mathbb{C}[x, y]$, the algebra of complex polynomials in two generators.

In the same way, one can deform function algebras on higher-dimensional vector spaces as well as function algebras on certain Lie groups. In this manner, one obtains the quantum group

$SU_q(2)$ as a deformation of a Hopf algebra of functions on SU(2). See, for example, the work of Faddeev–Reshetikhin–Takhtajan (1990), Manin (1988) and Wess–Zumino (1990) for more information on $q$-deformations of vector spaces, Lie groups, differential calculi, etc.

## Versal Deformations

In this section, and the ones that follow, we consider only germs of deformations, that is, deformations over parameter spaces of the form $(*, S)$. This means in particular that the structure sheaf only consists of its stalk $S$ at $*$, a commutative local $\Bbbk$-algebra. Let us now suppose that the sheaf morphism $\varphi : (Y, \mathcal{B}) \to (*, S)$ (over the canonical map $Y \to *$) is a deformation of the ringed space $(X, \mathcal{A})$ and that $\tau : T \to S$ is a homomorphism of commutative local $\Bbbk$-algebras. Then the sheaf morphism $\tau^*\varphi : \mathcal{B} \otimes_S T \to T$ with $(\tau^*\varphi)_y(t) = 1 \otimes t$ for $y \in Y$ and $t \in T$ is a deformation of $(X, \mathcal{A})$ over the parameter space $(*, T)$. One says that the deformation $\tau^*\varphi$ is induced by the homomorphism $\tau$.

**Definition 5** A deformation $\varphi : (Y, \mathcal{B}) \to S$ of $(X, \mathcal{A})$ is called versal if every (germ of a) deformation of $(X, \mathcal{A})$ is isomorphic to a deformation germ induced by a homomorphism of $\Bbbk$-algebras $\tau : T \to S$. A versal deformation is called universal, if the inducing homomorphism $\tau : T \to S$ is unique, and *miniversal* if $S$ is of minimal dimension.

**Example 6**

(i) In the section "Families of matrices as deformations," the construction of a versal deformation of a complex matrix $A$ has been sketched.
(ii) According to Kuranishi, every compact complex manifold has a versal deformation by an analytic germ. See Kuranishi (1971) for a detailed exposition and the section "The Kodaira–Spencer algebra controlling deformations of compact complex manifolds" for a description of the principal ideas.
(iii) Grauert has shown that for isolated singularities there exists a versal analytic deformation.
(iv) By the work of Douady–Verdier, Grauert, and Palamodov one knows that for every compact complex space there exists a miniversal analytic deformation. One of the essential methods in the existence proof hereby is Palamodov's construction of the cotangent complex (see Palamodov (1990).
(v) Bingener (1987) has further established Palomodov's approach and thus has provided a unified and quite general method for constructing versal deformations in analytic geometry.
(vi) Fialowski–Fuchs have constructed miniversal deformations of Lie algebras.

## Schlessinger's Theorem

According to Grothendieck, spaces in algebraic geometry are represented by functors from a category of commutative rings to the category of sets. In this picture, an affine algebraic variety $X$ over the base field $\Bbbk$ and with coordinate ring $A$ is equivalently described by the functor $\mathrm{Hom}_{\mathrm{alg}}(A, -)$ defined on the category of commutative $\Bbbk$-algebras. As will be shown by examples in the next section, versal deformations are often encoded by functors representing spaces. More precisely, a deformation problem leads to a so-called functor of Artin rings, which means a covariant functor $F$ from the category of (local) Artinian $\Bbbk$-algebras to the category of sets such that the set $F(\Bbbk)$ has exactly one element. The question now arises as to under which conditions the functor $F$ is representable, that is, there exists a commutative $\Bbbk$-algebra $A$ such that $F \cong \mathrm{Hom}_{\mathrm{alg}}(A, -)$. In the work of Schlessinger (1968), the structure of functors of Artin rings has been studied in detail. Moreover, criteria have been established, when such a functor is pro-presentable, which means that it can be represented by a complete local algebra $\hat{A}$, where "completeness" is understood with respect to the $\mathfrak{m}$-adic topology. Because of its importance for deformation theory, we will state Schlessinger's theorem in this section. Before we come to its details, let us recall some notation.

**Definition 7** By an Artinian $\Bbbk$-algebra over a field $\Bbbk$ one understands a commutative $\Bbbk$-algebra $R$ which satisfies the following descending chain condition:

(Dec) Every descending chain $I_1 \supset \cdots \supset I_k \supset I_{k+1} \supset \cdots$ of ideals in $R$ becomes stationary.

Among others, an Artinian algebra $R$ has the following properties:

1. $R$ is Noetherian, that is, it satisfies the ascending chain condition.
2. Every prime ideal in $R$ is maximal.
3. (Chinese remainder theorem) $R$ is isomorphic to a finite product $\Pi_{i=1}^{n} R_i$, where each $R_i$ is a local Artinian algebra.
4. Every maximal ideal $\mathfrak{m}$ of $R$ is nilpotent, that is, $\mathfrak{m}^k = 0$ for some $k \in \mathbb{N}$.
5. Every quotient $R/\mathfrak{m}^k$ with $\mathfrak{m}$ maximal is finite dimensional.

**Definition 8** Assume that $f : B \to A$ is a surjective homomorphism in the category $\Bbbk$-$\mathsf{Alg}_{\mathsf{l,Art}}$ of local Artinian $\Bbbk$-algebras. Then $f$ is called a small extension if ker $f$ is a nonzero principal ideal $(b)$ in $B$ such that $\mathfrak{m}b = (0)$, where $\mathfrak{m}$ is the maximal ideal of $B$.

**Theorem 9** (Schlessinger (1968, theorem 2.11)). *Let F be a functor of Artin rings* (*over the base field* $\Bbbk$). *Assume that* $A' \to A$ *and* $A'' \to A$ *are morphisms in* $\Bbbk$-$\mathsf{Alg}_{\mathsf{l,Art}}$, *and consider the map*

$$F(A' \times_A A'') \to F(A') \times_{F(A)} F(A'') \qquad [6]$$

*Then F is pro-representable if and only if F has the following properties*:

(H1) *The map* [6] *is a surjection whenever* $A'' \to A$ *is a small extension.*
(H2) *The map* [6] *is a bijection*, *when* $A = \Bbbk$ and $A'' = \Bbbk[\varepsilon]$.
(H3) *One has* $\dim_\Bbbk(t_F) < \infty$ *for the tangent space* $t_F := F(\Bbbk[\varepsilon])$.
(H4) *For every small extension* $A' \to A$, *the map*

$$F(A' \times_A A') \to F(A') \times_{F(A)} F(A')$$

*is an isomorphism.*

Suppose that the functor $F$ satisfies conditions (H1)–(H4), and let $\hat{A}$ be an arbitrary complete local $\Bbbk$-algebra. By Yoneda's lemma, every element

$$\xi = \operatorname*{proj\,lim}_{n \in \mathbb{N}} \xi_n \in \hat{A} = \operatorname*{proj\,lim}_{n \in \mathbb{N}} \hat{A}/\mathfrak{m}^n \hat{A}$$

induces a natural transformation

$$\mathrm{Hom}_{\mathrm{alg}}(\hat{A}, -) \to F, \quad \left(u : \hat{A} \to R\right) \mapsto F(u_n)(\xi_n) \quad [7]$$

where $n \in \mathbb{N}$ is chosen large enough such that the homomorphism $u : \hat{A} \to R$ factors through some $u_n : \hat{A}/\mathfrak{m}^n \to R$. This is possible indeed, since $R$ is Artinian. In the course of the proof of Schlessinger's theorem, $\hat{A}$ and the element $\xi \in \hat{A}$ are now constructed in such a way that [7] is an isomorphism.

## Differential Graded Lie Algebras and Deformation Problems

According to a philosophy going back to Deligne "every deformation problem in characteristic zero is controlled by a differential graded Lie algebra, with quasi-isomorphic differential graded Lie algebras giving the same deformation theory" (cf. Goldman and Millson (1988), p. 48). In the following, we will explain the main idea of this concept and apply it to two particular examples.

### Differential Graded Lie Algebras

**Definition 10** By a graded algebra over a field $\Bbbk$ one understands a graded $\Bbbk$-vector space $A^\bullet = \bigoplus_{k \in \mathbb{Z}} A^k$ together with a bilinear map

$$\mu : A^\bullet \times A^\bullet \to A^\bullet, \quad (a, b) \mapsto a \cdot b = \mu(a, b)$$

such that $A^k \cdot A^l \subset A^{k+l}$ for all $k, l \in \mathbb{Z}$. The graded algebra $A^\bullet$ is called associative if $(ab)c = a(bc)$ for all $a, b, c \in A^\bullet$.

A graded subalgebra of $A^\bullet$ is a graded subspace $B^\bullet = \bigoplus_{k \in \mathbb{Z}} B^k \subset A^\bullet$ which is closed under $\mu$, a graded ideal is a graded subalgebra $I^\bullet \subset A^\bullet$ such that $I^\bullet \cdot A^\bullet \subset I^\bullet$ and $A^\bullet \cdot I^\bullet \subset I^\bullet$.

A homomorphism between graded algebras $A^\bullet$ and $B^\bullet$ is a homogeneous map $f : A^\bullet \to B^\bullet$ of degree 0 such that $f(a \cdot b) = f(a) \cdot f(b)$ for all $a, b \in A^\bullet$.

From now on, assume that $\Bbbk$ has characteristic $\neq 2, 3$. A graded Lie algebra then is a graded $\Bbbk$-vector space $\mathfrak{g}^\bullet = \bigoplus_{k \in \mathbb{Z}} \mathfrak{g}^k$ together with a bilinear map

$$[\cdot, \cdot] : \mathfrak{g}^\bullet \times \mathfrak{g}^\bullet \to \mathfrak{g}^\bullet, \quad (a, b) \mapsto [a, b]$$

such that the following axioms hold true:

1. $[\mathfrak{g}^k, \mathfrak{g}^l] \subset \mathfrak{g}^{k+l}$ for all $k, l \in \mathbb{Z}$.
2. $[\xi, \zeta] = -(-1)^{kl}[\zeta, \xi]$ for all $\xi \in \mathfrak{g}^k, \zeta \in \mathfrak{g}^l$.
3. $(-1)^{k_1 k_3}[[\xi_1, \xi_2], \xi_3] + (-1)^{k_2 k_1}[[\xi_2, \xi_3], \xi_1] + (-1)^{k_3 k_2}[[\xi_3, \xi_1], \xi_2] = 0$ for all $\xi_i \in \mathfrak{g}^{k_i}$ with $i = 1, 2, 3$.

By axiom (1), it is clear that a graded Lie algebra is in particular a graded algebra. So the above-defined notions of a graded ideal, homomorphism, etc., apply as well to graded Lie algebras.

**Example 11** Let $A^\bullet = \bigoplus_{k \in \mathbb{Z}} A^k$ be a graded associative algebra. Then $A^\bullet$ becomes a graded Lie algebra with the bracket

$$[a, b] = ab - (-1)^{kl} ba \quad \text{for } a \in A^k \text{ and } b \in A^l$$

The space $A^\bullet$ regarded as a graded Lie algebra is often denoted by $\mathfrak{lie}^\bullet(A^\bullet)$.

**Definition 12** A linear map $D : A^\bullet \to A^\bullet$ defined on a graded algebra $A^\bullet$ is called a *derivation* of *degree l* if

$$D(ab) = (Da)b + (-1)^{kl} a(Db) \quad \text{for all } a \in A^k \text{ and } b \in A^\bullet$$

A graded (Lie) algebra $A^\bullet$ together with a derivation $d$ of degree 1 is called a differential graded (Lie) algebra if $d \circ d = 0$. Then $(A^\bullet, d)$ becomes a cochain complex. Since ker $d$ is a graded

subalgebra of $A^\bullet$ and im $d$ a graded ideal in ker $d$, the cohomology space

$$H^\bullet(A^\bullet, d) = \ker d / \mathrm{im}\, d$$

inherits the structure of a graded (Lie) algebra from $A^\bullet$.

Let $f : A^\bullet \to B^\bullet$ be a homomorphism of differential graded (Lie) algebras $(A^\bullet, d)$ and $(B^\bullet, \partial)$. Assume further that $f$ is a cochain map, that is, that $f \circ d = \partial \circ f$. Then one says that $f$ is quasi-isomorphism or that the differential graded (Lie) algebras $A^\bullet$ and $B^\bullet$ are quasi-isomorphic if the induced homomorphism on the cohomology level $\overline{f} : H^\bullet(A^\bullet, d) \to H^\bullet(B^\bullet, \partial)$ is an isomorphism. Finally, a differential graded (Lie) algebra $(A^\bullet, d)$ is called formal if it is quasi-isomorphic to its cohomology $(H^\bullet(A^\bullet, d), 0)$.

### Maurer–Cartan Equation

Assume that $(\mathfrak{g}^\bullet, [\cdot,\cdot], d)$ is a differential graded Lie algebra over $\mathbb{C}$. Define the space $\mathcal{MC}(\mathfrak{g}^\bullet)$ of solutions of the Maurer–Cartan equation by

$$\mathcal{MC}(\mathfrak{g}^\bullet) := \{\omega \in \mathfrak{g}^1 \mid d\omega - \tfrac{1}{2}[\omega, \omega] = 0\} \qquad [8]$$

In case the differential graded Lie algebra $\mathfrak{g}^\bullet$ is nilpotent, this space naturally possesses a groupoid structure or, in other words, a set of arrows which are all invertible. The reason for this is that, under the assumption of nilpotency, the space $\mathfrak{g}^0$ is equipped with the Campbell–Hausdorff multiplication

$$\mathfrak{g}^0 \times \mathfrak{g}^0 \to \mathfrak{g}^0, \quad (X, Y) \mapsto \log(\exp X, \exp Y)$$

and the group $\mathfrak{g}^0$ acts on $\mathfrak{g}^1$ by the exponential function. More precisely, in this situation one can define for two objects $\alpha, \beta \in \mathcal{MC}(\mathfrak{g}^\bullet)$ the space of arrows $\alpha \to \beta$ as the set of all $\lambda \in \mathfrak{g}^0$ such that $\exp \lambda \cdot \alpha = \beta$.

We have now the means to define for every complex differential graded Lie algebra $\mathfrak{g}^\bullet$ its deformation functor $\mathrm{Def}_{\mathfrak{g}^\bullet}$. This functor maps the category of local Artinian $\mathbb{C}$-algebras to the category of groupoids and is defined on objects as follows:

$$\mathrm{Def}_{\mathfrak{g}^\bullet}(R) := \mathcal{MC}(\mathfrak{g}^\bullet \otimes \mathfrak{m}) \qquad [9]$$

Hereby, $R$ is a complex local Artinian algebra, and $\mathfrak{m}$ its maximal ideal. Note that since $R$ is Artinian, $\mathfrak{g}^\bullet \otimes \mathfrak{m}$ is a nilpotent differential graded Lie algebra, hence $\mathrm{Def}_{\mathfrak{g}^\bullet}(R)$ carries a groupoid structure as constructed above. Clearly, $\mathrm{Def}_{\mathfrak{g}^\bullet}$ is also a functor of Artin rings as defined in the previous section.

With appropriate choices of the differential graded Lie algebra $\mathfrak{g}^\bullet$, essentially all deformation problems from the section "Basic definitions and examples" can be recovered via a functor of the form $\mathrm{Def}_{\mathfrak{g}^\bullet}$. Below, we will show in some detail how this works for two examples, namely the deformation theory of complex manifolds and the deformation quantization of Poisson manifolds. But before we come to this, let us state a result which shows how the deformation functor behaves under quasi-isomorphisms of the underlying differential graded Lie algebra. This result is crucial in a sense that it allows to equivalently describe a deformation problem with controlling $\mathfrak{g}^\bullet$ by any other differential graded Lie algebra within the quasi-isomorphism class of $\mathfrak{g}^\bullet$. So, in particular in the case where the differential graded Lie algebra is formal, one often obtains a direct solution of the deformation problem.

**Theorem 13** (Deligne, Goldman–Millson). *Assume that $f : \mathfrak{g}^\bullet \to \mathfrak{h}^\bullet$ is a quasi-isomorphism of differential graded Lie algebras. For every local Artinian $\mathbb{C}$-algebra $R$ the induced functor $f_* : \mathrm{Def}_{\mathfrak{g}^\bullet}(R) \to \mathrm{Def}_{\mathfrak{h}^\bullet}(R)$ then is an equivalence of groupoids.*

### The Kodaira–Spencer Algebra Controlling Deformations of Compact Complex Manifolds

Let $M$ be a compact complex $n$-dimensional manifold. Recall that then the complexified tangent bundle $T_{\mathbb{C}}M$ has a decomposition into a holomorphic tangent bundle $T^{1,0}M$ and an antiholomorphic tangent bundle $T^{0,1}M$. This leads to a decomposition of the space of complex $n$-forms into the spaces $\Omega^{p,q}M$ of forms on $M$ of type $(p, q)$. More generally, a smooth subbundle $J^{0,1} \subset T_{\mathbb{C}}M$ which induces a decomposition of the form $T_{\mathbb{C}}M = J^{1,0} \oplus J^{0,1}$, where $J^{1,0} := \overline{J^{0,1}}$, is called an almost complex structure on $M$. Clearly, the decomposition of $T_{\mathbb{C}}M$ into the holomorphic and antiholomorphic part is an almost complex structure, and an almost complex structure which is induced by a complex structure is called integrable. Assume that an almost complex structure $J^{0,1}$ is given on $M$ and that it has finite distance to the complex structure on $M$. The latter means that the restriction $\varrho_J^{0,1}$ of the projection $\varrho : T_{\mathbb{C}}M \to T^{0,1}M$ along $T^{1,0}M$ to the subbundle $J^{0,1}$ is an isomorphism. Denote by $\beta$ the inverse of $\varrho_J^{0,1}$, and let $\omega \in \Omega^{0,1}(M, T^{1,0}M)$ be the composition $-\varrho \circ \beta$. One checks immediately that every almost complex structure with finite distance to the complex structure on $M$ is uniquely characterized by a section $\omega \in \Omega^{0,1}(M, T^{1,0}M)$ and that every element of $\Omega^{0,1}(M, T^{1,0}M)$ comes from an almost complex structure on $M$.

As a consequence of the Newlander–Nirenberg theorem, one can now show that the almost

complex structure $J^{0,1}$ resp. $\omega$ is integrable if and only if the equation

$$\overline{\partial}\omega - \tfrac{1}{2}[\omega,\omega] = 0 \qquad [10]$$

is fulfilled. But this is nothing else than the Maurer–Cartan equation in the Kodaira–Spencer differential graded Lie algebra

$$(\mathfrak{L}^\bullet, \overline{\partial}, [\cdot,\cdot]) = \left( \bigoplus_{p\in\mathbb{N}} \Omega^{0,p}(M, T^{1,0}M), \overline{\partial}, [\cdot\,,\cdot] \right)$$

Hereby, $\Omega^{0,p}(M, T^{1,0}M)$ denotes the $T^{1,0}M$-valued differential forms on $M$ of type $(0,p), \overline{\partial}$: $\Omega^{0,p}(M,T^{1,0}M) \to \Omega^{0,p+1}(M,T^{1,0}M)$ the Dolbeault operator, and $[\,\cdot\,,\cdot\,]$ is induced by the Lie bracket of holomorphic vector fields. As a consequence of these considerations, deformations of the complex manifold $M$ can equivalently be described by families $(\omega_p)_{p\in P} \subset \mathfrak{L}^1$ which satisfy eqn [10] and $\omega_* = 0$. Thus, it remains to determine the associated deformation functor $\mathrm{Def}_{\mathfrak{L}^\bullet}$.

According to Schlessinger's theorem, the functor $\mathrm{Def}_{\mathfrak{L}^\bullet}$ is pro-representable. Hence, there exists a local $\mathbb{C}$-algebra $R_{\mathfrak{L}^\bullet}$ complete with respect to the $\mathfrak{m}$-adic topology such that

$$\mathrm{Def}_{\mathfrak{L}^\bullet}(R) = \mathrm{Hom}_{\mathrm{alg}}(R_{\mathfrak{L}^\bullet}, R) \qquad [11]$$

for every local Artinian $\mathbb{C}$-algebra $R$. Moreover, by Artin's theorem, there exists a "convergent" solution of the Maurer–Cartan equation, that is, $R_{\mathfrak{L}^\bullet}$ can be replaced in eqn. [11] by a ring $\overline{R}_{\mathfrak{L}^\bullet}$ representing an analytic germ.

**Theorem 14** (Kodaira–Spencer, Kuranishi). *The ringed space* $(\overline{R}_{\mathfrak{L}^\bullet}, (0))$ *is a miniversal deformation of the complex structure on* $M$.

### Deformation Quantization of Poisson Manifolds

Let $A$ be an associative $\mathbb{k}$-algebra with $\mathrm{char}\,\mathbb{k} = 0$. Put for every integer $k \geq -1$

$$\mathfrak{g}^k := \mathrm{Hom}_{\mathbb{k}}(A^{\otimes(k+1)}, A)$$

Then $\mathfrak{g}^\bullet$ becomes a graded vector space. Let us impose a differential and a bracket on $\mathfrak{g}^\bullet$. The differential is the usual *Hochschild coboundary* $b : \mathfrak{g}^k \to \mathfrak{g}^{k+1}$,

$$\begin{aligned} bf(a_0 \otimes \cdots \otimes a_{k+1}) &:= a_0 f(a_1 \otimes \cdots \otimes a_{k+1}) \\ &\quad + \sum_{i=0}^{k} (-1)^{i+1} f(a_0 \otimes \cdots \otimes a_i a_{i+1} \otimes \cdots \otimes a_{k+1}) \\ &\quad + (-1)^k f(a_0 \otimes \cdots \otimes a_k) a_{k+1} \end{aligned}$$

The bracket is the Gerstenhaber bracket

$$[\cdot,\cdot] : \mathfrak{g}^{k_1} \times \mathfrak{g}^{k_2} \to \mathfrak{g}^{k_1+k_2}$$
$$[f_1, f_2] := f_1 \circ f_2 - (-1)^{k_1 k_2} f_2 \circ f_1$$

where

$$\begin{aligned} &f_1 \circ f_2(a_0 \otimes \cdots \otimes a_{k_1+k_2}) \\ &:= \sum_{i=0}^{k_1} (-1)^{ik_2} f_1\big(a_0 \otimes \cdots \otimes a_{i-1} \otimes f_2(a_i \otimes \cdots \otimes a_{i+k_2}) \\ &\qquad \otimes a_{i+k_2+1} \otimes \cdots \otimes a_{k_1+k_2}\big) \end{aligned}$$

The triple $(\mathfrak{g}^\bullet, b, [\,\cdot\,,\cdot\,])$ then is a differential graded Lie algebra.

Consider the Maurer–Cartan equation $b\gamma - (1/2)[\gamma,\gamma] = 0$ in $\mathfrak{g}^1$. Obviously, it is equivalent to the equality

$$\begin{aligned} &a_0\gamma(a_1,a_2) - \gamma(a_0 a_1, a_2) + \gamma(a_0, a_1 a_2) - \gamma(a_0,a_1)a_2 \\ &\quad = \gamma(\gamma(a_0,a_1),a_2) - \gamma(a_0, \gamma(a_1,a_2)) \\ &\qquad \text{for } a_0, a_1, a_2 \in A \end{aligned} \qquad [12]$$

If one defines now for some $\gamma \in \mathfrak{g}^1$ the bilinear map $m : A \times A \to A$ by $m(a,b) = ab + \gamma(a,b)$, then [12] implies that $m$ is associative if and only if $\gamma$ satisfies the Maurer–Cartan equation.

Let us apply these observations to the case where $A$ is the algebra $\mathcal{C}^\infty(M)[[t]]$ of formal power series in one variable with coefficients in the space of smooth functions on a Poisson manifold $M$. By (a variant of) the theorem of Hochschild–Kostant–Rosenberg and Connes, one knows that in this case the cohomology of $(\mathfrak{g}^\bullet, b)$ is given by formal power series with coefficients in the space $\Gamma^\infty(\Lambda^\bullet TM)$ of antisymmetric vector fields. Now, $\Gamma^\infty(\Lambda^\bullet TM)$ carries a natural Lie algebra bracket as well, namely the Schouten bracket. Thus, one obtains a second differential graded Lie algebra $(\Gamma^\infty(\Lambda^\bullet TM)[[t]], 0, [\,\cdot\,,\cdot\,])$. Unfortunately, the projection onto cohomology $(\mathfrak{g}^\bullet, b) \to \Gamma^\infty(\Lambda^\bullet TM)[[t]]$ does not preserve the natural brackets, hence is not a quasi-isomorphism in the category of differential graded Lie algebras. It has been the fundamental observation by Kontsevich that this defect can be cured as follows.

**Theorem 15** (Kontsevich 2003). *For every Poisson manifold M the differential graded Lie algebra* $(\mathfrak{g}^\bullet, b, [\,\cdot\,,\cdot])$ *is formal in the sense that there exists a quasi-isomorphism* $(\mathfrak{g}^\bullet, b, [\,\cdot\,,\cdot]) \to (\Gamma^\infty(\Lambda^\bullet TM)[[t]], 0, [\,\cdot\,,\cdot])$ *in the category of* $L^\infty$*-algebras.*

Note that the theorem only claims the existence of a quasi-isomorphism in the category of $L^\infty$-algebras or, in other words, in the category of homotopy Lie algebras. This is a notion somewhat weaker than a differential graded Lie algebra, but Theorem 13 also holds in the context of $L^\infty$-algebras.

Since the solutions of the Maurer–Cartan equation in $(\Gamma^\infty(\Lambda^\bullet TM)[[t]], 0, [\cdot\,,\cdot])$ are exactly the formal paths of Poisson bivector fields on $M$, Kontsevich's formality theorem entails:

**Corollary 16** *Every Poisson manifold has a formal deformation quantization.*

## Introduction to Deformation Quantization

The framework of classical mechanics, in its Hamiltonian formulation on the motion space, employs a symplectic manifold (or more generally a Poisson manifold). Observables are families of smooth functions on that manifold $M$. The dynamics is defined in terms of a Hamiltonian $H \in C^\infty(M)$ and the time evolution of an observable $f_t \in C^\infty(M \times \mathbb{R})$ is governed by the equation: $(\mathrm{d}/\mathrm{d}t)f_t = -\{H, f_t\}$.

The quantum-mechanical framework, in its usual Heisenberg's formulation, employs a Hilbert space (states are rays in that space). Observables are families of self-adjoint operators on the Hilbert space. The dynamics is defined in terms of a Hamiltonian $H$, which is a self-adjoint operator, and the time evolution of an observable $A_t$ is governed by the equation $\mathrm{d}A_t/\mathrm{d}t = (\mathrm{i}/\hbar)[H, A_t]$.

Quantization of a classical system is a way to pass from classical to quantum results. A first idea for quantization is to define a correspondence $Q : f \mapsto Q(f)$ mapping a function $f$ to a self-adjoint operator $Q(f)$ on a Hilbert space $\mathscr{H}$ in such a way that $Q(1) = \mathrm{Id}$ and $[Q(f), Q(g)] = \mathrm{i}\hbar Q(\{f, g\})$. Unfortunately, there is no such correspondence defined on all smooth functions on $M$ when one puts an irreducibility requirement (which is necessary not to violate Heisenberg's principle).

Different mathematical treatments of quantization have appeared:

- Geometric quantization of Kostant and Souriau: first, prequantization of a symplectic manifold $(M, \omega)$ where one builds a Hilbert space and a correspondence $Q$ defined on all smooth functions on $M$ but with no irreducibility; second, polarization to "cut down the number of variables."
- Berezin's quantization where one builds on a particular class of symplectic manifolds (some

Kähler manifolds) a family of associative algebras using a symbolic calculus, that is, a dequantization procedure.

- Deformation quantization introduced by Flato, Lichnerowicz, and Sternheimer in 1976 where they "suggest that quantization be understood as a deformation of the structure of the algebra of classical observables rather than a radical change in the nature of the observables."

This deformation approach to quantization is part of a general deformation approach to physics (a seminal idea stressed by Flato): one looks at some level of a theory in physics as a deformation of another level.

Deformation quantization is defined in terms of a star product which is a formal deformation of the algebraic structure of the space of smooth functions on a Poisson manifold. The associative structure given by the usual product of functions and the Lie structure given by the Poisson bracket are simultaneously deformed.

In this article we concentrate on some mathematical results concerning deformations of the Poisson bracket on a symplectic manifold, classification of star products on symplectic manifolds, group actions on star products, convergence properties of some star products, and star products on cotangent bundles.

## Deformations of the Poisson Bracket on a Symplectic Manifold

**Definition 1** A Poisson bracket defined on the space of smooth functions on a manifold $M$ is an $\mathbb{R}$-bilinear map on $C^\infty(M), (u,v) \mapsto \{u,v\}$ such that for any $u,v,w \in C^\infty(M)$:

(i) $\{u,v\} = -\{v,u\}$;
(ii) $\{\{u,v\},w\} + \{\{v,w\},u\} + \{\{w,u\},v\} = 0$;
(iii) $\{u,vw\} = \{u,v\}w + \{u,w\}v$.

A Poisson bracket is given in terms of a contravariant skew-symmetric 2-tensor $P$ on $M$ (called the Poisson tensor) by $\{u,v\} = P(\mathrm{d}u \wedge \mathrm{d}v)$. The Jacobi identity for the Poisson bracket is equivalent to the vanishing of the Schouten bracket $[P,P] = 0$. (The Schouten bracket is the extension – as a graded derivation for the exterior product – of the bracket of vector fields to skew-symmetric contravariant tensor fields.) A Poisson manifold $(M,P)$ is a manifold $M$ with a Poisson bracket defined by $P$.

A particular class of Poisson manifolds, essential in classical mechanics, is the class of "symplectic manifolds." If $(M,\omega)$ is a symplectic manifold (i.e., $\omega$ is a closed nondegenerate 2-form on $M$) and if $u,v \in C^\infty(M)$, the Poisson bracket of $u$ and $v$ is

$$\{u,v\} := X_u(v) = \omega(X_v, X_u)$$

where $X_u$ denotes the Hamiltonian vector field corresponding to the function $u$, that is, such that $\mathrm{i}(X_u)\omega = \mathrm{d}u$. In coordinates the components of the Poisson tensor $P^{ij}$ form the inverse matrix of the components $\omega_{ij}$ of $\omega$.

Duals of Lie algebras form the class of linear Poisson manifolds. If $\mathfrak{g}$ is a Lie algebra, then its dual $\mathfrak{g}^*$ is endowed with the Poisson tensor $P$ defined by $P_\xi(X,Y) := \xi([X,Y])$ for $X, Y \in \mathfrak{g} = (\mathfrak{g}^*)^* \sim (T_\xi \mathfrak{g}^*)^*$.

**Definition 2** A Poisson deformation of the Poisson bracket on a Poisson manifold $(M,P)$ is a Lie algebra deformation of $(C^\infty(M), \{\,,\})$ which is a derivation in each argument, that is, of the form $\{u,v\}_\nu = P_\nu(\mathrm{d}u, \mathrm{d}v)$, where $P_\nu = P + \sum \nu^k P_k$ is a series of skew-symmetric contravariant 2-tensors on $M$ (such that $[P_\nu, P_\nu] = 0$).

Two Poisson deformations $P_\nu$ and $P'_\nu$ of the Poisson bracket $P$ on a Poisson manifold $(M,P)$ are equivalent if there exists a formal path in the diffeomorphism group of $M$, starting at the identity, that is, a series $T = \exp D = \mathrm{Id} + \sum_j (1/j!) D^j$ for $D = \sum_{r\geq 1} \nu^r D_r$ where the $D_r$ are vector fields on $M$, such that

$$T\{u,v\}_\nu = \{Tu, Tv\}'_\nu$$

where $\{u,v\}_\nu = P_\nu(\mathrm{d}u,\mathrm{d}v)$ and $\{u,v\}'_\nu = P'_\nu(\mathrm{d}u,\mathrm{d}v)$.

**Proposition 3** (Flato *et al.* 1975, Lecomte 1987). *On a symplectic manifold* $(M,\omega)$, *any Poisson deformation of the Poisson bracket corresponds to a series of closed 2-forms on M*, $\Omega_\nu = \omega + \sum_{r>0} \nu^r \omega_r$ *and is given by*

$$\{u,v\}_\nu = P_\nu(\mathrm{d}u,\mathrm{d}v) = \Omega_\nu\left(X^\nu_u, X^\nu_v\right)$$

*with* $\mathrm{i}(X^\nu_u)\Omega_\nu = \mathrm{d}u$. *The equivalence classes of Poisson deformations of the Poisson bracket P are parametrized by* $H^2(M;\mathbb{R})[[\nu]]$.

Poisson deformations are used in classical mechanics to express some constraints on the system. To deal with quantum mechanics, Flato *et al.* (1976) introduced star products. These give, by skew-symmetrization, Lie deformations of the Poisson bracket.

**Definition 4** A "star product" on $(M,P)$ is an $\mathbb{R}[\![\nu]\!]$-bilinear associative product $*$ on $C^\infty(M)[\![\nu]\!]$ given by

$$u * v = u *_\nu v := \sum_{r\geq 0} \nu^r C_r(u,v)$$

for $u, v \in C^\infty(M)$ (we consider here real-valued functions; the results for complex-valued functions are similar), such that $C_0(u,v) = uv$, $C_1(u,v) - C_1(v,u) = \{u,v\}$, $1 * u = u * 1 = u$.

When the $C_r$'s are bidifferential operators on $M$, one speaks of a differential star product. When each $C_r$ is a bidifferential operator of order at most $r$ in each argument, one speaks of a natural star product.

One finds in the literature other normalizations for the skew-symmetric part of $C_1$ such as $(i/2)\{\,,\}$; these amount to a rescaling of the parameter $\nu$. For physical applications, in the above convention for the formal parameter, $\nu$ corresponds to $\mathrm{i}\hbar$, where $\hbar$ is Planck's constant.

In the case of complex-valued functions, one can add the further requirement that the complex conjugation is a $^*$-involution for $*$, that is, $\overline{f * g} = \bar{g} * \bar{f}$. According to the interpretation of $\nu$ as being $\mathrm{i}\hbar$, we have to require $\bar{\nu} = -\nu$. Star products satisfying this additional property are called symmetric or Hermitian.

A star product can also be defined not on the whole of $C^\infty(M)$ but on a subspace $N$ which is stable under pointwise multiplication and Poisson bracket.

The simplest example of a deformation quantization is the Moyal product for the Poisson structure $P$ on a vector space $V = \mathbb{R}^m$ with constant coefficients:

$$P = \sum_{i,j} P^{ij} \partial_i \wedge \partial_j, \quad P^{ij} = -P^{ji} \in \mathbb{R}$$

where $\partial_i = \partial/\partial y^i$ is the partial derivative in the direction of the coordinate $y^i$, $i = 1, \ldots, n$. The formula for the Moyal product is

$$(u *_M v)(z) = \exp\left(\frac{\nu}{2} P^{rs} \partial_{y^r} \partial_{y'^s}\right)(u(y)v(y'))\big|_{y=y'=z} \qquad [1]$$

When $P$ is nondegenerate (so $V = \mathbb{R}^{2n}$), the space of formal power series of polynomials on $V$ with Moyal product is called the formal Weyl algebra $W = (S(V)[[\nu]], *_M)$.

Let $\mathfrak{g}^*$ be the dual of a Lie algebra $\mathfrak{g}$. The algebra of polynomials on $\mathfrak{g}^*$ is identified with the symmetric algebra $S(\mathfrak{g})$. One defines a new associative law on this algebra by a transfer of the product $\circ$ in the universal enveloping algebra $U(\mathfrak{g})$, via the bijection between $S(\mathfrak{g})$ and $U(\mathfrak{g})$ given by the total symmetrization $\sigma$:

$$\sigma : S(\mathfrak{g}) \to U(\mathfrak{g}) : X_1 \ldots X_k \mapsto \frac{1}{k!} \sum_{\rho \in S_k} X_{\rho(1)} \circ \cdots \circ X_{\rho(k)}$$

Then $U(\mathfrak{g}) = \oplus_{n \geq 0} U_n$, where $U_n := \sigma(S^n(\mathfrak{g}))$ and we decompose an element $u \in U(\mathfrak{g})$; accordingly $u = \sum u_n$. We define, for $P \in S^p(\mathfrak{g})$ and $Q \in S^q(\mathfrak{g})$,

$$P * Q = \sum_{n \geq 0} (\nu)^n \sigma^{-1}((\sigma(P) \circ \sigma(Q))_{p+q-n}) \qquad [2]$$

This yields a differential star product on $\mathfrak{g}^*$ (Gutt 1983). This star product can be written with an integral formula (for $\nu = 2\pi\mathrm{i}$)(Drinfeld 1987):

$$u * v(\xi) = \int_{\mathfrak{g} \times \mathfrak{g}} \hat{u}(X)\hat{v}(Y) \mathrm{e}^{2\mathrm{i}\pi\langle \xi, \mathrm{CBH}(X,Y)\rangle} \, \mathrm{d}X \, \mathrm{d}Y$$

where $\hat{u}(X) = \int_{\mathfrak{g}^*} u(\eta) \mathrm{e}^{-2\mathrm{i}\pi\langle \eta, X\rangle}$ and CBH denotes Campbell–Baker–Hausdorff formula for the product of elements in the group in a logarithmic chart ($\exp X \exp Y = \exp \mathrm{CBH}(X, Y)\ \forall\ X, Y \in \mathfrak{g}$). We call this the standard (or CBH) star product on the dual of a Lie algebra.

De Wilde and Lecomte (1983) proved that on any symplectic manifold there exists a differential star product. Fedosov (1994) gave a recursive construction of a star product on a symplectic manifold $(M, \omega)$ constructing flat connections on the Weyl bundle. Omori *et al.* (1991) gave an alternative proof of existence of a differential star product on a symplectic manifold, gluing local Moyal star products. In 1997, Kontsevich gave a proof of the existence of a star product on any Poisson manifold and gave an explicit formula for a star product for any Poisson structure on $V = \mathbb{R}^m$. This appeared as a consequence of the proof of his formality theorem.

### Fedosov's Construction of Star Products

Fedosov's construction gives a star product on a symplectic manifold $(M, \omega)$, when one has chosen a symplectic connection and a sequence of closed 2-forms on $M$. The star product is obtained by identifying the space $C^\infty(M)[[\nu]]$ with an algebra of flat sections of the so-called Weyl bundle endowed with a flat connection whose construction is related to the choice of the sequence of closed 2-forms on $M$.

**Definition 5** The symplectic group $\mathrm{Sp}(n, \mathbb{R})$ acts by automorphisms on the formal Weyl algebra $W$. If $(M, \omega)$ is a symplectic manifold, we can form its bundle $F(M)$ of symplectic frames which is a principal $\mathrm{Sp}(n, \mathbb{R})$-bundle over $M$. The associated bundle $\mathscr{W} = F(M) \times_{\mathrm{Sp}(n,\mathbb{R})} W$ is a bundle of associative algebras on $M$ called the Weyl bundle. Sections of the Weyl bundle have the form of formal series

$$a(x, y, \nu) = \sum_{2k+l \geq 0} \nu^k a_{(k)i_1 \ldots i_l}(x) y^{i_1} \cdots y^{i_l}$$

where the coefficients $a_{(k)}$ are symmetric covariant $l$-tensor fields on $M$. The product of two sections taken pointwise makes the space of sections into an algebra, and in terms of the above representation of sections the multiplication has the form

$$(a \circ b)(x, y, \nu) = \left( \exp\left( \frac{\nu}{2} P^{ij} \frac{\partial}{\partial y^i} \frac{\partial}{\partial z^j} \right) a(x, y, \nu) b(x, z, \nu) \right) \Big|_{y=z}$$

Note that the center of this algebra coincides with $C^\infty(M)[[\nu]]$.

A symplectic connection on $M$ is a linear torsion-free connection $\nabla$ such that $\nabla\omega = 0$.

**Remark 6** It is well known that such connections always exist but, unlike the Riemannian case, are not unique. To see the existence, take any torsion-free connection $\nabla'$ and set $T(X, Y, Z) = (\nabla'_X \omega)(Y, Z)$. Define $S$ by $\omega(S(X, Y), Z) = (1/3)(T(X, Y, Z) + T(Y, X, Z))$, then $\nabla_X Y = \nabla'_X Y + S(X, Y)$ defines a symplectic connection.

The connection $\nabla$ induces a covariant derivative on sections of the Weyl bundle, denoted $\partial$. The idea is to try to modify it to have zero curvature. Consider $Da = \partial a - \delta(a) - (1/\nu)[r, a]$, where $r$ is a 1-form with values in $\mathscr{W}$, with $[a, a'dx] = (a \circ a' - a' \circ a)dx$ and $\delta(a) = (1/\nu)[\sum_{ij} \omega_{ij} y^i dx^j, a]$.

**Theorem 7** (Fedosov 1994). *For a given series $\Omega = \sum_{i \geq 1} \nu^i \omega_i$ of closed 2-forms on M, there is a unique $r \in \Gamma(\mathscr{W} \otimes \Lambda^1)$ satisfying some normalization condition, so that $Da = \partial a - \delta(a) - (1/\nu)[r, a]$ is flat. For any $a_\circ \in C^\infty(M)[[\nu]]$, there is a unique a in the subspace $\mathscr{W}_D$ of flat sections of $\mathscr{W}$, such that $a(x, 0, \nu) = a_0(x, \nu)$. The use of this linear isomorphism to transport the algebra structure of $\mathscr{W}_D$ to $C^\infty(M)[[\nu]]$ defines the star product of Fedosov $*_{\nabla,\Omega}$.*

Writing $*_{\nabla,\Omega} = \sum_{i \geq 0} \nu^r C_r^\Omega$, $C_r^\Omega$ only depends on $\omega_i$ for $i < r$ and $C_{r+1}^\Omega(u, v) = c\omega_r(X_u, X_v) + \tilde{C}_{r+1}(u, v)$, where $c \in \mathbb{R}$ and the last term does not depend on $\omega_r$.

## Classification of Star Products on a Symplectic Manifold

Star products on a manifold $M$ are examples of deformations of associative algebras (in the sense of Gerstenhaber). Their study uses the Hochschild cohomology of the algebra (here $C^\infty(M)$ with values in $C^\infty(M)$) where $p$-cochains are $p$-linear maps from $(C^\infty(M))^p$ to $C^\infty(M)$ and where the Hochschild coboundary operator maps the $p$-cochain $C$ to the $(p+1)$-cochain

$$\begin{aligned}(\partial C)(u_0, \ldots, u_p) = {} & u_0 C(u_1, \ldots, u_p) \\ & + \sum_{r=1}^{p} (-1)^r C(u_0, \ldots, u_{r-1}u_r, \ldots, u_p) \\ & + (-1)^{p+1} C(u_0, \ldots, u_{p-1})u_p\end{aligned}$$

For differential star products, we consider differential cochains given by differential operators on each argument. The associativity condition for a star product at order $k$ in the parameter $\nu$ reads

$$\begin{aligned}(\partial C_k)(u, v, w) = \sum_{r+s=k, r,s>0} & (C_r(C_s(u, v), w) \\ & - C_r(u, C_s(v, w)))\end{aligned}$$

If one has cochains $C_j$, $j < k$ such that the star product they define is associative to order $k - 1$, then the right-hand side above is a cocycle ($\partial(\text{RHS}) = 0$) and one can extend the star product to order $k$ if it is a coboundary ($\text{RHS} = \partial(C_k)$).

Denoting by $m$ the usual multiplication of functions, and writing $* = m + C$, where $C$ is a formal series of multidifferential operators, the associativity also reads $\partial C = [C, C]$ where the bracket on the right-hand side is the graded Lie algebra bracket on $D_{\text{poly}}(M)[[\nu]] = \{\text{multidifferential operators}\}$.

**Theorem 8** (Vey 1975). *Every differential p-cocycle C on a manifold M is the sum of the coboundary of a differential $(p - 1)$-cochain and a 1-differential skew-symmetric p-cocycle A: $C = \partial B + A$. In particular, a cocycle is a coboundary if and only if its total skew-symmetrization, which is automatically 1-differential in each argument, vanishes. Given a connection $\nabla$ on M, B can be defined from C by universal formulas* (Cahen and Gutt 1982). *Also*

$$H^p_{\text{diff}}(C^\infty(M), C^\infty(M)) = \Gamma(\Lambda^p TM)$$

The similar result about continuous cochains is due to Connes (1985). In the somewhat pathological case of completely general cochains, the full cohomology is not known.

**Definition 9** Two star products $*$ and $*'$ on $(M, P)$ are said to be equivalent if there is a series of linear operators on $C^\infty(M)$, $T = \text{Id} + \sum_{r=1}^\infty \nu^r T_r$ such that

$$T(f * g) = Tf *' Tg \qquad [3]$$

Remark that the $T_r$ automatically vanish on constants since 1 is a unit for $*$ and for $*'$.

If $*$ and $*'$ are equivalent differential star products, then the equivalence is given by differential operators $T_r$; if they are natural, the equivalence is given by $T = \text{Exp}\, E$ with $E = \sum_{r=1}^\infty \nu^r E_r$, where the $E_r$ are differential operators of order at most $r + 1$.

Nest and Tsygan (1995), then Deligne (1995) and Bertelson *et al.* (1995, 1997) proved that any differential star product on a symplectic manifold $(M, \omega)$ is equivalent to a Fedosov star product and that its equivalence class is parametrized by the corresponding element in $H^2(M; \mathbb{R})[[\nu]]$.

Kontsevich (IHES preprint 97) proved that the coincidence of the set of equivalence classes of star and Poisson deformations is true for general Poisson manifolds:

**Theorem 10** (Kontsevich). *The set of equivalence classes of differential star products on a Poisson manifold* $(M, P)$ *can be naturally identified with the set of equivalence classes of Poisson deformations of* $P$: $P_\nu = P\nu + P_2\nu^2 + \cdots \in \Gamma(X, \wedge^2 T_X)[[\nu]]$, $[P_\nu, P_\nu] = 0$.

Deligne (1995) defines cohomological classes associated to differential star products on a symplectic manifold; this leads to an intrinsic way to parametrize the equivalence class of such a differential star product. The characteristic class $c(*)$ is given in terms of the skew-symmetric part of the term of order 2 in $\nu$ in the star product and in terms of local ("$\nu$-Euler") derivations of the form $D = \nu(\partial/\partial\nu) + X + \sum_{r\geq 1}\nu^r D'_r$. This characteristic class has the following properties:

- The map $C$ from equivalence classes of star products on $(M, \omega)$ to the affine space $-[\omega]/\nu + H^2(M; \mathbb{R})[\![\nu]\!]$ mapping $[*]$ to $c(*)$ is a bijection.
- The characteristic class is natural relative to diffeomorphisms and is equivariant under a change of parameter (Gutt and Rawnsley 1995).
- The characteristic class $c(*)$ coincides (cf. Deligne (1995) and Neumaier (1999)) for Fedosov-type star products with their characteristic class introduced by Fedosov as the de Rham class of the curvature of the generalized connection used to build them (up to a sign and factors of 2).

Index theory has been introduced in the framework of deformation quantization by Fedosov (1996) and by Nest and Tsygan (1995, 1996). We refer to the papers of Bressler, Nest, and Tsygan for further developments in that subject. A first tool in that theory is the existence of a trace for the deformed algebra; this trace is essentially unique in the framework of symplectic manifolds (an elementary proof is given in Karabegov (1998) and Gutt and Rawnsley (2003)); the trace is not unique for more general Poisson manifolds.

**Definition 11** A homomorphism from a differential star product $*$ on $(M, P)$ to a differential star product $*'$ on $(M', P')$ is an $\mathbb{R}$-linear map $A : C^\infty(M)[\![\nu]\!] \to C^\infty(M')[\![\nu]\!]$, continuous in the $\nu$-adic topology, such that

$$A(u * v) = Au *' Av$$

It is an isomorphism if the map is bijective.

Any isomorphism between two differential star products on symplectic manifolds is the combination of a change of parameter and a $\nu$-linear isomorphism. Any $\nu$-linear isomorphism between two star products $*$ on $(M, \omega)$ and $*'$ on $(M', \omega')$ is the combination of the action on functions of a symplectomorphism $\psi : M' \to M$ and an equivalence between $*$ and the pullback via $\psi$ of $*'$. It exists if and only if those two star products are equivalent, that is, if and only if $(\psi^{-1})^* c(*') = c(*)$, where $(\psi^{-1})^*$ denotes the action of $\psi^{-1}$ on the second de Rham cohomology space. In particular, a symplectomorphism $\psi$ of a symplectic manifold can be extended to a $\nu$-linear automorphism of a given differential star product on $(M, \omega)$ if and only if $(\psi)^* c(*) = c(*)$ (Gutt and Rawnsley 1999).

The notion of homomorphism and its relation to modules has been studied by Bordemann (2004).

The link between the notion of star product on a symplectic manifold and symplectic connections already appears in the seminal paper of Bayen *et al.* (1978), and was further developed by Lichnerowicz (1982), who showed that any Vey star product (i.e., a star product defined by bidifferential operators whose principal symbols at each order coincide with those of the Moyal star product) determines a unique symplectic connection. Fedosov's construction yields a Vey star product on any symplectic manifold starting from a symplectic connection and a formal series of closed 2-forms on the manifold. Furthermore, any star product is equivalent to a Fedosov star product and the de Rham class of the formal 2-form determines the equivalence class of the star product. On the other hand, many star products which appear in natural contexts (e.g., cotangent bundles or Kähler manifolds) are not Vey star products but are natural star products.

**Theorem 12** (Gutt and Rawnsley 2004). *Any natural star product on a symplectic manifold* $(M, \omega)$ *determines uniquely*

(i) *A symplectic connection* $\nabla = \nabla(*)$.
(ii) *A formal series of closed 2-forms* $\Omega = \Omega(*) \in \nu\Lambda^2(M)[\![\nu]\!]$.
(iii) *A formal series* $E = \sum_{r\geq 1}\nu^r E_r$ *of differential operators of order* $\leq r+1$ ($E_2$ *of order* $\leq 2$), *with* $E_r u = \sum_{k=2}^{r+1}(E_r^{(k)})^{i_1\ldots i_k}\nabla^k_{i_1\ldots i_k} u$, *where the* $E_r^{(k)}$ *are symmetric contravariant* $k$*-tensor fields*

*such that*

$$u * v = \exp -E\big((\exp Eu) *_{\nabla,\Omega} (\exp Ev)\big) \qquad [4]$$

*We denote* $* = *_{\nabla,\Omega,E}$. *If* $\tau$ *is a diffeomorphism of* $M$ *then the data for* $\tau \cdot *$ *is* $\tau\cdot\nabla$, $\tau\cdot\Omega$, *and* $\tau \cdot E$. *In*

*particular, a vector field X is a derivation of a natural star product* $*$, *if and only if* $\mathscr{L}_X\omega=0$, $\mathscr{L}_X\Omega=0$, $\mathscr{L}_X\nabla=0$, *and* $\mathscr{L}_X E=0$.

## Group Actions on Star Products

Symmetries in quantum theories are automorphisms of an algebra of observables. In the framework where quantization is defined in terms of a star product, a symmetry $\sigma$ of a star product $*$ is an automorphism of the $\mathbb{R}[\![\nu]\!]$-algebra $C^\infty(M)[\![\nu]\!]$ with multiplication given by $*$:

$$\sigma(u * v) = \sigma(u) * \sigma(v), \qquad \sigma(1) = 1$$

where $\sigma$, being determined by what it does on $C^\infty(M)$, will be a formal series $\sigma(u)=\sum_{r\geq 0}\nu^r\sigma_r(u)$ of linear maps $\sigma_r\cdot C^\infty(M)\to C^\infty(M)$. We denote by $\mathrm{Aut}_{\mathbb{R}[\![\nu]\!]}(M,*)$ the set of those symmetries.

Any such automorphism $\sigma$ of $*$ then can be written as $\sigma(u)=T(u\circ\tau^{-1})$, where $\tau$ is a Poisson diffeomorphism of $(M,P)$ and $T=\mathrm{Id}+\sum_{r\geq 1}\nu^r T_r$ is a formal series of linear maps. If $*$ is differential, then the $T_r$ are differential operators; if $*$ is natural, then $T=\mathrm{Exp}\,E$ with $E=\sum_{r\geq 1}\nu^r E_r$ and $E_r$ is a differential operator of order at most $r+1$.

If $\sigma_t$ is a one-parameter group of symmetries of the star product $*$, then its generator $D$ will be a derivation of $*$. Denote the Lie algebra of $\nu$-linear derivations of $*$ by $\mathrm{Der}_{\mathbb{R}[\![\nu]\!]}(M,*)$.

An action of a Lie group $G$ on a star product $*$ on a Poisson manifold $(M,P)$ is a homomorphism $\sigma: G\to \mathrm{Aut}_{\mathbb{R}[\![\nu]\!]}(M,*)$; then $\sigma_g=(\tau_g)^{-1*}+\mathrm{O}(\nu)$ and there is an induced Poisson action $\tau$ of $G$ on $(M,P)$.

Given a Poisson action $\tau$ of $G$ on $(M,P)$, a star product is said to be "invariant" under $G$ if all the $(\tau_g)^{-1*}$ are automorphisms of $*$.

An action of a Lie group $G$ on $*$ induces a homomorphism of Lie algebras $D:\mathfrak{g}\to\mathrm{Der}_{\mathbb{R}[\![\nu]\!]}(M,*)$. For each $\xi\in\mathfrak{g}, D_\xi=\xi^*+\sum_{r\geq 1}\nu^r D^r_\xi$, where $\xi^*$ is the fundamental vector field on $M$ defined by $\tau$; hence,

$$\xi^*(x) = \frac{\mathrm{d}}{\mathrm{d}t}|_0\tau(\exp - t\xi)x)$$

Such a homomorphism $D:\mathfrak{g}\to\mathrm{Der}_{\mathbb{R}[\![\nu]\!]}(M,*)$ is called an action of the Lie algebra $\mathfrak{g}$ on $*$.

**Proposition 13** (Arnal *et al.* 1983). *Given* $D:\mathfrak{g}\to\mathrm{Der}_{\mathbb{R}[\![\nu]\!]}(M,*)$ *a homomorphism so that for each* $\xi\in\mathfrak{g}$, $D_\xi=\xi^*+\sum_{r\geq 1}\nu^r D^r_\xi$, *where* $\xi^*$ *are the fundamental vector fields on M defined by an action* $\tau$ *of G on M and the* $D^r_\xi$ *are differential operators, then there exists a local homomorphism* $\sigma: U\subset G\to\mathrm{Aut}_{\mathbb{R}[\![\nu]\!]}(M,*)$ *so that* $\sigma_*=D$.

If we want the analog in our framework to the requirement that operators should correspond to the infinitesimal actions of a Lie algebra, we should ask the derivations to be inner so that functions are associated to the elements of the Lie algebra.

A derivation $D\in\mathrm{Der}_{\mathbb{R}[\![\nu]\!]}(M,*)$ is said to be essentially inner or Hamiltonian if $D=(1/\nu)\mathrm{ad}_* u$ for some $u\in C^\infty(M)[\![\nu]\!]$. We call an action of a Lie group almost $*$-Hamiltonian if each $D_\xi$ is essentially inner; this is equivalent to the knowledge of a linear map $\lambda:\mathfrak{g}\to C^\infty(M)[\![\nu]\!]\ \xi\mapsto\lambda_\xi$ so that $\mathrm{ad}_*(1/\nu)[\lambda_\xi,\lambda_\eta]_*=\mathrm{ad}_*\,\lambda_{[\xi,\eta]}$.

We say the action is $*$-Hamiltonian if $\lambda_\xi$ can be chosen to make

$$\mathfrak{g}\to C^\infty(M)[\![\nu]\!], \quad \xi\mapsto\lambda_\xi$$

a homomorphism of Lie algebras, where $C^\infty(M)[\![\nu]\!]$ is endowed with the bracket $(1/\nu)[\,,]_*$. Such a homomorphism is called a quantization in Arnal *et al.* (1983) and is called a generalized moment map in Bordemann *et al.* (1998).

When a map $\mu^0:\mathfrak{g}\to C^\infty(M)$ is a generalized moment map, that is,

$$\frac{1}{\nu}\left(\mu^0_\xi*\mu^0_\eta-\mu^0_\eta*\mu^0_\xi\right)=\mu^0_{[\xi,\eta]}$$

the star product is said to be covariant under $\mathfrak{g}$.

When a map $\mu:\mathfrak{g}\to C^\infty(M)[\![\nu]\!]$ is a generalized moment map, so that $D_\xi$ has no terms in $\nu$ of degree $>0$, thus $D_\xi=\xi^*$, this map is called a quantum moment map (Xu 1998). Clearly in that situation, the star product is invariant under the action of $\mathfrak{g}$ on $M$.

Covariant star products have been considered to study representations theory of some classes of Lie groups in terms of star products. In particular, an autonomous star formulation of the theory of representations of nilpotent Lie groups has been given by Arnal and Cortet (1984, 1985).

Consider a differential star product $*$ on a symplectic manifold, admitting an algebra $\mathfrak{g}$ of vector fields on $M$ consisting of derivations of $*$, and assume there is a symplectic connection $\nabla$ which is invariant under $\mathfrak{g}$; then $*$ is equivalent, through an equivariant equivalence ($T$ with $\mathscr{L}_X T=0$), to a Fedosov star product $*_{\nabla,\Omega}$; this yields to a classification of such invariant star products (Bertelson *et al.* 1998).

**Proposition 14** (Kravchenko, Gutt and Rawnsley, Müller-Bahns, Neumaier, and Hamachi). *Consider a Fedosov star product* $*_{\nabla,\Omega}$ *on a symplectic manifold. A vector field X is a derivation of* $*_{\nabla,\Omega}$ *if and only if* $\mathscr{L}_X\omega=0, \mathscr{L}_X\Omega=0$, *and* $\mathscr{L}_X\nabla=0$. *A vector field X is an inner derivation of* $*=*_{\nabla,\Omega}$ *if*

*and only if* $\mathscr{L}_X \nabla = 0$ *and there exists a series of functions* $\lambda_X$ *such that*

$$\mathrm{i}(X)\omega - \mathrm{i}(X)\Omega = \mathrm{d}\lambda_X$$

*In this case* $X(u) = (1/\nu)(\mathrm{ad}_* \lambda_X)(u)$.

On a symplectic manifold $(M, \omega)$, a vector field $X$ is an inner derivation of the natural star product $* = *_{\nabla,\Omega,E}$ if and only if $\mathscr{L}_X \nabla = 0, \mathscr{L}_X E = 0$, and there exists a series of functions $\lambda_X$ such that

$$\mathrm{i}(X)\omega - \mathrm{i}(X)\Omega = \mathrm{d}\lambda_X$$

Then $X = (1/\nu)\mathrm{ad}_* \mu_X$ with $\mu_X = \mathrm{Exp}(E^{-1})\lambda_X$.

Let $G$ be a compact Lie group of symplectomorphisms of $(M, \omega)$ and $\mathfrak{g}$ the corresponding Lie algebra of symplectic vector fields on $M$. Consider a star product $*$ on $M$ which is invariant under $G$. The Lie algebra $\mathfrak{g}$ consists of inner derivations for $*$ if and only if there exists a series of functions $\lambda_X$ and a representative $(1/\nu)(\omega - \Omega)$ of the characteristic class of $*$ such that $\mathrm{i}(X)\omega - \mathrm{i}(X)\Omega = \mathrm{d}\lambda_X$.

Star products which are invariant and covariant are used in the problem of reduction: this is a device in symplectic geometry which allows one to reduce the number of variables. An important issue in quantization is to know if and how quantization commutes with reduction. This problem has been studied by Fedosov for the action of a compact group on the particular star products constructed by him with trivial characteristic class ( $*_{\nabla,0}$ ). Here, one indeed obtains some "quantization commutes with reduction" statements. More generally, Bordemann, Herbig, and Waldmann considered covariant star products. In this case, one can construct a classical and quantum BRST complex whose cohomology describes the algebra of observables for the reduced system. While this is well known classically – at least under some regularity assumptions on the group action – for the quantized situation, the nontrivial question is whether the quantum BRST cohomology is "as large as" the classical one. Clearly, from the physical point of view, this is crucial. It turns out that whereas for strongly invariant star products one indeed obtains a quantization of the reduced phase space, in general the quantum BRST cohomology might be too small. More general situations of reduction have also been discussed by, for example, Bordemann as well as Cattaneo and Felder, when a coisotropic (i.e., first class) constraint manifold is given.

## Convergence of Some Star Products on a Subclass of Functions

Let $(M, P)$ be a Poisson manifold and let $*$ be a differential star product on it with 1 acting as the identity. Observe that if there exists a value $k$ of $\nu$ such that

$$u * v = \sum_{r=0}^{\infty} \nu^r C_r(u, v)$$

converges (for the pointwise convergence of functions), for all $u, v \in C^\infty(M)$, to $F_k(u, v)$ in such a way that $F_k$ is associative, then $F_k(u, v) = uv$. This is easy to see as the order of differentiation in the $C_r$ necessarily is at least $r$ in each argument and thus the Borel lemma immediately gives the result. So assuming "too much" convergence kills all deformations. On the other hand, in any physical situation, one needs some convergence properties to be able to compute the spectrum of quantum observables in terms of a star product (as in Bayen *et al.* 1978).

In the example of Moyal star product on the symplectic vector space $(\mathbb{R}^{2n}, \omega)$, the formal formula

$$(u *_M v)(z) = \exp\left(\frac{\nu}{2} P^{rs} \partial_{x^r} \partial_{y^s}\right)(u(x)v(y))\Big|_{x=y=z}$$

obviously converges when $u$ and $v$ are polynomials. On the other hand, there is an integral formula for Moyal star product given by

$$(u * v)(\xi) = (\pi\hbar)^{-2n} \int u(\xi')v(\xi'') \times \exp\left(\frac{2\mathrm{i}}{\hbar}\Big(\omega(\xi, \xi'') + \omega(\xi'' + \xi') + \omega(\xi', \xi)\Big)\right) \mathrm{d}\xi' \, \mathrm{d}\xi''$$

and this product $*$ gives a structure of associative algebra on the space of rapidly decreasing functions $\mathscr{S}(\mathbb{R}^{2n})$. The formal formula converges (for $\nu = \mathrm{i}\hbar$) in the topology of $\mathscr{S}'$ for $u$ and $v$ with compactly supported Fourier transform.

Some works have been done about convergence of star products.

- The method of quantization of Kähler manifolds due to Berezin as the inverse of taking symbols of operators, to construct on Hermitian symmetric spaces star products which are convergent on a large class of functions on the manifold (Moreno, Cahen Gutt, and Rawnsley, Karabegov, Schlichenmaier).

- The constructions of operator representations of star products (Fedosov, Bordemann, Neumaier, and Waldmann).
- The work of Rieffel and the notion of strict deformation quantization. Examples of strict (Fréchet) quantization have been given by Omori, Maeda, Niyazaki, and Yoshioka, and by Bieliavsky.

### Convergence of Berezin-Type Star Products on Hermitian Symmetric Spaces

The method to construct a star product involves making a correspondence between operators and functions using coherent states, transferring the operator composition to the symbols, introducing a suitable parameter into this Berezin composition of symbols, taking the asymptotic expansion in this parameter on a large algebra of functions, and then showing that the coefficients of this expansion satisfy the cocycle conditions to define a star product on the smooth functions (Cahen *et al.* 1995). The idea of an asymptotic expansion appears in Berezin (1975) and in Moreno and Ortega-Navarro (1983, 1986).

This asymptotic expansion exists for compact $M$, and defines an associative multiplication on formal power series in $k^{-1}$ with coefficients in $C^\infty(M)$ for compact coadjoint orbits. For $M$ a Hermitian symmetric space of compact type and more generally for compact coadjoint orbits (i.e., flag manifolds), this formal power series converges on the space of symbols (Karabegov 1998).

For general Hermitian symmetric spaces of noncompact type, using their realization as bounded domains, one defines an analogous algebra of symbols of polynomial differential operators.

Reshetikhin and Takhtajan have constructed an associative formal star product given by an asymptotic expansion on any Kähler manifold. This they do in two steps, first building an associative product for which 1 is not a unit element, then passing to a star product.

We denote by $(L,\nabla,h)$ a quantization bundle for the Kähler manifold $(M,\omega,J)$ (i.e., a holomorphic line bundle $L$ with connection $\nabla$ admitting an invariant Hermitian structure $h$, such that the curvature is $\operatorname{curv}(\nabla)=-2i\pi\omega$). We denote by $\mathscr{H}$ the Hilbert space of square-integrable holomorphic sections of $L$ which we assume to be nontrivial. The coherent states are vectors $e_q\in\mathscr{H}$ such that

$$s(x)=\langle s,e_q\rangle q,\quad \forall q\in\mathscr{L}_x,\ x\in M,\ s\in\mathscr{H}$$

($\mathscr{L}$ is the complement of the zero section in $L$). The function $\epsilon(x)=|q|^2\|e_q\|^2, q\in\mathscr{L}_x$, is well defined and real analytic.

Let $A:\mathscr{H}\to\mathscr{H}$ be a bounded linear operator and let

$$\widehat{A}(x)=\frac{\langle Ae_q,e_q\rangle}{\langle e_q,e_q\rangle},\quad q\in\mathscr{L}_x,\ x\in M$$

be its symbol. The function $\widehat{A}$ has an analytic continuation to an open neighborhood of the diagonal in $M\times\bar{M}$ given by

$$\widehat{A}(x,y)=\frac{\langle Ae_{q'},e_q\rangle}{\langle e_{q'},e_q\rangle},\quad q\in\mathscr{L}_x,\ q'\in\mathscr{L}_y$$

which is holomorphic in $x$ and antiholomorphic in $y$. We denote by $\hat{E}(L)$ the space of symbols of bounded operators on $\mathscr{H}$. We can extend this definition of symbols to some unbounded operators provided everything is well defined.

The composition of operators on $\mathscr{H}$ gives rise to an associative product $*$ for the corresponding symbols:

$$(\widehat{A}*\widehat{B})(x)=\int_M \widehat{A}(x,y)\widehat{B}(y,x)\psi(x,y)\epsilon(y)\frac{\omega^n(y)}{n!}$$

where

$$\psi(x,y)=\frac{|\langle e_{q'},e_q\rangle|^2}{\|e_{q'}\|^2\|e_q\|^2},\quad q\in\mathscr{L}_x,\ q'\in\mathscr{L}_y$$

is a globally defined real analytic function on $M\times M$ provided $\epsilon$ has no zeros ($\psi(x,y)\le 1$ everywhere, with equality where the lines spanned by $e_q$ and $e_{q'}$ coincide).

Let $k$ be a positive integer. The bundle $(L^k=\otimes^k L,\nabla^k,h^k)$ is a quantization bundle for $(M,k\omega,J)$ and we denote by $\mathscr{H}^k$ the corresponding space of holomorphic sections and by $\hat{E}(L^k)$ the space of symbols of linear operators on $\mathscr{H}^k$. We let $\epsilon^{(k)}$ be the corresponding function. We say that the quantization is regular if $\epsilon^{(k)}$ is a nonzero constant for all non-negative $k$ and if $\psi(x,y)=1$ implies $x=y$. (Remark that if the quantization is homogeneous, all $\epsilon^{(k)}$ are constants.)

**Theorem 15** (Cahen *et al.*). *Let $(M,\omega,J)$ be a Kähler manifold and $(L,\nabla,h)$ be a regular quantization bundle over M. Let $\widehat{A},\widehat{B}$ be in $\mathscr{B}$, where $\mathscr{B}\subset C^\infty(M)$ consists of functions f which have an analytic continuation in $M\times\bar{M}$ so that $f(x,y)\psi(x,y)^l$ is globally defined, smooth and bounded on $K\times M$ and $M\times K$ for each compact subset K of M for some positive power l. Then*

$$(\widehat{A}*_k\widehat{B})(x)=\int_M \widehat{A}(x,y)\widehat{B}(y,x)\psi^k(x,y)\epsilon^{(k)}k^n\frac{\omega^n}{n!}(y)$$

*defined for k sufficiently large, admits an asymptotic expansion in $k^{-1}$ as $k \to \infty$*

$$(\widehat{A} *_k \widehat{B})(x) \sim \sum_{r \geq 0} k^{-r} C_r(\widehat{A}, \widehat{B})(x)$$

*and the cochains $C_r$ are smooth bidifferential operators, invariant under the automorphisms of the quantization and determined by the geometry alone. Furthermore, $C_0(\widehat{A}, \widehat{B}) = \widehat{A}\widehat{B}$ and $C_1(\widehat{A}, \widehat{B}) - C_1(\widehat{B}, \widehat{A}) = (\mathrm{i}/\pi)\{\widehat{A}, \widehat{B}\}$.*

*If M is a flag manifold, this defines a star product on $C^\infty(M)$ and the $*_k$ product of two symbols is convergent (it is a rational function of k without pole at infinity) (cf. Karabegov in that generality).*

*If $\mathscr{D}$ be a bounded symmetric domain and $\mathscr{E}$ the algebra of symbols of polynomial differential operators on a homogeneous holomorphic line bundle L over $\mathscr{D}$ which gives a realization of a holomorphic discrete series representation of $G_0$, then for f and g in $\mathscr{E}$ the Berezin product $f *_k g$ has an asymptotic expansion in powers of $k^{-1}$ which converges to a rational function of k. The coefficients of the asymptotic expansion are bidifferential operators which define an invariant and covariant star product on $C^\infty(\mathscr{D})$.*

## Star Products on Cotangent Bundles

Since from the physical point of view cotangent bundles $\pi : T^*Q \to Q$ over some configuration space $Q$, endowed with their canonical symplectic structure $\omega_0$, are one of the most important phase spaces, any quantization scheme should be tested and exemplified for this class of classical mechanical systems.

We first recall that on $T^*Q$ there is a canonical vector field $\xi$, the Euler or Liouville vector field which is locally given by $\xi = p_k(\partial/\partial p_k)$. Here and in the following, we use local bundle coordinates $(q^k, p_k)$ induced by local coordinates $x^k$ on $Q$. Using $\xi$ we can characterize those functions $f \in C^\infty(T^*Q)$ which are polynomial in the fibers of degree $k$ by $\xi f = kf$. They are denoted by $\mathrm{Pol}^k(T^*Q)$, whereas $\mathrm{Pol}^\bullet(T^*Q)$ denotes the subalgebra of all functions which are polynomial in the fibers. Clearly, most of the physically relevant observables such as the kinetic energy, potentials, and generators of point transformations are in $\mathrm{Pol}^\bullet(T^*Q)$. Moreover, $\mathrm{Pol}^\bullet(T^*Q)$ is a Poisson subalgebra with

$$\left\{\mathrm{Pol}^k(T^*Q), \mathrm{Pol}^\ell(T^*Q)\right\} \subseteq \mathrm{Pol}^{k+\ell-1}(T^*Q) \qquad [5]$$

since $\mathscr{L}_\xi \omega_0 = \omega_0$ is conformally symplectic.

All this suggests that for a quantization of $T^*Q$, the polynomials $\mathrm{Pol}^\bullet(T^*Q)$ should play a crucial role. In deformation quantization this is accomplished by the notion of a homogeneous star product (De Wilde and Lecomte 1983). If the operator

$$\mathsf{H} = \nu \frac{\partial}{\partial \nu} + \mathcal{L}_\xi \qquad [6]$$

is a derivation of a formal star product $\star$, then $\star$ is called homogeneous. It immediately follows that $\mathrm{Pol}(T^*Q)[\nu] \subseteq C^\infty(T^*Q)[[\nu]]$ is a subalgebra over the ring $\mathbb{C}[\nu]$ of polynomials in $\nu$. Hence for homogeneous star products, the question of convergence (in general quite delicate) has a simple answer.

Let us now describe a simple construction of a homogeneous star product (following Bordemann *et al.* (1998)). We choose a torsion-free connection $\nabla$ on $Q$ and consider the operator of the symmetrized covariant derivative, locally given by

$$\mathsf{D} = \mathrm{d}x^k \vee \nabla_{\partial/\partial x^k} : \Gamma^\infty(\mathrm{S}^k T^*Q) \to \Gamma^\infty(\mathrm{S}^{k+1} T^*Q) \qquad [7]$$

Clearly, $\mathsf{D}$ is a global object and a derivation of the symmetric algebra $\bigoplus_{k=0}^\infty \Gamma^\infty(\mathrm{S}^k T^*Q)$. Let now $f \in \mathrm{Pol}^\bullet(T^*Q)$ and $\psi \in C^\infty(Q)$ be given. Then one defines the standard-ordered quantization $\varrho_{\mathrm{Std}}(f)$ of $f$ with respect to $\nabla$ to be the differential operator $\varrho_{\mathrm{Std}}(f) : C^\infty(Q) \to C^\infty(Q)$ locally given by

$$\varrho_{\mathrm{Std}}(f)\psi = \sum_{r=0}^\infty \frac{(-\nu)^r 1}{r!} \left. \frac{\partial^r f}{\partial p_{k_1} \cdots \partial p_{k_r}} \right|_{p=0} \times \mathrm{i_s}\left(\frac{\partial}{\partial x^{k_1}}\right) \cdots \mathrm{i_s}\left(\frac{\partial}{\partial x^{k_r}}\right) \frac{1}{r!} \mathsf{D}^r \psi \qquad [8]$$

where $\mathrm{i_s}$ denotes the symmetric insertation of vector fields in symmetric forms. Again, this is independent of the coordinate system $x^k$. The infinite sum is actually finite as long as $f \in \mathrm{Pol}^\bullet(T^*Q)$ whence we can safely set $\nu = \mathrm{i}\hbar$ in this case. Indeed, [8] is the well-known symbol calculus for differential operators and it establishes a linear bijection

$$\varrho_{\mathrm{Std}} : \mathrm{Pol}^\bullet(T^*Q) \to \mathrm{DiffOp}(C^\infty(Q)) \qquad [9]$$

which generalizes the usual canonical quantization in the flat case of $T^*Q = T^*\mathbb{R}^n = \mathbb{R}^{2n}$. Using this linear bijection, we can define a new product $\star_{\mathrm{Std}}$ for $\mathrm{Pol}^\bullet(T^*Q)$ by

$$f \star_{\mathrm{Std}} g = \varrho_{\mathrm{Std}}^{-1}(\varrho_{\mathrm{Std}}(f)\varrho_{\mathrm{Std}}(g)) = \sum_{r=0}^\infty \nu^r C_r(f, g) \qquad [10]$$

It is now easy to see that $\star_{\mathrm{Std}}$ fulfills all requirements of a homogeneous star product except for the fact that the $C_r(\,\cdot\,,\cdot\,)$ are bidifferential. In this approach

this is far from being obvious as we only worked with functions polynomial in the fibers so far. Nevertheless, it is true whence $\star_{\mathrm{Std}}$ indeed defines a star product for $C^\infty(T^*Q)[[\nu]]$.

In fact, there is a different characterization of $\star_{\mathrm{Std}}$ using a slightly modified Fedosov construction: first one uses $\nabla$ to define a torsion-free symplectic connection on $T^*Q$ by a fairly standard lifting. Moreover, using $\nabla$ one can define a standard-ordered fiberwise product $\circ_{\mathrm{Std}}$ for the formal Weyl algebra bundle over $T^*Q$, being the starting point of the Fedosov construction of star products. With these two ingredients one finally obtains $\star_{\mathrm{Std}}$ from the Fedosov construction with the big advantage that now the order of differentiation in the $C_r$ can easily be determined to be $r$ in each argument, whence $\star_{\mathrm{Std}}$ is even a natural star product. Moreover, $C_r$ differentiates the first argument only in momentum directions which reflects the standard ordering.

Already in the flat situation the standard ordering is not an appropriate quantization scheme from the physical point of view as it maps real-valued functions to differential operators which are not symmetric in general. To pose this question in a geometric framework, we have to specify a positive density $\mu \in \Gamma^\infty(|\Lambda^n|T^*Q)$ on the configuration space $Q$ first, as for functions there is no invariant meaning of integration. Specifying $\mu$ we can consider the pre-Hilbert space $C_0^\infty(Q)$ with inner product

$$\langle \phi, \psi \rangle = \int_Q \bar{\phi}\psi\mu \qquad [11]$$

Now the adjoint with respect to [11] of $\varrho_{\mathrm{Std}}(f)$ can be computed explicitly. We first consider the second-order differential operator

$$\Delta = \frac{\partial^2}{\partial q^k \partial p_k} + p_k \Gamma^k_{\ell m} \frac{\partial^2}{\partial p_\ell \partial p_m} + \Gamma^k_{k\ell} \frac{\partial}{\partial p_\ell} \qquad [12]$$

where $\Gamma^k_{\ell m}$ are the Christoffel symbols of $\nabla$. In fact, $\Delta$ is defined independently of the coordinates and coincides with the Laplacian of the pseudo-Riemannian metric on $T^*Q$ which is obtained from the natural pairing of vertical and horizontal spaces defined by using $\nabla$. Moreover, we need the 1-form $\alpha$ defined by $\nabla_X \mu = \alpha(X)\mu$ and the corresponding vertical vector field $\alpha^{\mathrm{v}} \in \Gamma^\infty(T(T^*Q))$ locally given by $\alpha^{\mathrm{v}} = \alpha_k(\partial/\partial p_k)$. Then

$$\varrho_{\mathrm{Std}}(f)^\dagger = \varrho_{\mathrm{Std}}(N^2\bar{f}), \quad N = \mathrm{e}^{(\nu/2)(\Delta + \alpha^{\mathrm{v}})} \qquad [13]$$

Note that due to the curvature contributions, this statement is a highly nontrivial partial integration compared to the flat case. Note also that for $f \in \mathrm{Pol}(T^*Q)[\nu]$, we have $Nf \in \mathrm{Pol}(T^*Q)[\nu]$ as well, and $N$ commutes with H. As in the flat case this allows one to define a Weyl-ordered quantization by

$$\varrho_{\mathrm{Weyl}}(f) = \varrho_{\mathrm{Std}}(Nf) \qquad [14]$$

together with a so-called Weyl-ordered star product

$$f \star_{\mathrm{Weyl}} g = N^{-1}(Nf \star_{\mathrm{Std}} Ng) \qquad [15]$$

which is now a Hermitian and homogeneous star product such that $\varrho_{\mathrm{Weyl}}$ becomes a $^*$-representation of $\star_{\mathrm{Weyl}}$, that is, we have $\varrho_{\mathrm{Weyl}}(f \star_{\mathrm{Weyl}} g) = \varrho_{\mathrm{Weyl}}(f)\,\varrho_{\mathrm{Weyl}}(g)$ and $\varrho_{\mathrm{Weyl}}(f)^\dagger = \varrho_{\mathrm{Weyl}}(\bar{f})$. Note that in the flat case this is precisely the Moyal star product $*_M$ from [1].

The star products $\star_{\mathrm{Std}}$ and $\star_{\mathrm{Weyl}}$ have been extensively studied by Bordemann, Neumaier, Pflaum, and Waldmann and provide now a well-understood quantization on cotangent bundles. We summarize a few highlights of this theory:

1. In the particular case of a Levi-Civita connection $\nabla$ for some Riemannian metric $g$ and the corresponding volume density $\mu_g$, the 1-form $\alpha$ vanishes. This simplifies the operator $N$ and describes the physically most interesting situation.
2. If the configuration space is a Lie group $G$, then its cotangent bundle $T^*G \cong G \times \mathfrak{g}^*$ is trivial by using, for example, left-invariant 1-forms. In this case the star products $\star_{\mathrm{Weyl}}$ and $\star_{\mathrm{Std}}$ restrict to the CBH star product on $\mathfrak{g}^*$. Moreover, $\star_{\mathrm{Weyl}}$ coincides with the star product found by Gutt (1983) on $T^*G$.
3. Using the operator $N$ one can interpolate between the two different ordering descriptions $\varrho_{\mathrm{Std}}$ and $\varrho_{\mathrm{Weyl}}$ by inserting an additional ordering parameter $\kappa$ in the exponent, that is, $N_\kappa = \exp(\nu\kappa(\Delta + \alpha^{\mathrm{v}}))$. Thus, one obtains $\kappa$-ordered representations $\varrho_\kappa$ together with corresponding $\kappa$-ordered star products $\star_\kappa$, where $\kappa = 0$ corresponds to standard ordering and $\kappa = 1/2$ corresponds to Weyl ordering. For $\kappa = 1$, one obtains antistandard ordering and in general one has the relation $\overline{f \star_\kappa g} = \bar{g} \star_{1-\kappa} \bar{f}$ as well as $\varrho_\kappa(f)^\dagger = \varrho_{1-\kappa}(\bar{f})$.
4. One can describe also the quantization of an electrically charged particle moving in a magnetic background field $B$. This is modeled by a closed 2-form $B \in \Gamma^\infty(\Lambda^2 T^*Q)$ on $Q$. Using local vector potentials $A \in \Gamma^\infty(T^*Q)$ with $B = \mathrm{d}A$ locally, and by minimal coupling, one obtains a star product $\star_B$ which depends only on $B$ and not on the local potentials $A$. It will be equivalent to $\star_{\mathrm{Weyl}}$ if and only if $B$ is exact. In general, its characteristic class is, up to a factor, given by the class $[B]$ of the magnetic field $B$. While the observable

algebra always exists, a Schrödinger-like representation of $\star_B$ only exists if $B$ satisfies the usual integrality condition. In this case, there exists a representation on sections of a line bundle whose first Chern class is given by $[B]$. This manifests Dirac's quantization condition for magnetic charges in deformation quantization. Another equivalent interpretation of this result is obtained by Morita theory: the star products $\star_{\text{Weyl}}$ and $\star_B$ are Morita equivalent if and only if $B$ satisfies Dirac's integrality condition.

5. Analogously, one can determine the unitary equivalence classes of representations for a fixed, exact magnetic field $B$. It turns out that the representations depend on the choice of the global vector potential $A$ and are unitarily equivalent if the difference between the two vector potentials satisfies an integrality condition known from the Aharonov–Bohm effect. This way, the Aharonov–Bohm effect can be formulated within the representation theory of deformation quantization.
6. There are several variations of the representations $\varrho_{\text{Std}}$ and $\varrho_{\text{Weyl}}$. In particular, one can construct a representation on half-forms instead of functions, thereby avoiding the choice of the integration density $\mu$. Moreover, all the Weyl-ordered representations can be understood as GNS representations coming from a particular positive functional, the Schrödinger functional. For $\varrho_{\text{Weyl}}$ this functional is just the integration over the configuration space $Q$.
7. All the (formal) star products and their representations can be understood as coming from formal asymptotic expansions of integral formulas. From this point of view, the formal representations and star products are a particular kind of global symbol calculus.
8. At least for a projectible Lagrangian submanifold $L$ of $T^*Q$, one finds representations of the star product algebras on the functions on $L$. This leads to explicit formulas for the WKB expansion corresponding to this Lagrangian submanifold.
9. The relation between configuration space symmetries, the corresponding phase-space reduction, and the reduced star products has been analyzed extensively by Kowalzig, Neumaier, and Pflaum.

# $\bar{\partial}$-Approach to Integrable Systems

**P G Grinevich**, L D Landau Institute for Theoretical Physics, Moscow, Russia

## Introduction

The $\bar{\partial}$-approach is one of the most generic methods for constructing solutions of completely integrable systems. Taking into account that most soliton systems are represented as compatibility condition for a set of linear differential operators (Lax pairs, zero-curvature representations, L–A–B Manakov triples), it is sufficient to construct these operators. Such compatible families can be defined by presenting their common eigenfunctions. If it is possible to show that some analytic constraints imply that a function is a common eigenfunction of a family of operators, solutions of original nonlinear system are also generated.

The main idea of the $\bar{\partial}$ method is to impose the following analytic constraints: if $\lambda$ denotes the spectral parameter and $\boldsymbol{x}$ the physical variables, then, for arbitrary fixed values $\boldsymbol{x}$, the $\partial_{\bar{\lambda}}$ derivative of the wave function is expressed as a linear combination of the wave functions at other values of $\lambda$ with $\boldsymbol{x}$-independent coefficients. In specific examples, this property is either derived from the

direct spectral transform or imposed *a priori*. Of course, the specific realization of this scheme depends critically on the nonlinear system.

The origin of the $\bar{\partial}$-method came from the following observation. A solution of the one-dimensional inverse-scattering problem (the problem of reconstructing the potential by discrete spectrum and scattering amplitude at positive energies) for the one-dimensional time-independent Schrödinger operator

$$L = -\partial_x^2 + u(x) \qquad [1]$$

was obtained by Gelfand, Levitan, and Marchenko in the 1950s. It essentially used analytic continuation of the wave function from the real momenta to the complex ones. If the potential $u(x)$ decays sufficiently fast as $|x| \to \infty$, then the eigenfunction equation

$$L\psi(k,x) = k^2\psi(k,x) \qquad [2]$$

has two solutions $\psi_+(k,x)$ and $\psi_-(k,x)$ such that

1. $\psi_\pm(k,x) = (1 + o(1))e^{ikx}$ as $x \to \pm\infty$.
2. The functions $\psi_+(k,x), \psi_-(k,x)$ are holomorphic in $k$ in the upper half-plane and the lower half-plane, respectively.

Existence of analytic continuation to complex momenta is typical for one-dimensional systems. But in the multidimensional case the situation is different. For example, wave functions for the mutlidimensional Schrödinger operator constructed by Faddeev are well defined for all complex momenta $\boldsymbol{k}$, but they are nonholomorphic in $\boldsymbol{k}$, and they become holomorphic only after restriction to some special one-dimensional subspaces. The last property was one of the key points in the Faddeev approach.

Beals and Coifman (1981–82) and Ablowitz *et al.* (1983) discovered that departure from holomorphicity for multidimensional wave functions can be interpreted as spectral data. Such spectral transforms proved to be very natural and suit perfectly the purposes of the soliton theory. Some other famous methods, including the Riemann–Hilbert problem, can be interpreted as special reductions of the $\bar{\partial}$ method.

## Nonlocal $\bar{\partial}$-Problem and Local $\bar{\partial}$-Problem

The most generic formulation of the $\bar{\partial}$-method is the nonlocal $\bar{\partial}$-problem. Assume that the following data is given:

1. A rational $n \times n$ matrix-valued normalization function $\eta(\lambda)$.
2. An $n \times n$ matrix-valued function $g(\lambda, \boldsymbol{x})$ (it describes the dynamics) such that
   - $g(\lambda, \boldsymbol{x})$ depends on the spectral parameter $\lambda \in \mathbb{C}$ and "physical" variables $\boldsymbol{x} = (x_1, \ldots, x_N)$; the physical variables $x_k$ are either continuous ($x_k$ belongs to a domain in $\mathbb{R}$ or in $\mathbb{C}$) or discrete ($x_k$ takes integer values);
   - $g(\lambda, \boldsymbol{x})$ is analytic in $\lambda$, defined for all $\lambda \in \mathbb{C}$, except for a finite number of singular points, and is single valued; and
   - $\det g(\lambda, \boldsymbol{x})$ has only finite number of zeros.

   For problems with continuous physical variables the typical form of $g(\lambda, \boldsymbol{x})$ is $g(\lambda, \boldsymbol{x}) = \exp(\sum_i x_j K_j(\lambda))$, where $K_j(\lambda)$ are meromorphic matrices, mutually commuting for all $\lambda$. The discrete variables are usually encoded in orders of poles and zeros.
3. An $n \times n$ matrix-valued function $R(\lambda, \mu)$ – the "generalized spectral data." Usually, it is a regular function of four real variables $\Re\lambda, \Im\lambda, \Re\mu, \Im\mu$. (We write this as a function of two complex variables, but we do not assume it to be holomorphic. It would be more precise to write it as $R(\lambda, \bar{\lambda}, \mu, \bar{\mu})$, but to avoid long notations we omit the $\bar{\lambda}$, $\bar{\mu}$ dependence.) To avoid analytical complications, the function $R(\lambda, \mu)$ is usually assumed to vanish as $\lambda$ or $\mu$ tend to singular points of $\eta(\lambda)$, $g(\lambda, \boldsymbol{x})$.

Then the wave function $\Psi$ is defined by the data using the following properties:

1. $\Psi = \Psi(\lambda, \boldsymbol{x})$ takes values in complex $n \times n$ matrices:

$$\Psi(\lambda, \boldsymbol{x}) = \begin{bmatrix} \psi_{11}(\lambda, \boldsymbol{x}) & \ldots & \psi_{1n}(\lambda, \boldsymbol{x}) \\ \vdots & \cdots & \vdots \\ \psi_{n1}(\lambda, \boldsymbol{x}) & \ldots & \psi_{nn}(\lambda, \boldsymbol{x}) \end{bmatrix} \qquad [3]$$

2. For all $\lambda \in \mathbb{C}$ outside the singular points, the $\eta(\lambda)$, $g(\lambda, \boldsymbol{x})$ wave function $\Psi$ satisfies the $\bar{\partial}$-equation of inverse-spectral problem,

$$\frac{\partial\Psi(\lambda, \boldsymbol{x})}{\partial\bar{\lambda}} = \iint_{\mu\in\mathbb{C}} d\mu \wedge d\bar{\mu}\, \Psi(\mu, \boldsymbol{x}) R(\lambda, \mu) \qquad [4]$$

   It is important that condition [4] is $\boldsymbol{x}$-independent.
3. The function $\chi(\lambda, \boldsymbol{x}) - \eta(\lambda)$, where $\chi(\lambda, \boldsymbol{x}) = \Psi(\lambda, \boldsymbol{x}) g^{-1}(\lambda, \boldsymbol{x})$, is regular for all $\lambda \in \mathbb{C}$ and

$$\chi(\lambda, \boldsymbol{x}) - \eta(\lambda) \to 0 \quad \text{as } |\lambda| \to \infty \qquad [5]$$

The wave function $\Psi(\lambda, \boldsymbol{x})$ is calculated by employing the data $\eta(\lambda), g(\lambda, \boldsymbol{x}), R(\lambda, \mu)$ using the following procedure. Taking into account that the

functions $\eta(\lambda)$, $g(\lambda, \boldsymbol{x})$ are holomorphic in $\lambda$, eqn [4] can be rewritten in terms of $\chi(\lambda, \boldsymbol{x})$:

$$\frac{\partial[\chi(\lambda, \boldsymbol{x}) - \eta(\lambda)]}{\partial \bar{\lambda}} = \iint_{\mu \in \mathbb{C}} \mathrm{d}\mu \wedge \mathrm{d}\bar{\mu}\, \chi(\mu, \boldsymbol{x}) g(\lambda, \boldsymbol{x}) \times R(\lambda, \mu) g^{-1}(\mu, \boldsymbol{x}) \qquad [6]$$

The right-hand side of [6] is regular; therefore, this relation is valid for all complex $\lambda$ values.

Equation [6] with the boundary condition [5] is equivalent to the following integral equation:

$$\chi(\lambda, \boldsymbol{x}) = \eta(\lambda) + \frac{1}{2\pi \mathrm{i}} \iint_{\nu \in \mathbb{C}} \frac{\mathrm{d}\nu \wedge \mathrm{d}\bar{\nu}}{\nu - \lambda} \times \iint_{\mu \in \mathbb{C}} \mathrm{d}\mu \wedge \mathrm{d}\bar{\mu}\, \chi(\mu, \boldsymbol{x}) g(\nu, \boldsymbol{x}) \times R(\nu, \mu) g^{-1}(\mu, \boldsymbol{x}) \qquad [7]$$

This equation can be derived using the generalized Cauchy formula. Let $f(z)$ be a smooth (not necessarily holomorphic) function in a bounded domain $D$ in the complex plane. Then

$$f(z) = \frac{1}{2\pi \mathrm{i}} \oint_{\partial D} \frac{\mathrm{d}\chi}{\chi - z} f(\chi) + \frac{1}{2\pi \mathrm{i}} \iint_{D} \frac{\mathrm{d}\chi \wedge \mathrm{d}\bar{\chi}}{\chi - z} \frac{\partial f(\chi)}{\partial \bar{\chi}} \qquad [8]$$

If the kernel $g(\lambda, \boldsymbol{x}) R(\lambda, \mu) g^{-1}(\mu, \boldsymbol{x})$ is sufficiently good (e.g., it is sufficient to assume, that $(1 + |\lambda|)^{1+\epsilon} g(\lambda, \boldsymbol{x}) R(\lambda, \mu) g^{-1}(\mu, \boldsymbol{x})(1 + \mu\bar{\mu})^2$, $\epsilon > 0$, is a continuous function at both finite and infinite points), then we have a Fredholm equation (the operator on the right-hand side of [7] is compact). If it has no unit eigenvalues, eqn [7] is uniquely solvable. But, for some values of $\boldsymbol{x}$, one of the eigenvalues may become equal to 1, and it results in singularities of solutions.

If the norm of the integral operator is smaller than 1, eqn [7] is uniquely solvable. To generate solutions that are regular for all values of physical variables, it is natural to restrict the class of admissible spectral data by assuming the kernel $g(\lambda, \boldsymbol{x}) R(\lambda, \mu) g^{-1}(\mu, \boldsymbol{x})$ to be bounded in $\boldsymbol{x}$ for all $\lambda, \mu$. In the scalar case $n = 1$, this restriction implies:

$$R(\lambda, \mu) = 0 \quad \text{for all } \lambda, \mu \text{ such that } g(\lambda, \boldsymbol{x}) g^{-1}(\mu, \boldsymbol{x}) \text{ is unbounded in } \boldsymbol{x} \qquad [9]$$

For specific examples like the Kadomtsev–Petviashvili-II (KP-II), direct scattering transform automatically generates spectral data satisfying [9]. In KP-II, [9] implies

$$R(\lambda, \mu) = A(\lambda)\delta(\lambda - \mu) + T(\lambda)\delta(\lambda - \bar{\mu}) \qquad [10]$$

The coefficient $A(\lambda)$ can be eliminated by multiplying the wave function to an appropriate function of $\lambda$; therefore, in standard texts, $A(\lambda) \equiv 0$.

If for every $\lambda$ the kernel $R(\lambda, \mu)$ is equal to 0 everywhere except at finite number of points $\mu_1(\lambda), \ldots, \mu_k(\lambda)$, one has the so-called local $\bar{\partial}$-problem. Such kernels are rather typical.

## Examples of Soliton Systems Integrable by the $\bar{\partial}$-Problem Method

Let us discuss some important examples.

### The KP-II Hierarchy

The first nontrivial equation from the KP hierarchy has the following form:

$$(u_t + 6uu_x - u_{xxx})_x = 3\alpha^2 u_{yy} \qquad [11]$$

From a physical point of view, the case of real $\alpha^2$ is the most interesting one. Equation [11] is called KP-I if $\alpha^2 = -1$ and KP-II if $\alpha^2 = +1$. The Lax pair for KP-II reads:

$$[L, A] = 0$$

where

$$\begin{aligned} L &= \partial_y - \partial_x^2 + u(x, y, t) \\ A &= \partial_t - 4\partial_x^3 + 6u(x, y, t)\partial_x + 3u_x(x, y, t) + 3w(x, y, t) \end{aligned} \qquad [12]$$

The Cauchy problem for initial data $u(x, y, 0)$ decaying at infinity is solved by using the nonlocal Riemann problem for KP-I and local $\bar{\partial}$-problem for KP-II. The wave function is assumed to be scalar valued ($n = 1$), and $\bar{\partial}$-equation [4] takes the following form:

$$\frac{\partial \Psi(\lambda, x, y, t)}{\partial \bar{\lambda}} = T(\lambda) \Psi(\bar{\lambda}, x, y, t) \qquad [13]$$

The wave function $\Psi(\lambda, x, y, t)$ is assumed to be regular for finite $\lambda$'s and to have the following essential singularity as $\lambda = \infty$:

$$\Psi(\lambda, x, y, t) = \exp(\lambda x + \lambda^2 y + 4\lambda^3 t)(1 + o(1)) \qquad [14]$$

Equivalently, $\eta(\lambda) \equiv 1$ and the function $g(\lambda, x, t)$ has one essential singularity at $\lambda = \infty$,

$$g(\lambda, x, t) = \exp(\lambda x + \lambda^2 y + 4\lambda^3 t) \qquad [15]$$

Higher times $t_k$ from the KP hierarchy are incorporated into this scheme by assuming that

$$g(\lambda, \boldsymbol{t}) = \exp\left(\sum_{k=1}^{\infty} \lambda^k t_k\right) \qquad [16]$$

Here $x = t_1$, $y = t_2$, $t = 4t_3$.

Equation [13] was originally derived (Ablowitz *et al.* 1983) from the direct spectral transform. If the potential $u(x, y)$ is sufficiently small and $u(x, y) = O(1/(x^2 + y^2)^{1+\epsilon})$ for $x^2 + y^2 \to \infty$, then the wave function $\Psi(\lambda, x, y)$ for the $L$-operator [12]

$$\begin{aligned} &L\Psi(\lambda, x, y) = 0 \\ &\quad \Psi(\lambda, x, y) = \exp(\lambda x + \lambda^2 y)[1 + o(1)] \\ &\quad \text{for } x^2 + y^2 \to \infty \end{aligned} \qquad [17]$$

can be constructed by solving the following integral equation for the pre-exponent $\chi(\lambda, x, y) = \Psi(\lambda, x, y) \exp(-\lambda x - \lambda^2 y)$:

$$\begin{aligned} \chi(\lambda, x, y) = 1 - \iint G(\lambda, x - x', y - y') u(x, y) \\ \times \chi(\lambda, x, y)\, \mathrm{d}x'\, \mathrm{d}y' \end{aligned} \qquad [18]$$

where the Green function $G(\lambda, x, y)$ is given by

$$G(\lambda, x, y) = \frac{1}{4\pi^2} \iint \frac{\mathrm{e}^{\mathrm{i}(p_x x + p_y y)}}{p_x^2 + \mathrm{i}p_y - 2\mathrm{i}\lambda p_x} \mathrm{d}p_x\, \mathrm{d}p_y \qquad [19]$$

It is not holomorphic in $\lambda$, but

$$\frac{\partial G(\lambda, x, y)}{\partial \bar{\lambda}} = -\frac{\mathrm{i}}{2\pi} \mathrm{sgn}(\Re\lambda)\, \mathrm{e}^{-2\mathrm{i}\Re\lambda x - 4\mathrm{i}\Re\lambda\Im\lambda y} \qquad [20]$$

The nonholomorphicity of $G(\lambda, x, y)$ results in the special nonholomorphicity of $\Psi(\lambda, x, y)$ of the form [13].

**Remark** We see that one function of two real variables $T(\lambda)$ is sufficient to solve the Cauchy problem in the plane. But it is also possible to construct solutions of KP-II starting from generic nonlocal kernels $R(\lambda, \mu)$ (to guarantee at least local existence of solutions, it is enough to assume that $R(\lambda, \mu)$ is small and has finite support). It looks like a paradox, but the situation is exactly the same in the linear case. In the standard Fourier method, only exponents with real momenta are used, but local solutions can be constructed as combinations of exponents with arbitrary complex momenta.

#### Novikov–Veselov Hierarchy and Two-Dimensional Schrödinger Operator

Equations from this hierarchy admit representation in terms of Manakov L–A–B triples,

$$\frac{\partial L}{\partial t_n} = [A_n, L] + B_n L \qquad [21]$$

where

$$\begin{aligned} L &= -4\partial_z \partial_{\bar{z}} + u(z, t) \\ A_n &= 2^{2n+1}\left(\partial_z^{2n+1} + \partial_{\bar{z}}^{2n+1}\right) + \cdots \end{aligned} \qquad [22]$$

The order of $B_n$ is smaller than $2n + 1$. In particular, for $n = 1$,

$$\begin{aligned} A_1 &= 8\left(\partial_z^3 + \partial_{\bar{z}}^3\right) + 2(w\partial_z + \bar{w}\partial_{\bar{z}}) \\ B_1 &= w_z + \bar{w}_{\bar{z}} \end{aligned} \qquad [23]$$

$$u_t = 8\partial_z^3 u + 8\partial_{\bar{z}}^3 u + 2\partial_{\bar{z}}(uw) + 2\partial_z(u\bar{w}) \qquad [24]$$

where

$$u(z, t) = \bar{u}(z, t), \qquad \partial_{\bar{z}} w(z, t) = -3\partial_{\bar{z}} u(z, t) \qquad [25]$$

This hierarchy is integrated using the scattering transform at zero energy for the two-dimensional Schrödinger operator $L$. If Cauchy data with asymptotic

$$u(z) \to -E_0, \quad w(z) \to 0, \qquad \text{for } |z| \to \infty \qquad [26]$$

is considered, the scattering transform for the operator $\tilde{L} = L + E_0$ with the potential $\tilde{u}(z) = u(z) + E_0$ at fixed energy $E_0$ and decaying at infinity is used. In fact, the fixed-energy scattering problem is one of the basic problems of mathematical physics, and the Novikov–Veselov hierarchy can be treated as an infinite-dimensional Abel symmetry algebra for this problem. The scattering transform essentially depends on the sign of $E_0$. The case $E_0 = 0$, studied by Boiti, Leon, Manna, and Pempinelli is the most complicated from the analytic point of view, and we do not discuss it now.

If $E_0 < 0$, the wave function satisfies a pure local $\bar{\partial}$-relation:

$$\frac{\partial \Psi(\lambda, z)}{\partial \bar{\lambda}} = T(\lambda)\Psi\left(\frac{1}{\bar{\lambda}}, z\right) \qquad [27]$$

with $\eta(\lambda) \equiv 1$, and

$$g(\lambda, z) = \mathrm{e}^{(\kappa/2)(\lambda\bar{z} + z/\lambda)}, \quad \kappa^2 = -E_0 \qquad [28]$$

Starting from generic spectral data $T(\lambda)$, one obtains a fixed-energy eigenfunction for a second-order operator,

$$\begin{aligned} \tilde{L}\Psi(\lambda, z) &= E_0 \Psi(\lambda, z) \\ L &= -4\partial_z \partial_{\bar{z}} + V(z)\partial_z + \tilde{u}(z) \end{aligned} \qquad [29]$$

To generate pure potential operators ($V(z) \equiv 0$), it is necessary to impose additional symmetry constraints of the spectral data (see the section "Reductions on the $\bar{\partial}$ data").

If $E_0 > 0$, there are two types of generalized spectral data – $\bar{\partial}$-data and nonlocal Riemann problem data. The wave function satisfies the $\bar{\partial}$-relation:

$$\frac{\partial \Psi(\lambda, z)}{\partial \bar{\lambda}} = T(\lambda)\Psi\left(-\frac{1}{\bar{\lambda}}, z\right), \quad |\lambda| \neq 1 \qquad [30]$$

and has a jump at the unit circle $|\lambda| = 1$. The boundary values $\Psi_{\pm}(\lambda, z) = \Psi(\lambda(1 \pm 0), z)$ are connected by the following relation:

$$\Psi_{+}(\lambda, z) = \Psi_{-}(\lambda, z) + \oint_{|\mu|=1} R(\lambda, \mu)\Psi_{-}(\mu, z)|d\mu| \qquad [31]$$

$$g(\lambda, z) = e^{i(\kappa/2)(\lambda\bar{z} + z/\lambda)}, \quad \kappa^2 = E_0 \qquad [32]$$

Constraints on the spectral data associated with pure potential operators were found by Novikov and Grinevich for $R(\lambda, \mu)$, and by Manakov and Grinevich for $T(\lambda)$. Existence of two different types of generalized scattering data has a very transparent physical meaning: there is a one-to-one correspondence between the classical scattering amplitude at energy $E_0$ and the nonlocal Riemann problem data $R(\lambda, \mu)$. The $\bar{\partial}$-data $T(\lambda)$ can be treated as a complete set of additional parameters enumerating all potentials with a given scattering amplitude at one energy.

### Davey–Stewartson-II and Ishimori-I Equations

The Davey–Stewartson-II (DS-II) equation

$$i\partial_t q + 2\left(\partial_z^2 + \partial_{\bar{z}}^2\right)q + (g + \bar{g})q = 0 \qquad [33]$$

$$\partial_{\bar{z}} g = -\kappa \partial_z |q|^2 \qquad [34]$$

$$q = q(z, t), \qquad g = g(z, t), \qquad z = x + iy \qquad [35]$$

can be treated as an integrable $(2 + 1)$-dimensional extension of nonlinear Schrödinger equation. The Ishimori-I equation

$$\partial_t S + S \times \left(\partial_x^2 S + \partial_y^2 S\right) + \partial_x w \partial_y S + \partial_y w \partial_x S = 0 \qquad [36]$$

$$\partial_x^2 w - \partial_y^2 w + 2S(\partial_x S \times \partial_y S) = 0 \qquad [37]$$

$$S = S(x, y, t), \quad S = (S_1, S_2, S_3), \quad S^2 = 1 \qquad [38]$$

is an integrable $(2 + 1)$-dimensional extension of the Heisenberg magnetic equation. Both systems are integrated by using the following zero-curvature representation:

$$\begin{pmatrix} \partial_{\bar{z}} & 0 \\ 0 & \partial_z \end{pmatrix}\Psi = \frac{1}{2}\begin{pmatrix} 0 & q(z,t) \\ \kappa\overline{q(z,t)} & 0 \end{pmatrix}\Psi \qquad [39]$$

$$\partial_t \Psi = \begin{pmatrix} 2i\partial_z^2 + ig & iq_{\bar{z}} - iq\partial_{\bar{z}} \\ -i\kappa\bar{q}_z + i\kappa q\partial_z & -2i\partial_{\bar{z}}^2 - ig \end{pmatrix}\Psi \qquad [40]$$

The wave function satisfies the following "scattering" equation:

$$\begin{pmatrix} \partial_{\bar{k}} & 0 \\ 0 & \partial_k \end{pmatrix}\Psi^{T} = \begin{pmatrix} 0 & \kappa\bar{b}(k) \\ b(k) & 0 \end{pmatrix}\Psi^{T} \qquad [41]$$

Here $\Psi^{T}$ denotes the transposed matrix. Let us point out the amazing symmetry between the direct and inverse transforms.

### Discrete Systems

In the examples discussed above, continuous variables are "encoded" in essential singularities of $g(\lambda, \boldsymbol{x})$. Discrete variables correspond to orders of zeros and poles. For example, assuming that the function $g(\lambda, \boldsymbol{t})$ in the KP integration scheme depends on extra continuous variables $t_{-1}, t_{-2}, \ldots, t_{-n}, \ldots$ and discrete variable $t_0 = n$,

$$g(\lambda, \boldsymbol{t}) = \lambda^{t_0} \exp\left(\sum_{k \neq 0}^{\infty} \lambda^k t_k\right) \qquad [42]$$

one obtains solutions of the so-called two-dimensional Toda–KP hierarchy.

Assume that we have a nonlocal $\bar{\partial}$-problem for a scalar function with $\eta \equiv 1$ and

$$g(\lambda, n_1, \ldots, n_k) = \prod_{j=1}^{k}\left(\frac{\lambda - P_k}{\lambda - Q_k}\right)^{n_k} \qquad [43]$$

The wave function defines a map $\mathbb{Z}^k \to \mathbb{C}^N$,

$$(n_1, \ldots, n_k) \to (\Psi(\lambda_1, n_1, \ldots, n_k), \ldots, \Psi(\lambda_N, n_1, \ldots, n_k)) \qquad [44]$$

where $\lambda_1, \ldots, \lambda_N$ are some points in $\mathbb{C}$. This construction generates the so-called quadrilateral lattices (each two-dimensional face is planar).

### Multidimensional Problems

The $\bar{\partial}$-approach can also be applied to multidimensional inverse-scattering problems, but typically the scattering data are overdetermined and satisfy additional nonlinear compatibility conditions. For

example, the Faddeev wave functions for the $n$-dimensional stationary Schr̈odinger operator

$$\left(-\partial_{x_1}^2 - \cdots - \partial_{x_n}^2 + u(\boldsymbol{x})\right)\Psi(\boldsymbol{k},\boldsymbol{x}) = (\boldsymbol{k}\cdot\boldsymbol{k})\Psi(\boldsymbol{k},\boldsymbol{x}) \quad [45]$$

$$\Psi(\boldsymbol{k},\boldsymbol{x}) = e^{i\boldsymbol{k}\cdot\boldsymbol{x}}(1+o(1)) \quad [46]$$

in the nonphysical domain $\boldsymbol{k}_I \neq 0$ ($\boldsymbol{k}_R$ and $\boldsymbol{k}_I$ denote the real and imaginary parts of $\boldsymbol{k}$, respectively) satisfy the following $\bar{\partial}$-equation:

$$\frac{\partial\Psi(\boldsymbol{k},\boldsymbol{x})}{\partial\bar{k}_j} = -2\pi\int_{\boldsymbol{\xi}\in\mathbb{R}^n}\xi_j h(\boldsymbol{k},\boldsymbol{k}_R+\boldsymbol{\xi})\Psi(\boldsymbol{k}+\boldsymbol{\xi},\boldsymbol{x}) \times\delta(\boldsymbol{\xi}\cdot\boldsymbol{\xi}+2\boldsymbol{k}\cdot\boldsymbol{\xi})\mathrm{d}\xi_1\cdots\mathrm{d}\xi_n \quad [47]$$

The characterization of admissible spectral data $h(\boldsymbol{k},\boldsymbol{l}), \boldsymbol{k}\in\mathbb{C}^n, \boldsymbol{l}\in\mathbb{R}^n$ is based on the following compatibility equation:

$$\frac{\partial h(\boldsymbol{k},\boldsymbol{l})}{\partial\bar{k}_j} + \frac{1}{2}\frac{\partial h(\boldsymbol{k},\boldsymbol{l})}{\partial l_j} = -2\pi\int_{\boldsymbol{\xi}\in\mathbb{R}^n}\xi_j h(\boldsymbol{k},\boldsymbol{k}_R+\boldsymbol{\xi})h(\boldsymbol{k}+\boldsymbol{\xi},\boldsymbol{l}) \times\delta(\boldsymbol{\xi}\cdot\boldsymbol{\xi}+2\boldsymbol{k}\cdot\boldsymbol{\xi})\mathrm{d}\xi_1\cdots\mathrm{d}\xi_n \quad [48]$$

More details can be found in Novikov and Henkin (1987).

## Reductions on the $\bar{\partial}$-Data

The most generic $\bar{\partial}$-data usually result in solutions from wrong functional class (they may, e.g., be complex or singular), or extra constraints on the auxiliary linear operators are necessary to obtain solutions of the zero-curvature representation. For example, to obtain real KP-II solutions using the local $\bar{\partial}$-problem [13], the following reduction on the $\bar{\partial}$-data should be implied:

$$T(\bar{\lambda}) = -\bar{T}(\lambda) \quad [49]$$

It can be easily derived from the direct transform. But it is not always the case. For example, the selection of pure potential two-dimensional Schrödinger operators originally was not so evident. To formulate the answer, it is convenient to introduce a new function $b(\lambda), T(\lambda) = b(\lambda)\pi\,\mathrm{sgn}(\lambda\bar{\lambda}-1)/\bar{\lambda}$.

For $E_0 < 0$, the following constraints select real potential operators:

$$b\left(-\frac{1}{\bar{\lambda}}\right) = b(\lambda), \qquad b\left(\frac{1}{\bar{\lambda}}\right) = \bar{b}(\lambda) \quad [50]$$

In some situations, the problem of finding appropriate reductions is the most difficult part of the integration procedure. It is true not only for the $\bar{\partial}$-approach, but also for other techniques including the finite-gap method. For example, the inverse-spectral transform for the two-dimensional Schrödinger operator was first developed for finite-gap (quasiperiodic) potentials and only later for the decaying ones. For operators with finite gap at one energy the first-order terms were constructed by Dubrovin, Krichever, and Novikov in 1976, but only in 1984 the potentiality reduction was found by Novikov and Veselov.

## Nonsingular Solutions

As mentioned above, one can construct regular solutions by choosing sufficiently small (in an appropriate norm) scattering data. But for some special systems the regularity follows automatically from reality reductions. For example, for arbitrary large $\bar{\partial}$-data, real KP-II solutions constructed by the local $\bar{\partial}$-problem [13] with reduction [49] are regular. The proof is based on the theory of generalized analytic functions (in the Vekua sense). Another example is the two-dimensional Schr̈odinger operator at a fixed negative energy $E_0 < 0$. The potentiality and reality constraints imply that the potential is nonsingular for arbitrary large $T(\lambda)$. But, unfortunately, the $\bar{\partial}$-problem with regular data covers only a part of the space of potentials. In fact, each such operator possesses a strictly positive real eigenfunction at the level $E_0$, exponentially growing in all directions (it also follows from the generalized analytic functions theory). Existence of such function implies that the whole discrete spectrum is located above the energy $E_0$, and it gives a restriction on the potential. (For more details, see the review by Grinevich (2000).)

## Some Explicit Solutions

The generic $\bar{\partial}$-problem results in potentials that could not be expressed in terms of elementary or standard special functions. But for degenerate kernels, a solution of the inverse-spectral problem can be written explicitly. For example, if

$$R(\lambda,\mu) = \sum_{k=1}^{n} r_k(\lambda)s_k(\mu) \quad [51]$$

the wave function and solutions can be expressed in quadratures.

In particular, if all $r_k(\lambda)$ and $s_k(\mu)$ are $\delta$-functions, $r_k(\lambda) = R_k\delta(\lambda-\lambda_k)$ and $s_k(\mu) = S_k\delta(\mu-\mu_k)$, the wave function is rational in $\lambda$ and can be expressed as a rational combination of exponents of $x_k$. If for some $k$ and $l$, $\lambda_k = \mu_l$, this procedure needs some

regularization. For example, it is possible to assume, that $\delta(\lambda-\lambda_0)/(\lambda-\lambda_0)=0$.

If for all $k$, $\lambda_k=\mu_k$, the $\bar{\partial}$-problem generates rational in $\boldsymbol{x}$ solutions (lumps). It is possible to show that, the Novikov–Veselov real rational solitons for $E_0>0$ are always nonsingular, decay at $\infty$ as $1/(x^2+y^2)$, and the potential $u(z)$ has zero scattering in all directions for the waves with energy $E_0$.

## The $\bar{\partial}$-Problem on Riemann Surfaces

In all examples discussed above, the spectral variable is defined in a Riemann sphere. It is natural to generalize it by considering wave functions depending on a spectral parameter defined on a Riemann surface of higher genus. Spectral transforms of such type arise in the theory of localized perturbation of periodic solutions. Assume that the KP-II potential $u(x,y)$ has the form

$$u(x,y)=u_0(x,y)+u_1(x,y) \qquad [52]$$

where $u_0(x,y)$ is a real nonsingular finite-gap potential and $u_1(x,y)$ decays sufficiently fast at infinity. Denote by $\Psi_0(\gamma,x,y)$ the wave function of the operator $L_0=\partial_y-\partial_x^2+u_0(x,y)$, where $\gamma\in\Gamma$, the spectral curve $\Gamma$ is a compact Riemann surface of genus $g$ with a distinguished point $\infty$. In addition to essential singularity at the point $\infty$, the wave function $\Psi_0(\gamma,x,y)$ has $g$ simple poles at points $\gamma_1,\ldots,\gamma_g$ and is holomorphic in $\gamma$ outside these singular points. For a real nonsingular potential, $\Gamma$ is an $M$-curve, that is, there exists an antiholomorphic involution $\tau:\Gamma\to\Gamma, \tau\infty=\infty$, the set of fixed points form $g+1$ ovals $a_0,\ldots,a_g,\infty\in a_0,\gamma_k\in a_k$. The wave function $\Psi(\gamma,x,y)$ of the perturbed operator $L=\partial_y-\partial_x^2+u(x,y)$ is defined at the same spectral curve $\Gamma$, but it is not holomorphic any more. It has the following properties:

1. At the point $\infty$, the wave function $\Psi(\gamma,x,y)$ has an essential singularity: $\Psi(\gamma,x,y)=\Psi_0(\gamma,x,y)(1+o(1))$.
2. In the neighborhoods of the points $\gamma_k,\Psi(\gamma,x,y)$ can be written as a product of a continuous function by a simple pole at $\gamma_k$.
3. The wave function $\Psi(\gamma,x,y)$ satisfies the $\bar{\partial}$ equation

$$\frac{\partial\Psi(\gamma,x,y,t)}{\partial\bar{\gamma}}\mathrm{d}\bar{\gamma}=T(\gamma)\Psi(\tau\gamma,x,y,t) \qquad [53]$$

where the (0, 1)-form $T(\gamma)=t(\gamma)\mathrm{d}\bar{\gamma}$ is regular outside the divisor points $\gamma_k$ and in the neighborhood of $\gamma_k$ it possible to define local coordinate such that $t(\gamma)=\mathrm{sgn}(\Im\gamma)t_1(\gamma)\overline{(\gamma-\gamma_k)}/(\gamma-\gamma_k), t_1(\gamma)$ is regular.

A solution of the inverse problem can be obtained by using appropriate analogs of Cauchy kernels on Riemann surfaces.

## Quasiclassical Limit

The systems integrable by the $\bar{\partial}$-method usually describe integrable systems with high-order derivatives. It is well known that by applying some limiting procedures to integrable systems one can construct new completely integrable equations, but integration methods for these equations are based on completely different analytic tools. One of most important examples is the theory of dispersionless hierarchies. The limiting procedure for the $\bar{\partial}$-problem (quasiclassical $\partial$-problem) was developed by Konopelchenko and collaborators. In the KP case, the quasiclassical limit of the wave function $\Psi(\lambda,\boldsymbol{t})$ is assumed to have the following form:

$$\Psi\left(\lambda,\frac{\boldsymbol{t}}{\epsilon}\right)=\hat{\chi}(\lambda,\boldsymbol{t},\epsilon)\exp\left(\frac{S(\lambda,\boldsymbol{t})}{\epsilon}\right) \qquad [54]$$

It is possible to show that the function $S(\lambda,\boldsymbol{t})$ satisfies a Beltrami-type equation:

$$\frac{S(\lambda,\boldsymbol{t})}{\partial\bar{\lambda}}=W\left(\lambda,\frac{S(\lambda,\boldsymbol{t})}{\partial\lambda}\right) \qquad [55]$$

which is treated as a dispersionless limit of [13]. Higher-order corrections were also discussed in the literature (see Konopelchenko and Moro (2003)).

# Derived Categories

**E R Sharpe**, University of Utah, Salt Lake City, UT, USA

## Introduction

In this article we shall briefly outline derived categories and their relevance for physics. Derived categories (and their enhancements) classify off-shell states in a two-dimensional topological field theory on Riemann surfaces with boundary known as the open-string B model. We briefly review pertinent aspects of that topological field theory and its relation to derived categories, the Bondal–Kapranov enhancement and its relation to the open-string B model, as well as B model twists of two-dimensional theories known as Landau–Ginzburg models, and how information concerning stability of D-branes is encoded in this language. We concentrate on more physical aspects of derived categories; for a very readable short review concentrating on the mathematics, see, for example, Thomas (2000).

## Sheaves and Derived Categories in the Open-String B Model

Derived categories are mathematical constructions which are believed to be related to D-branes in the open-string B model. We shall begin by briefly reviewing the B model, as well as D-branes.

The A and B models are two-dimensional topological field theories, closely related to nonlinear sigma models, which are supersymmetrizations of theories summing over maps from a Riemann surface (the world sheet of the string) into some "target space" $X$. In both the A and B models, one considers only certain special correlation functions, involving correlators closed under the action of a nilpotent scalar operator known as the "BRST operator," $Q$, which is part of the original supersymmetry transformations. In considering the pertinent correlation functions, only certain types of maps contribute. The A model has the properties of being invariant under complex structure deformations of the target space $X$, and its pertinent correlation functions are computed by summing over holomorphic maps into the target $X$. The A model will not be relevant for us here. The B model has the properties of being invariant under Kähler moduli of the target $X$, and its pertinent correlation functions are computed by summing over constant maps into the target $X$. In the closed-string B model, the states of the theory are counted by the cohomology groups $H^*(X, \Lambda^* TX)$, where $X$ is constrained to be Calabi–Yau. The BRST operator in the B model $Q$ can be identified with $\overline{\partial}$ for many purposes. The open-string B model is the same topological field theory, but now defined on a Riemann surface with boundaries. As with all open-string theories, we specify boundary conditions on the fields, which force the ends of the string to live on some submanifold of the target, and we associate to the boundaries degrees of freedom (known as the Chan–Paton factors) which describe a (possibly twisted) vector bundle over the submanifold. In the case of the B model, the submanifold is a complex submanifold, and the vector bundle is forced to be a holomorphic vector bundle over that submanifold.

To lowest order, that combination of a submanifold $S$ of $X$ together with a (possibly twisted) holomorphic vector submanifold, is a "D-brane" in the open-string B model. We shall denote the twisted bundle by $\mathcal{E} \otimes \sqrt{K_S}$, where $K_S$ is the canonical bundle of $S$, and the $\sqrt{K_S}$ factor is an explicit incorporation of something known as the Freed–Witten anomaly. Now, if $i: S \hookrightarrow X$ is the inclusion map, then to this D-brane we can associate a sheaf $i_* \mathcal{E}$.

Technically, a sheaf is defined by associating sets, or modules, or rings, to each open set on the underlying space, together with restriction maps saying how data associated to larger open sets restricts to smaller open sets, obeying the obvious consistency conditions, together with some gluing conditions that say how local sections can be patched back together. A vector bundle defines a

sheaf by associating to any open set sections of the bundle over that open set. Sheaves of the form "$i_*\mathcal{E}$" look like, intuitively, vector bundles over submanifolds, with vanishing fibers off the submanifold. A more detailed discussion of sheaves is beyond the scope of this article; see instead, for example, Sharpe (2003).

To "associate a sheaf" means finding a sheaf such that physical properties of the D-brane system are well modeled by mathematics of the sheaf. (In particular, the physical definition of D-brane has, on the face of it, nothing at all to do with the mathematical definition of a sheaf, so one cannot directly argue that they are the same, but one can still use one to give a mathematical model of the other.) For example, the spectrum of open-string states in the B model stretched between two D-branes, associated to sheaves $i_*\mathcal{E}$ and $j_*\mathcal{F}$, turn out to be calculated by a cohomology group known as $\mathrm{Ext}^*_X(i_*\mathcal{E}, j_*\mathcal{F})$.

There are many more sheaves not of the form $i_*\mathcal{E}$, that is, that do not look like vector bundles over submanifolds. It is not known in general whether they also correspond to (on-shell) D-branes, but in some special cases the answer has been worked out. For example, structure sheaves of nonreduced schemes turn out to correspond to D-branes with nonzero nilpotent Higgs vevs.

For a set of ordinary D-branes, the description above suffices. However, more generally one would like to describe collections of D-branes and anti-D-branes, and tachyons. An anti-D-brane has all the same physical properties as an ordinary D-brane, modulo the fact that they try to annihilate each other. The open-string spectrum between coincident D-branes and anti-D-branes contains tachyons. One can give an (off-shell) vacuum expectation value to such tachyons, and then the unstable brane–antibrane–tachyon system will evolve to some other, usually simpler, configuration. For example, given a single D-brane wrapped on a curve, with trivial line bundle, and an anti-D-brane wrapped on the same curve, with line bundle $\mathcal{O}(-1)$, and a nonzero tachyon $\mathcal{O}(-1) \to \mathcal{O}$, then one expects that the system will dynamically evolve to a smaller D-brane sitting at a point on the curve.

Now, one would like to find some mathematics that describes such systems, and gives information about the endpoints of their evolution. Technically, one would like to classify universality classes of world-sheet boundary renormalization group flow.

It has been conjectured that derived categories of sheaves provide such a classification. To properly explain derived categories is well beyond the scope of this article (see instead the "Further reading" section at the end), but we shall give a short outline below.

Mathematically, derived categories of sheaves concern complexes of sheaves, that is, sets of sheaves $\mathcal{E}_i$ together with maps $d_i : \mathcal{E}_i \to \mathcal{E}_{i+1}$

$$\cdots \longrightarrow \mathcal{E}_i \xrightarrow{d_i} \mathcal{E}_{i+1} \xrightarrow{d_{i+1}} \mathcal{E}_{i+2} \xrightarrow{d_{i+2}} \cdots$$

such that $d_{i+1} \circ d_i = 0$. A category is defined by a collection of "objects" together with maps between the objects, known as morphisms. In a derived category of coherent sheaves, the objects are complexes of sheaves, and the maps are equivalence classes of maps between complexes.

Physically, if the complex consists of locally free sheaves (equivalently, vector bundles), then we can associate a brane/antibrane/tachyon system, by identifying the $\mathcal{E}_i$ for $i$ even, say, with D-branes, and the $\mathcal{E}_i$ for $i$ odd with anti-D-branes. If the $\mathcal{E}_i$ are all locally free sheaves, then there are tachyons between the branes and antibranes, and we can identify the $d_i$'s with those tachyons. In the open-string world-sheet theory, giving a tachyon a vacuum expectation value modifies the BRST operator $Q$, and a necessary condition for the new theory to still be a topological field theory is that $Q^2 = 0$, a condition which turns out to imply that $d_{i+1} \circ d_i = 0$.

To re-create the structure of a derived category, we need to impose some equivalence relations. To see what sorts of equivalence relations one would like to impose, note the following. Physically, we would like to identify, for example, a configuration consisting of a brane, an antibrane, and a tachyon, which we can describe as a complex

$$\mathcal{O}(-D) \longrightarrow \mathcal{O}$$

with a one-element complex

$$\mathcal{O}_{\mathrm{D}}$$

corresponding to the D-brane which we believe is the endpoint of the evolution of the brane/antibrane configuration.

One natural mathematical way to create identifications of this form is to identify complexes that differ by "quasi-isomorphisms," meaning, a set of maps $(f^n : C^n \to D^n)$ compatible with $d$'s, and inducing an isomorphism $\tilde{f}^n : H^n(C) \cong H^n(D)$ on the cohomologies of the complexes. In particular, in the example above, there is a natural set of maps

$$\begin{array}{ccc} \mathcal{O}(-D) & \longrightarrow & \mathcal{O} \\ \downarrow & & \downarrow \\ 0 & \longrightarrow & \mathcal{O}_{\mathrm{D}} \end{array}$$

that define a quasi-isomorphism. More generally, in homological algebra, one typically does computations by replacing ordinary objects with projective or injective resolutions, that is, complexes with special properties, in which the desired computation becomes trivial, and defining the result for the original object to be the same as the result for the resolution. To formalize this procedure, one would like a mathematical setup in which objects and their projective and injective resolutions are isomorphic.

However, to define an equivalence relation, one usually needs an isomorphism, and the quasi-isomorphisms above are not, in general, isomorphisms. Creating an equivalence from nonisomorphisms, to resolve this problem, can be done through a process known as "localization" (generalizing the notion of localization in commutative algebra). The resulting equivalence relations on maps between complexes define the derived category.

The derived category is a category whose objects are complexes, and whose morphisms $C^{\cdot} \to D^{\cdot}$ are equivalence classes of pairs $(s, t)$ where $s : G^{\cdot} \to C^{\cdot}$ is a quasi-isomorphism between $C^{\cdot}$ and another complex $G^{\cdot}$, and $t : G^{\cdot} \to D^{\cdot}$ is a map of complexes. We take two such pairs $(s, t), (s', t')$ to be equivalent if there exists another pair $(r, h)$ between the auxiliary complexes $G^{\cdot}, G^{\cdot\prime}$, making the obvious diagram commute. This is, in a nutshell, what is meant by localization, and by working with such equivalence classes, this allows us to formally invert maps that are otherwise noninvertible. (We encourage the reader to consult the "Further reading" section for more details.)

Mathematically, this technology gives a very elegant way to rethink, for example, homological algebra. There is a notion of a derived functor, a special kind of functor between derived categories, and notions from homological algebra such as Ext and Tor can be re-expressed as cohomologies of the image complexes under the action of a derived functor, thus replacing cohomologies with complexes.

Physically, looking back at the physical realization of complexes, we see a basic problem: different representatives of (isomorphic) objects in the derived category are described by very different physical theories. For example, the sheaf $\mathcal{O}_D$ corresponds to a single D-brane, defined by a two-dimensional boundary conformal field theory (CFT), whereas the brane/antibrane/tachyon collection $\mathcal{O}(-D) \to \mathcal{O}$ is defined by a massive nonconformal two-dimensional theory. These are very different physical theories. If we want "localization on quasi-isomorphisms" to happen in physics, we have to explain which properties of the physical theories we are interested in, because clearly the entire physical theories are not and cannot be isomorphic.

Although the entire physical theories are not isomorphic, we can hope that under renormalization group flow, the theories will become isomorphic. That is certainly the physical content of the statement that the brane/antibrane system $\mathcal{O}(-D) \to \mathcal{O}$ should describe the D-brane corresponding to $\mathcal{O}_D$ – after world-sheet boundary renormalization group flow, the nonconformal two-dimensional theory describing the brane/antibrane system becomes a CFT describing a single D-brane.

More globally, this is the general prescription for finding physical meanings of many categories: we can associate physical theories to particular types of representatives of isomorphism classes of objects, and then although distinct representatives of the same object may give rise to very different physical theories, those physical theories at least lie in the same universality class of world-sheet renormalization group flow. In other words, (equivalence classes of) objects are in one-to-one correspondence with universality classes of physical theories.

Showing such a statement directly is usually not possible – it is usually technically impractical to follow renormalization group flow explicitly. There is no symmetry reason or other basic physics reason why renormalization group flow must respect quasi-isomorphism. The strongest constraint that is clearly applied by physics is that renormalization group flow must preserve D-brane charges (Chern characters, or more properly, $K$-theory), but objects in a derived category contain much more information than that.

However, indirect tests can be performed, and because many indirect tests are satisfied, the result is generally believed.

The reader might ask why it is not more efficient to just work with the cohomology complexes $H^{\cdot}(C)$ themselves, rather than the original complexes. One reason is that the original complexes contain more information than the cohomology – passing to cohomology loses information. For example, there exist examples of complexes that have the same cohomology, yet are not quasi-isomorphic, and so are not identified within the derived category, and so physically are believed to lie in different universality classes of boundary renormalization group flow.

Another motivation for relating physics to derived categories is Kontsevich's approach to mirror symmetry. Mirror symmetry relates pairs of Calabi–Yau manifolds, of the same dimension, in a fashion such that easy classical computations in one Calabi–Yau

are mapped to difficult "quantum" computations involving sums over holomorphic curves in the other Calabi–Yau. Because of this property, mirror symmetry has proved a fertile ground for algebraic geometers to study. Kontsevich proposed that mirror symmetry should be understood as a relation between derived categories of coherent sheaves on one Calabi–Yau and derived Fukaya categories on the other Calabi–Yau. At the time he made this proposal, no one had any idea how either could be realized in physics, but since that time, physicists have come to believe that Kontsevich was secretly talking about D-branes in the A and B models.

## Bondal–Kapranov Enhancements

Mathematically derived categories are not quite as ideal as one would like. For example, the cone construction used in triangulated categories does not behave functorially – the cone depends upon the representative of the equivalence class defining an object in a derived category, and not just the object itself.

Physically, our discussion of brane/antibrane systems was not the most general possible. One can give vacuum expectation values to more general vertex operators, not just the tachyons.

Curiously, these two issues solve each other. By incorporating a more general class of boundary vertex operators, one realizes a more general mathematical structure, due to Bondal and Kapranov, which repairs many of the technical deficiencies of ordinary derived categories. Ordinary complexes are replaced by generalized complexes in which arrows can map between non-neighboring elements of the complex. Schematically, the BRST operator is deformed by boundary vacuum expectation values to the form

$$Q = \overline{\partial} + \sum_a \phi_a$$

and demanding that the BRST operator square to zero implies that

$$\sum_a \overline{\partial}\phi_a + \sum_{a,b} \phi_b \circ \phi_a = 0$$

which is the same as the condition for a generalized complex. Note that for ordinary complexes, the condition above factors into

$$\overline{\partial}\phi_n = 0$$
$$\phi_{n+1} \circ \phi_n = 0$$

which yields an ordinary complex of sheaves (Figure 1).

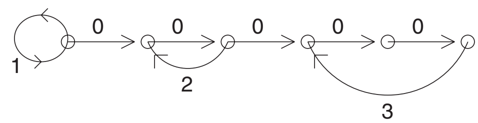

**Figure 1** 1. Example of generalized complex. Each arrow is labeled by the degree of the corresponding vertex operator.

## Landau–Ginzburg Models

So far we have described how derived categories are relevant to geometric compactifications, that is, sigma models on Calabi–Yau manifolds. However, there are also "nongeometric" theories – CFTs that do not come from sigma models on manifolds, of which Landau–Ginzburg models and their orbifolds are prominent examples. Landau–Ginzburg models can also be twisted into topological field theories, and the B-type topological twist of (an orbifold of) a Landau–Ginzburg model is believed to be isomorphic, as a topological field theory, to the B model obtained from a nonlinear sigma model, of the form we outlined earlier. Landau–Ginzburg models have a very different form than nonlinear sigma models, and so sometimes there can be practical computational advantages to working with one rather than the other.

A Landau–Ginzburg model is an ungauged sigma model with a nonzero superpotential (a holomorphic function over the target space that defines a bosonic potential and Yukawa couplings). (In "typical" cases, the target space is a vector space.) Because of the superpotential, a Landau–Ginzburg model is a massive theory – not itself a CFT, but many Landau–Ginzburg models are believed to flow to CFTs under the renormalization group.

In formulating open strings based on Landau–Ginzburg models, naive attempts fail because of something known as the Warner problem: if the superpotential is nonzero, then the obvious ways to try to define the theory on a Riemann surface with boundary have the undesirable property that the supersymmetry transformations only close up to a nonzero boundary term, proportional to derivatives of the superpotential. In order to find a description of open strings in which the supersymmetry transformations close, one must take a very nonobvious formulation of the boundary data. Specifically, to solve the Warner problem, one is led to work with pairs of matrices whose product is proportional to the superpotential.

This method of solving the Warner problem is known as matrix factorization, and D-branes in this theory are defined by the factorization chosen, that is, the choice of pairs of matrices. In simple cases, we can be more explicit as follows. Choose a set of

polynomials $F_\alpha, G_\alpha$ such that the Landau–Ginzburg superpotential $W$ is given by

$$W = \sum_\alpha F_\alpha G_\alpha + \text{constant.}$$

The $F_\alpha$ and $G_\alpha$ are used to define the boundary action – the $F$'s appear as part of the boundary superpotential and the $G$'s appear as part of the supersymmetry transformations of boundary fermi multiplets. The $F_\alpha$ and $G_\alpha$, that is, the factorization of $W$, determine the D-brane in the Landau–Ginzburg theory. We can also think of having a pair of holomorphic vector bundles $\mathcal{E}_1, \mathcal{E}_2$ of the same rank, and interpret $F$ and $G$ as holomorphic sections of $\mathcal{E}_1^\vee \otimes \mathcal{E}_2$ and $\mathcal{E}_2^\vee \otimes \mathcal{E}_1$, respectively, obeying $FG \propto W \cdot \text{Id}$ and $GF \propto W \cdot \text{Id}$, up to additive constants.

Although a Landau–Ginzburg model is not the same thing as a sigma model on a Calabi–Yau, orbifolds of Landau–Ginzburg models are often on the same Kähler moduli space. Perhaps, the most famous example of this relates sigma models on quintic hypersurfaces in $\boldsymbol{P}^4$ to a $\boldsymbol{Z}_5$ orbifold of a Landau–Ginzburg model over $\boldsymbol{C}^5$ with five chiral superfields $x_1, x_2, x_3, x_4, x_5$, and a superpotential of the form

$$W = x_1^5 + x_2^5 + x_3^5 + x_4^5 + x_5^5 + \psi x_1 x_2 x_3 x_4 x_5$$

for $\psi$ a complex number, corresponding to the equation of the degree-5 hypersurface in $\boldsymbol{P}^4$. The (complexified) Kähler moduli space in this example is a $\boldsymbol{P}^1$, with the sigma model on the quintic at one pole, the zero-volume limit of the sigma model along the equator, and the Landau–Ginzburg orbifold at the opposite pole.

Since the closed-string topological B model is independent of Kähler moduli, and the sigma model on the quintic and the Landau–Ginzburg orbifold above lie on the same Kähler moduli space, one would expect them both to have the same spectrum of D-branes, and indeed this is believed to be true.

## Pi-Stability

So far we have discussed D-branes in the topological B model, a topological twist of a physical sigma model. If we untwist back to a physical sigma model, then the stability of those D-branes becomes an issue.

To begin to understand what we mean by stability in this context, consider a set of $N$ D-branes wrapped on, say, a K3 surface, at large radius (so that world-sheet instanton corrections are small). On the world volume of the D-branes, we have a rank-$N$ vector bundle, and in the physical theory on that world volume we have a consistency condition for supersymmetric vacua, that the vector bundle be "Mumford–Takemoto stable." To understand what is meant by this condition on a Kähler manifold, let $\omega$ denote the Kähler form, and define the "slope" $\mu$ of a vector bundle $\mathcal{E}$ on a manifold $X$ of complex dimension $n$ to be given by

$$\mu(\mathcal{E}) = \frac{\int_X \omega^{n-1} \wedge c_1(\mathcal{E})}{\text{rank } \mathcal{E}}$$

where $\omega$ is the Kähler form. Then, we say that $\mathcal{E}$ is (semi-)stable if for all subsheaves $\mathcal{F}$ satisfying certain consistency conditions, $\mu(\mathcal{F})(\leq) < \mu(\mathcal{E})$.

Since the slope of a bundle depends upon the Kähler form, whether a given bundle is Mumford–Takemoto stable depends upon the metric. In general, on a Kähler manifold, the Kähler cone breaks up into subcones, with a different moduli space of (stable) holomorphic vector bundles in each subcone.

This is a mathematical notion of stability, but it also corresponds to physical stability, at least in a regime in which quantum corrections are small. If a given bundle is only stable in a proper subset of the Kähler cone, then when it reaches the boundary of the subcone in which it is stable, the gauge field configuration that satisfies the Donaldson–Uhlenbeck–Yau partial differential equation splits into a sum of two separate bundles. In a heterotic string compactification, this leads to a low-energy enhanced U(1) gauge symmetry and D-terms which realize the change in moduli space. In D-branes, this means the formerly bound state of D-branes (described by an irreducible holomorphic vector bundle) becomes only marginally bound; a decay becomes possible.

Pi-stability is a proposal for generalizing the considerations above to D-branes no longer wrapping the entire Calabi–Yau, and including quantum corrections.

In order to define pi-stability, we must first introduce a notion of grading $\varphi$ of a D-brane. Specifically, for a D-brane wrapped on the entire Calabi–Yau $X$ with holomorphic vector bundle $\mathcal{E}$, the grading is defined as the mirror to the expression $\int_X \text{ch}(\mathcal{E}) \wedge \Pi$, where $\Pi$ encodes the periods. Close to the large-radius limit, this has the form:

$$\varphi(\mathcal{E}) = \frac{1}{\pi} \text{Im} \log \int_X \exp(B + \mathrm{i}\omega) \wedge \text{ch}(\mathcal{E}) \times \wedge \sqrt{\text{td}(TX)} + \cdots$$

where $B$ is a 2-form, the "B field." As defined $\varphi$ is clearly $S^1$-valued; however, we must choose a

particular sheet of the log Riemann surface, to obtain an $\boldsymbol{R}$-valued function.

This notion of grading of D-branes is an ansatz, introduced as part of the definition of pi-stability. Physically, it is believed that the difference in grading between two D-branes corresponds to the fractional charge of the boundary-condition-changing vacuum between the two D-branes, though we know of no convincing first-principles derivation of that statement. In particular, unlike closed-string computations, the degree of the Ext group element corresponding to a particular boundary R-sector state is not always the same as the $U(1)_R$ charge – for example, it is often determined by the $U(1)_R$ charge minus the charge of the vacuum. The grading gives us the mathematical significance of that vacuum charge. This mismatch between Ext degrees and $U(1)_R$ charges is necessary for the grading to make sense: Ext group degrees are integral, after all, yet we want the grading to be able to vary continuously, so the grading had better not be the same as an Ext group degree.

Given an $\boldsymbol{R}$-valued function from a particular definition of log in the definition of $\varphi$ above, the statement of pi-stability is then that for all subsheaves $\mathcal{F}$, as in the statement of Mumford–Takemoto stability,

$$\varphi(\mathcal{F}) \leq \varphi(\mathcal{E})$$

Before trying to understand the physical meaning of $\varphi$, or the extension of these ideas to derived categories, let us try to confirm that Mumford–Takemoto stability emerges as a limit of pi-stability.

For simplicity, suppose that $X$ is a Calabi–Yau 3-fold. Then, for large Kähler form $\omega$, we can expand $\varphi(\mathcal{E})$ as,

$$\varphi(\mathcal{E}) \approx \frac{1}{\pi} \operatorname{Im} \log\left[-\frac{\mathrm{i}}{3!}\int_X \omega^3 (\operatorname{rk}\, \mathcal{E})\right] + \frac{3}{\pi}\frac{\int_X \omega^2 \wedge c_1(\mathcal{E})}{\int_X \omega^3(\operatorname{rk}\, \mathcal{E})} + \cdots$$

Thus, we see that to leading order in the Kähler form $\omega$, $\varphi(\mathcal{F}) \leq \varphi(\mathcal{E})$ if and only if

$$\frac{\int_X \omega^2 \wedge c_1(\mathcal{F})}{\operatorname{rk}\, \mathcal{F}} \leq \frac{\int_X \omega^2 \wedge c_1(\mathcal{E})}{\operatorname{rk}\, \mathcal{E}}$$

which is precisely the statement of Mumford–Takemoto stability on a 3-fold $X$.

One can define a notion of (classical) stability for more general sheaves, but what one wants is to apply pi-stability to derived categories, not just sheaves.

However, there is a technical problem that limits such an extension. Specifically, in a derived category, there is no meaningful notion of "subobject." Thus, a notion of stability formulated in terms of subobjects cannot be immediately applied to derived categories. There are two (equivalent) workarounds to this issue that have been discussed in the math and physics literatures, which can be briefly summarized as follows:

1. One workaround involves picking a subcategory of the derived category that does allow you to make sense of subobjects. Such a structure is known, loosely, as a "T-structure," and so one can imagine formulating stability by first picking a T-structure, then specifying a slope function on the elements of the subcategory picked out by the subcategory.
2. Another (equivalent) workaround is to work with a notion of "relative stability." Instead of speaking about whether a D-brane is stable against decay into any other object, one only speaks about whether it is stable against decay into pairs of specified objects.

In this fashion, one can make sense of pi-stability for derived categories.

# Determinantal Random Fields

**A Soshnikov**, University of California at Davis, Davis, CA, USA

## Introduction

The theory of random point fields has its origins in such diverse areas of science as life tables, particle physics, population processes, and communication engineering. A standard reference to the subject is the monograph by Daley and Vere-Jones (1988).

This article is concerned with a special class of random point fields, introduced by Macchi in the mid-1970s. The model that Macchi considered describes the statistical distribution of a fermion system in thermal equilibrium. Macchi proposed to call the new class of random point processes the fermion random point processes. The characteristic property of this family of random point processes is the condition that $k$-point correlation functions have the form of determinants built from a correlation kernel. This implies that the particles obey the Pauli exclusion principle. Until the mid-1990s, fermion random point processes attracted only a limited interest in mathematics and physics communities, with the exception of two important works by Spohn (1987) and Costin–Lebowitz (1995). This situation changed dramatically at the end of the last century, as the subject greatly benefited from the newly discovered connections to random matrix theory, representation theory, random growth models, combinatorics, and number theory. Things are rapidly developing at the moment. Even the terminology has not yet set in stone. Many experts currently use the term "determinantal random point fields" instead of "fermion random point fields." We follow this trend in our article.

This article is intended as a short introduction to the subject. The next section builds a mathematical framework and gives a formal mathematical definition of the determinantal random point fields. Then we discuss examples of determinantal random point fields from quantum mechanics, random matrix theory, random growth models, combinatorics, and representation theory. This is followed by a discussion of the ergodic properties of translation-invariant determinantal random point fields. We discuss the Gibbsian property of determinantal random point fields. Central-limit theorem type results for the counting functions and similar linear statistics are also discussed. The final section is devoted to some generalizations of determinantal point fields, namely immanantal and Pfaffian random point fields.

## Mathematical Framework

We start by building a standard mathematical framework for the theory of random point processes. Let $E$ be a one-particle space and $X$ a space of finite or countable configurations of particles in $E$. In general, $E$ can be a separable Hausdorff space. However, for our purposes it suffices to consider $E=\mathbb{R}^d$ or $E=\mathbb{Z}^d$. We usually assume in this section that $E=\mathbb{R}^d$, with the understanding that all constructions can be easily extended to the discrete case. We assume that each configuration $\xi=(x_i), x_i\in E$, $i\in\mathbb{Z}^1$ (or $i\in\mathbb{Z}^1_+$ for $d>1$), is locally finite. In other words, for every compact $K\subset E$, the number of particles in $K$, $\#_K(\xi)=\#(x_i\in K)$ is finite.

In order to introduce a $\sigma$-algebra of measurable subsets of $X$, we first define the cylinder sets. Let $B\subset E$ be a bounded Borel set and let $n\geq 0$. We call $C_n^B=\{\xi\in X:\#_B(\xi)=n\}$ a cylinder set. We define $\mathcal{B}$ as a $\sigma$-algebra generated by all cylinder sets (i.e., $\mathcal{B}$ is the minimal $\sigma$-algebra that contains all $C_n^B$).

**Definition 1** A random point field is a triplet $(X,\mathcal{B},\Pr)$, where Pr is a probability measure on $(X,\mathcal{B})$.

It was observed in the 1960–1970s (see, e.g., Lenard (1973, 1975)), that in many cases the most convenient way to define a probability measure on $(X,\mathcal{B})$ is via the point correlation functions. Let $E=\mathbb{R}^d$, equipped with the underlying Lebesgue measure.

**Definition 2** Locally integrable function $\rho_k:E^k\to\mathbb{R}^1_+$ is called a $k$-point correlation function of the random point field $(X,\mathcal{B},\Pr)$ if, for any disjoint bounded Borel subsets $A_1,\ldots,A_m$ of $E$ and for any $k_i\in\mathbb{Z}^1_+, i=1,\ldots,m$, $\sum_{i=1}^m k_i=k$, the following formula holds:

$$\mathbb{E}\prod_{i=1}^m\frac{(\#_{A_i})!}{(\#_{A_i}-k_i)!}=\int_{A_1^{k_1}\times\cdots\times A_m^{k_m}}\rho_k(x_1,\ldots,x_k)\mathrm{d}x_1\cdots\mathrm{d}x_k \qquad [1]$$

where by $\mathbb{E}$ we denote the mathematical expectation with respect to Pr. In particular, $\rho_1(x)$ is the particle density, since

$$\mathbb{E}\#_A=\int_A\rho_1(x)\mathrm{d}x$$

for any bounded Borel $A\subset E$. In general, $\rho_k(x_1,\ldots,x_k)$ has the following probabilistic interpretation. Let $[x_1,x_i+\mathrm{d}x_i], i=1,\ldots,k$, be infinitesimally small boxes around $x_i$, then $\rho_k(x_1,x_2,\ldots,x_k)$ $\mathrm{d}x_1\cdots\mathrm{d}x_k$ is the probability to find a particle in each of these boxes.

In the discrete case $E = \mathbb{Z}^d$, the construction of a random point field is very similar. The probability space $X$ and the $\sigma$-algebra $\mathcal{B}$ are constructed essentially in the same way as before. Moreover, in the discrete case, the set of the countable configurations of particles can be identified with the set of all subsets of $E$. Therefore, $X = \{0, 1\}^E$, and $\mathcal{B}$ is generated by the events $\{C_x, x \in E\}$, where $C_x = \{x \in \xi\}$. The $k$-point correlation function $\rho(x_1, \dots, x_k)$ is then just a probability that a configuration $\xi$ contains the sites $x_1, \dots, x_k$. In other words, $\rho_k(x_1, \dots, x_k) = \Pr(\bigcap_{i=1}^k C_{x_i})$. In particular, the one-point correlation function $\rho_1(x), x \in \mathbb{Z}^d$, is the probability that a configuration contains the site $x$, that is, $\rho_1(x) = \Pr(C_x)$.

The problem of the existence and the uniqueness of a random point field defined by its correlation functions was studied by Lenard (1973–1975). It is not surprising that Lenard's papers revealed many parallels to the classical moment problem. In particular, the random point field is uniquely defined by its correlation functions if the distribution of random variables $\{\#_A\}$ for bounded Borel sets $A$ is uniquely determined by its moments.

In this article we study a special class of random point fields introduced by Macchi (1975). To shorten the exposition, we give the definitions only in the continuous case $E = \mathbb{R}^d$. In the discrete case, the definitions are essentially the same.

Let $K : L^2(\mathbb{R}^d) \to L^2(\mathbb{R}^d)$ be an integral locally trace-class operator. The last condition means that for any compact $B \subset \mathbb{R}^d$ the operator $K\chi_B$ is trace class, where $\chi_B(x)$ is an indicator of $B$. The kernel of $K$ is defined up to a set of measure zero in $\mathbb{R}^d \times \mathbb{R}^d$. For our purposes, it is convenient to choose it in such a way that for any bounded measurable $B$ and any positive integer $n$

$$\mathrm{tr}((\chi_B K \chi_B)) = \int_B K(x, x)\mathrm{d}x \qquad [2]$$

We refer the reader to Soshnikov (2000, p. 927) for the discussion. We are now ready to define a determinantal (fermion) random point field on $\mathbb{R}^d$.

**Definition 3** A random point field on $E$ is said to be determinantal (or fermion) if its $n$-point correlation functions are of the form

$$\rho_n(x_1, \dots, x_n) = \det\big(K(x_i, x_j)\big)_{1 \le i \le n} \qquad [3]$$

**Remark 1** If the kernel is Hermitian-symmetric, then the non-negativity of $n$-point correlation functions implies that the kernel $K(x, y)$ is non-negative definite and, therefore $K$ must be a non-negative operator. It should be noted, however, that there exist determinantal random point fields corresponding to non-Hermitian kernels (see, e.g., [18] later). The kernel $K(x, y)$ is usually called a correlation kernel of the determinantal random point process.

In the Hermitian case, the necessary and sufficient conditions on the operator $K$ to define a determinantal random point filed were established by Soshnikov (2000); see also Macchi (1975).

**Theorem 1** *Hermitian locally trace class operator $K$ on $L^2(E)$ determines a determinantal random point field if and only if $0 \le K \le 1$ (in other words, both $K$ and $1 - K$ are non-negative operators). If the corresponding random point field exists, it is unique.*

The main technical part of the proof is the following proposition.

**Proposition 1** *Let $(X, B, P)$ be a determinantal random point field with the Hermitian-symmetric correlation kernel $K$. Let $f$ be a non-negative continuous function with compact support. Then*

$$\mathbb{E}e^{\langle \xi, f\rangle} = \det\Big(\mathrm{Id} - (1 - \mathrm{e}^{-f})^{1/2} K (1 - \mathrm{e}^{-f})^{1/2}\Big) \qquad [4]$$

*where $\langle \xi, f\rangle$ is the value of the linear statistics defined by the test function $f$ on the configuration $\xi = (x_i)$; in other words, $\langle \xi, f\rangle = \Sigma_i f(x_i)$.*

**Remark 2** The right-hand side (RHS) of [4] is well defined as the Fredholm determinant of a trace-class operator. Letting $f = \sum_{i=1}^k s_i \chi I_i$, one obtains $\mathbb{E}e^{\langle \xi, f\rangle} = \mathbb{E}\prod_{i=1}^k z_i^{\#_{I_i}}$, with $z_i = \mathrm{e}^{s_i}$. In this case, the left-hand side (LHS) of [4] becomes the generating function of the joint distribution of the counting random variables $\#_{I_i}, i = 1, \dots, k$.

Unfortunately, there are very few known results in the non-Hermitian case. In particular, the necessary and sufficient condition on $K$ for the existence of the determinantal random point field with the non-Hermitian correlation kernel is not known.

We end this section with the introduction of the Janossy densities (a.k.a. density distributions, exclusion probability densities, etc.) of a random point field.

The term Janossy densities in the theory of random point processes was introduced by Srinivasan in 1969, who referred to the 1950 paper by Janossy on particle showers. Let us assume that all point correlation functions exist and are locally integrable, and let $I$ be a bounded Borel subset of

$\mathbb{R}^d$. Intuitively, one can think of the Janossy density $\mathcal{J}_{k,I}(x_1,\ldots,x_k)$, $x_1,\ldots,x_k \in I$, as

$$\mathcal{J}_{k,I}(x_1,\ldots,x_k)\prod_{i=1}^{k}\mathrm{d}x_i = \Pr\{\text{there are exactly } k \text{ particles in } I \text{ and there is a particle in each of the } k \text{ infinitesimal boxes } (x_i, x_i+\mathrm{d}x_i),\ i=1,\ldots,k\} \quad [5]$$

To give a formal definition, we express point correlation functions in terms of Janossy densities and vice versa:

$$\rho_k(x_1,\ldots,x_k) = \sum_{j=1}^{\infty}\frac{1}{j!}\int_{I^j}\mathcal{J}_{k+j,I}(x_1,\ldots,x_k,x_{k+1},\ldots,x_{k+j}) \times \mathrm{d}x_{k+1}\ldots\mathrm{d}x_{k+j} \quad [6]$$

$$\mathcal{J}_{k,I}(x_1,\ldots,x_k) = \sum_{j=0}^{\infty}\frac{(-1)^j}{j!}\int_{I^j}\rho_{k+j}(x_1,\ldots,x_k,x_{k+1},\ldots,x_{k+j}) \times \mathrm{d}x_{k+1}\cdots\mathrm{d}x_{k+j} \quad [7]$$

A very useful property of the Janossy densities is that

$$\Pr\{\text{there are exactly } k \text{ particles in } I\} = \frac{1}{k!}\int_{I^k}\mathcal{J}_{k,I}(x_1,\ldots,x_k)\mathrm{d}x_1\cdots\mathrm{d}x_k \quad [8]$$

In the case of determinantal random point fields, Janossy densities also have a determinantal form, namely

$$\mathcal{J}_{k,I}(x_1,\ldots,x_k) = \det(\mathrm{Id}-K_I)\cdot\det\big(L_I(x_i,x_j)\big)_{1\le i,j\le k} \quad [9]$$

In the last equation, $K_I$ is the restriction of the operator $K$ to the $L^2(I)$. In other words, $K_I(x,y) = \chi_I(x)K(x,y)\chi_I(y)$, where $\chi_I$ is the indicator of $I$. The operator $L_I$ is expressed in terms of $K_I$ as $L_I = (\mathrm{Id}-K_I)^{-1}K_I$. For further results on the Janossy densities of determinantal random point processes we refer the reader to Soshnikov (2004) and references therein.

## Examples of Determinantal Random Point Fields

### Fermion Gas

Let $H = -\mathrm{d}^2/\mathrm{d}x^2 + V(x)$ be a Schrödinger operator with discrete spectrum on $L^2(E)$. We denote by $\{\varphi_\ell\}_{\ell=0}^{\infty}$ an orthonormal basis of the eigenfunctions, $H\varphi_\ell = \lambda_\ell\cdot\varphi_\ell, \lambda_0 < \lambda_1 \le \lambda_2 \le \cdots$. To define a Fermi gas, we consider the $n$th exterior power of $H$, $\wedge^n(H)\colon \wedge^n(L^2(E)) \to \wedge^n(L^2(E))$, where $\wedge^n(L^2(E))$ is the space of square-integrable antisymmetric functions of $n$ variables and $\wedge^n(H) = \sum_{i=1}^{n}(-\mathrm{d}^2/\mathrm{d}x_i^2 + V(x_i))$. The eigenstates of the Fermi gas are given by the normalized Slater determinants

$$\psi_{k_1,\ldots,k_n}(x_1,\ldots,x_n) = \frac{1}{\sqrt{n!}}\sum_{\sigma\in S_n}(-1)^\sigma\prod_{i=1}^{n}\varphi_{k_i}(x_{\sigma(i)}) = \frac{1}{\sqrt{n!}}\det(\varphi_{k_i}(x_j))_{1\le i,j\le n} \quad [10]$$

where $0 \le k_1 < k_2 < \cdots < k_n$. A probability distribution of $n$ particles in the Fermi gas is given by the squared absolute value of the eigenstate:

$$p(x_1,\ldots,x_n) = |\psi(x_1,\ldots,x_n)|^2 = \frac{1}{n!}\det\big(\varphi_{k_i}(x_j)\big)_{1\le i,j\le n} \times \det\Big(\overline{\varphi_{k_j}(x_i)}\Big)_{1\le i,j\le n} = \frac{1}{n!}\det\big(K_n(x_i,x_j)\big)_{1\le i,j\le n} \quad [11]$$

where $K_n(x,y) = \sum_{i=1}^{n}\varphi_{k_i}(x)\overline{\varphi_{k_i}(y)}$ is the kernel of the orthogonal projector onto the subspace spanned by the $n$ eigenfunctions $\{\varphi_{k_i}\}$ of $H$. The $n$-dimensional probability distribution [11] defines a determinantal random point field with $n$ particles. The $k$-point correlation functions are given by

$$\rho_k^{(n)}(x_1,\ldots,x_n) = \frac{n!}{(n-k)!}\int p_n(x_1,\ldots,x_n) \times \mathrm{d}x_{k+1}\cdots\mathrm{d}x_n = \det\big(K_n(x_1,x_j)\big)_{1\le i,j\le k} \quad [12]$$

### Random Matrix Models

Some of the most important ensembles of random matrices fall into the class of determinantal random point processes.

The archetypal ensemble of Hermitian random matrices is a so-called Gaussian unitary ensemble (GUE). Let us consider the space of $n\times n$ Hermitian matrices $\{A = (A_{ij})_{1\le i,j\le n}, \mathrm{Re}(A_{ij}) = \mathrm{Re}(A_{ji}), \mathrm{Im}(A_{ij}) = -\mathrm{Im}(A_{ji})\}$. A GUE random matrix is defined by its probability distribution

$$P(\mathrm{d}A) = \mathrm{const}_n\cdot\exp(-\mathrm{tr}A^2)\mathrm{d}A \quad [13]$$

where $\mathrm{d}A$ is a Lebesgue measure, that is, $\mathrm{d}A = \prod_{i<j}\mathrm{dRe}(A_{ij})\,\mathrm{dIm}(A_{ij})\prod_{k=1}^{n}\mathrm{d}A_{kk}$. The eigenvalues of a random Hermitian matrix are real random

variables, whose joint probability distribution is a determinantal random point process of $n$ particles on the real line. The correlation kernel has the Christoffel–Darboux form built from the Hermite polynomials.

The GUE ensemble of random matrices is invariant under the unitary transformation $A \to UAU^{-1}$, $U \in U(n)$. An important generalization of [13] that preserves the unitary invariance is

$$P(\mathrm{d}A) = \mathrm{const}_n \exp(-\mathrm{tr}\,V(A))\mathrm{d}A \qquad [14]$$

where, for example, $V(x)$ is a polynomial of even degree with positive leading coefficients. The correlation functions of the eigenvalues in [14] are again determinantal, and the Hermite polynomials in the correlation kernel have to be replaced by the orthonormal polynomials with respect to the weight $\exp(-V(x))$. For details, we refer the reader to the monographs by Mehta (2004) and Deift (2000).

There are many other ensembles of random matrices for which the joint distribution of the eigenvalues has determinantal point correlation functions: classical compact groups with respect to the Haar measure, complex non-Hermitian Gaussian random matrices, positive Hermitian random matrices of the Wishart type, and chains of correlated Hermitian matrices. We refer the reader to Soshnikov (2000) for more information.

## Discrete Translation-Invariant Determinantal Random Point Fields

Let $g : \mathbb{T}^d \to [0,1]$ be a Lebesgue-measurable function on the $d$-dimensional torus $\mathbb{T}^d$. Assume that $0 \le g \le 1$. A configuration $\xi$ in $\mathbb{Z}^d$ can be thought of as a 0–1 function on $\mathbb{Z}^d$, that is, $\xi(x) = 1$ if $x \in \xi$ and $\xi(x) = 0$ otherwise. We define a $\mathbb{Z}^d$-invariant probability measure Pr on the Borel sets of $X = \{0,1\}^{\mathbb{Z}^d}$ in such a way that

$$\rho_k(x_1, \ldots, x_k) = \Pr(\xi(x_1) = 1, \ldots, \xi(x_k) = 1) := \det\big(\hat{g}(x_i - x_j)\big)_{1 \le i,j \le k} \qquad [15]$$

for $x_1, \ldots, x_k \in \mathbb{Z}^d$. In the above formula, $\{g(n)\}$ are the Fourier coefficients of $g$, that is, $g(x) = \sum_n \hat{g}(n) \mathrm{e}^{in\cdot x}$. It is clear from Definition 3 that [15] defines a determinantal random point field on $\mathbb{Z}^d$ with the translation-invariant kernel $K(x,y) = \hat{g}(x - y)$. Below we discuss several examples that fall into this category. For further discussion we refer the reader to Lyons (2003) and Soshnikov (2000).

1. In the trivial case when $g$ is identically a constant $p \in [0,1]$, we obtain the i.i.d. Bernoulli probability measure.
2. The edges of the uniform spanning tree in $\mathbb{Z}^2$ parallel to the horizontal axis can be viewed as the determinantal random point field in $Z^2$ with

$$g(x,y) = \frac{\sin^2 \pi x}{\sin^2 \pi x + \sin^2 \pi y}$$

   Similarly, the edges of the uniform spanning forest in $Z^d$ parallel to the $x_1$-axis correspond to the function

$$g(x_1, \ldots, x_d) = \frac{\sin^2 \pi x_1}{\sum_{i=1}^d \sin^2 \pi x_i}$$

   (the uniform spanning forest on $\mathbb{Z}^d$ is a tree only for $d \le 4$). The result is due to Burton and Pemantle (1993).
3. Let $d = 1$ and $\gamma$ be a parameter between 0 and 1. Consider

$$g(x) = \frac{(1-\gamma)^2}{|\mathrm{e}^{2\pi i x} - \gamma|^2}$$

   The corresponding probability measure is a renewal process and

$$K(n) = \hat{g}(n) = \frac{1-\gamma}{1+\gamma}\gamma^{|n|}$$

   (see Soshnikov (2000)).
4. The process with $g(x) = \chi_I(x)$, where $I$ is an arbitrary arc of a unit circle, appeared in the work of Borodin and Olshanski (2000). The corresponding correlation kernel is known as the discrete sine kernel. The determinantal random point process on $\mathbb{Z}^1$ with the discrete sine kernel describes the typical form of large Young diagrams "in the bulk" (see the next subsection).
5. The discrete sine correlation kernel with $g = \chi_{[0,1/2]}$ appeared in the zig-zag process (Johansson 2002) derived from the uniform domino tilings in the plane. It corresponds to $g = \chi_{[0,1/2]}$.

## Determinantal Measures on Partitions

By a partition of $n = 1, 2, \ldots$ we understand a collection of non-negative integers $\lambda = (\lambda_1, \ldots, \lambda_m)$ such that $\lambda_1 + \cdots + \lambda_m = n$ and $\lambda_1 \ge \lambda_2 \ge \cdots \ge \lambda_m$. We shall use a notation Par$(n)$ for the set of all partitions of $n$.

The Plancherel measure $M_n$ on the set Par$(n)$ is defined as

$$M_n(\lambda) = \frac{(\dim \lambda)^2}{n!} \qquad [16]$$

where $\dim \lambda$ is the dimension of the corresponding irreducible representation of the symmetric group

$S_n$. Let $\text{Par} = \bigsqcup_{n=0}^{\infty} \text{Par}(n)$. Consider a probability measure $M^\theta$ on Par

$$M^\theta(\lambda) = e^{-\theta}\frac{\theta^n}{n!}M_n(\lambda) \quad \text{where}$$
$$\lambda \in \text{Par}(n),\ n = 0,1,2,\ldots,\quad 0 \le \theta < \infty \qquad [17]$$

$M^\theta$ is called the Poissonization of the measures $M_n$. The analysis of the asymptotic properties of $M_n$ and $M^\theta$ has been important in connection to the famous Ulam problem and related questions in representation theory.

It was shown by Borodin and Okounkov (2000), and, independently, Johansson (2001) that $M^\theta$ is a determinantal random point field. The corresponding correlation kernel $K$ (in the so-called modified Frobenius coordinates) is a so-called discrete Bessel kernel on $\mathbb{Z}^1$,

$$K(x,y) = \begin{cases} \sqrt{\theta}\,\dfrac{J_{|x|-1/2}(2\sqrt{\theta})J_{|y|+1/2}(2\sqrt{\theta}) - J_{|x|+1/2}(2\sqrt{\theta})J_{|y|-1/2}(2\sqrt{\theta})}{|x|-|y|} \\ \text{if } xy > 0 \\ \sqrt{\theta}\,\dfrac{J_{|x|-1/2}(2\sqrt{\theta})J_{|y|-1/2}(2\sqrt{\theta}) - J_{|x|+1/2}(2\sqrt{\theta})J_{|y|+1/2}(2\sqrt{\theta})}{x-y} \\ \text{if } xy < 0 \end{cases} \qquad [18]$$

where $J_x(\cdot)$ is the Bessel function of order $x$. One can observe that the kernel $K(x,y)$ is not Hermitian, but the restriction of this kernel to the positive and negative semiaxis is Hermitian.

$M^\theta$ is a special case of an infinite parameter family of probability measures on Par, called the Schur measures, and defined as

$$M(\lambda) = \frac{1}{Z}s_\lambda(x)s_\lambda(y) \qquad [19]$$

where $s_\lambda$ are the Schur functions, $x = (x_1, x_2, \ldots)$ and $y = (y_1, y_2, \ldots)$ are parameters such that

$$Z = \sum_{\lambda \in \text{Par}} s_\lambda(x)s_\lambda(y) = \prod_{i,j}(1 - x_i y_j)^{-1} \qquad [20]$$

is finite and $\{x_i\}_{i=1}^\infty = \overline{\{y_i\}_{i=1}^\infty}$. It was shown by Okounkov (2001), that the Schur measures belong to the class of the determinantal random point fields.

### NonIntersecting Paths of a Markov Process

Let $p_{t,s}(x,y)$ be the transition probability of a Markov process $\xi(t)$ on $\mathbb{R}$ with continuous trajectories and let $(\xi_1(t), \xi_2(t), \ldots, \xi_n(t))$ be $n$ independent copies of the process. A classical result of Karlin and McGregor (1959) states that if $n$ particles start at the positions $x_1^{(0)} < x_2^{(0)} < \cdots < x_n^{(0)}$, then the probability density of their joint distribution at time $t_1 > 0$, given that their paths have not intersected for all $0 \le t \le t_1$, is equal to

$$\pi_{t_1}(x_1^{(1)}, \ldots, x_n^{(1)}) = \frac{1}{Z}\det(p_{0,t_1}(x_i^{(0)}, x_j^{(1)}))_{i,j=1}^n$$

provided the process $(\xi_1(t), \xi_2(t), \ldots, \xi_n(t))$ in $\mathbb{R}^n$ has a strong Markovian property.

Let $0 < t_1 < t_2 < \cdots < t_{M+1}$. The conditional probability density that the particles are in the positions $x_1^{(1)} < x_2^{(1)} < \cdots < x_n^{(1)}$ at time $t_1$, at the positions $x_1^{(2)} < x_2^{(2)} < \cdots < x_n^{(2)}$ at time $t_2, \ldots,$ at the positions $x_1^{(M)} < x_2^{(M)} < \cdots < x_n^{(M)}$ at time $t_M$, given that at time $t_{M+1}$ they are at the positions $x_1^{(M+1)} < x_2^{(M+1)} < \cdots < x_n^{(M+1)}$ and their paths have not intersected, is then equal to

$$\pi_{t_1,t_2,\ldots,t_M}(x_1^{(1)}, \ldots, x_n^{(M)}) = \frac{1}{Z_n, M}\prod_{l=0}^{M}\det(p_{t_l,t_{l+1}}(x_i^{(l)}, x_j^{(l+1)}))_{i,j=1}^n \qquad [21]$$

where $t_0 = 0$.

It is not difficult to show that [21] can be viewed as a determinantal random point process (see, e.g., Johansson (2003).

The formulas of a similar type also appeared in the papers by Johansson, Prähofer, Spohn, Ferrari, Forrester, Nagao, Katori, and Tanemura in the analysis of polynuclear growth models, random walks on a discrete circle, and related problems.

## Ergodic Properties

As before, let $(X, \mathcal{B}, \Pr)$ be a random point field with a one-particle space $E$. Hence, $X$ is a space of the locally finite configurations of particles in $E$, $\mathcal{B}$ a Borel $\sigma$-algebra of measurable subsets of $X$, and Pr a probability measure on $(X, B)$. Throughout this section, we assume $E = \mathbb{R}^d$ or $\mathbb{Z}^d$. We define an action $\{T^t\}_{t \in E}$ of the additive group $E$ on $X$ in the following natural way:

$$T^t : X \to X,\ (T^t\xi)_i = (\xi)_i + t \qquad [22]$$

We recall that a random point field $(X, \mathcal{B}, P)$ is called translation invariant if, for any $A \in \mathcal{B}$, any $t \in E$, $\Pr(T^{-t}A) = \Pr(A)$. The translation invariance of the correlation kernel $K(x,y) = K(x-y, 0) =: K(x-y)$ implies the translation invariance of $k$-point correlation functions

$$\rho_k(x_1 + t, \ldots, x_k + t) = \rho_k(x_1, \ldots, x_k)$$
$$\text{a.e. } k = 1, 2, \ldots,\quad t \in E \qquad [23]$$

which, in turn, implies the translation invariance of the random point field. The ergodic properties

of such point fields were studied by several mathematicians (Soshnikov 2000, Shirai and Takahashi, 2003, Lyons and Steif 2003). The first general result in this direction was obtained by Soshnikov (2000).

**Theorem 2** *Let* $(X, B, P)$ *be a determinantal random point field with a translation-invariant correlation kernel. Then the dynamical system* $(X, B, P, \{T^t\})$ *is ergodic, has the mixing property of any multiplicity and its spectra is absolutely continuous.*

We refer the reader to the article on ergodic theory for the definitions of ergodicity, mixing property, absolute continuous spectrum of the dynamical system, etc.

In the discrete case [15], $E = \mathbb{Z}^d$, more is known. Lyons and Steif (2003) proved that the shift dynamical system is Bernoulli, that is, it is isomorphic (in the ergodic theory sense) to an i.i.d. process. Under the additional conditions $\mathrm{Spec}(K) \subset (0,1)$ and $\sum_n |n||K(n)|^2 < \infty$, Shirai and Takahashi (2003a) proved the uniform mixing property.

## Gibbsian Properties

Costin and Lebowitz (1995) were the first to question the Gibbsian nature of the determinantal random point fields; they studied the continuous determinantal random point process on $\mathbb{R}^1$ with a so-called sine correlation kernel

$$K(x, y) = \frac{\sin(\pi(x-y))}{\pi(x-y)}$$

The first rigorous result (in the discrete case) was established by Shirai and Takahashi (2003b).

**Theorem 3** *Let E be a countable discrete space and K a symmetric bounded operator on* $l^2(E)$. *Assume that* $\mathrm{Spec}(K) \subset (0,1)$. *Then* $(X, B, P)$ *is a Gibbs measure with the potential U given by* $U(x|\xi) = -\log(J(x,x) - \langle J_\xi^{-1} j_\xi^x, j_\xi^x \rangle)$, *where* $x \in E, \xi \in X$, $\{x\} \cap \xi = \emptyset$. *Here* $J(x,y)$ *stands for the kernel of the operator* $J = (\mathrm{Id} - K)^{-1} K$, *and we set* $J_\xi = (J(y,z))_{y,z \in \xi}$ *and* $j_\xi^x = (J(x,y))_{y \in \xi}$.

We recall that the Gibbsian property of the probability measure $P$ on $(X, \mathcal{B})$ means that

$$E[F|\mathcal{B}_{\Lambda^c}](\xi) = \frac{1}{Z_{\Lambda,\xi}} \sum_{\eta \subset \Lambda} \mathrm{e}^{-U(\eta|\xi_{\Lambda^c})} F(\eta \cup \xi_{\Lambda^c})$$

where $\Lambda$ is a finite subset of $E$, $\mathcal{B}_{\Lambda^c}$ is the $\sigma$-algebra generated by the $\mathcal{B}$-measurable functions with the support outside of $\Lambda$, $E[F|\mathcal{B}_{\Lambda^c}]$ is the conditional mathematical expectation of the integrable function $F$ on $(X, \mathcal{B}, P)$ with respect to the $\sigma$-algebra $\mathcal{B}_{\Lambda^c}$. The potential $U$ is uniquely defined by the values of $U(x, \xi)$, as follows from the following recursive relation:

$$\begin{aligned} U(\{x_1, \ldots, x_n\}|\xi) &= U(x_n|\{x_1, \ldots, x_{n-1}\} \cup \xi) \\ &\quad + U(x_{n-1}|\{x_1, \ldots, x_{n-2}\} \cup \xi) \\ &\quad + \cdots + U(x_1|\xi) \end{aligned}$$

For additional information about the Gibbsian property, *see* Introductory Articles: Equilibrium Statistical Mechanics. Much less is known in the continuous case. Some generalized form of Gibbsianness, under quite restrictive conditions, was recently established by Georgii and Yoo (2004).

## Central Limit Theorem for Counting Function

In this section, we discuss the central-limit theorem type results for the linear statistics. The first important result in this direction was established by Costin and Lebowitz in 1995, who proved the central-limit theorem for the number of particles in the growing box, $\#_{[-L,L]}, L \to \infty$, in the case of the determinantal random point process on $\mathbb{R}^1$ with the sine correlation kernel

$$K(x, y) = \frac{\sin(\pi(x-y))}{\pi(x-y)}$$

Below we formulate the Costin–Lebowitz theorem in its general form due to Soshnikov (1999, 2000).

**Theorem 4** *Let E be a one-particle space,* $\{0 \le K_t \le 1\}$ *a family of locally trace-class operators in* $L^2(E), \{(X, \mathcal{B}, P_t)\}$ *a family of the corresponding determinantal random point fields in E, and* $\{I_t\}$ *a family of measurable subsets in E such that*

$$\begin{aligned} &\mathrm{Var}\#_{I_t} \\ &\quad = \mathrm{tr}(K_t \cdot \chi_{I_t} - (K_t \cdot \chi_{I_t})^2) \to \infty \quad \text{as } t \to \infty \end{aligned} \qquad [24]$$

*Then the distribution of the normalized number of particles in* $I_t$ *(with respect to* $P_t$*) converges to the normal law, that is,*

$$\frac{\#_{I_t} - \mathbb{E}\#_{I_t}}{\sqrt{\mathrm{Var}\#_{I_t}}} \xrightarrow{w} N(0,1)$$

An analogous result holds for the joint distribution of the counting functions $\{\#_{I_{t1}}, \ldots, \#_{I_{tk}}\}$, where $I_t^1, \ldots, I_t^k$ are disjoint measurable subsets in $E$.

The proof of the Costin–Lebowitz theorem uses the $k$-point cluster functions. In the determinantal case, the cluster functions have a simple form

$$r_k(x_1, \ldots, x_k) = (-1)^l \frac{1}{l} \sum_{\sigma \in S_k} K(x_{\sigma(1)}, x_{\sigma(2)}) K(x_{\sigma(2)}, x_{\sigma(3)}) \cdots \times K(x_{\sigma(k)}, x_{\sigma(1)}) \qquad [25]$$

The importance of the cluster function stems from the fact that the integrals of the $k$-point cluster function over the $k$-cube with a side $I$ can be expressed as a linear combination of the first $k$ cumulants of the counting random variable $\#_I$. In other words,

$$\int_{I \times \ldots \times I} r_k(x_1, \ldots, x_k)\, dx_1 \cdots dx_k = \sum_{l=1}^{k} \beta_{kl} C_l(\#_I) \qquad [26]$$

It follows from [25] that the integral at the LHS of [26] equals, up to a factor $(-1)^l (l-1)!$, to the trace of the $k$th power of the restriction of $K$ to $I$. This allows one to estimate the cumulants of the counting random variable $\#_I$. For details, we refer the reader to Soshnikov (2000). The central-limit theorem for a general class of linear statistics, under some technical assumptions on the correlation kernel was proved in Soshnikov (2002). Finally, we refer the reader to Soshnikov (2000) for the functional central-limit theorem for the empirical distribution function of the nearest spacings.

## Generalizations: Immanantal and Pfaffian Point Processes

In this section, we discuss two important generalizations of the determinantal point processes.

### Immanantal Processes

Immanantal random point processes were introduced by P Diaconis and S N Evans in 2000. Let $\lambda$ be a partition of $n$. Denote by $\chi^\lambda$ the character of the corresponding irreducible representation of the symmetric group $S_n$. Let $K(x, y)$, be a non-negative-definite, Hermitian kernel. An immanantal random point process is defined through the correlation functions

$$\rho_k(x_1, \ldots, x_k) = \sum_{\sigma \in S_n} \chi^\lambda(\sigma) \prod_{i=1}^{n} K(x_i, x_{\sigma(i)}) \qquad [27]$$

In other words, the correlation functions are given by the immanants of the matrix with the entries $K(x_i, x_j)$. We will denote the RHS of [27] by $K^\lambda[x_1, \ldots, x_n]$.

In the special case $\lambda = (1^n)$ (i.e., $\lambda$ consists of $n$ parts, all of which equal to 1), one obtains that $\chi^\lambda(\sigma) = (-1)^\sigma$, and $K^\lambda[x_1, \ldots, x_n] = \det(K(x_i, x_j))$. Therefore, in the case $\lambda = (1^n)$ the random point process with the correlation functions [27] is a determinantal random point process. When $\lambda = (n)$ (i.e., the permutation has only one part, namely $n$) we have $\chi^\lambda = 1$ identically, and $K^\lambda[x_1, \ldots, x_n] = \mathrm{per}(K(x_i, x_j))$, the permanent of the matrix $K(x_i, x_j)$. The corresponding random point process is known as the boson random point process.

### Pfaffian Processes

Let

$$K(x, y) = \begin{pmatrix} K_{11}(x, y) & K_{12}(x, y) \\ K_{21}(x, y) & K_{22}(x, y) \end{pmatrix}$$

be an antisymmetric $2 \times 2$ matrix-valued kernel, that is, $K_{ij}(x, y) = -K_{ji}(y, x)$, $i, j = 1, 2$. The kernel defines an integral operator acting on $L^2(E) \bigoplus L^2(E)$, which we assume to be locally trace class. A random point process on $E$ is called Pfaffian if its point correlation functions have a Pfaffian form

$$\rho_k(x_1, \ldots, x_k) = \mathrm{pf}(K(x_i, x_j))_{i,j=1,\ldots,k}, \quad k \geq 1 \qquad [28]$$

The RHS of [28] is the Pfaffian of the $2k \times 2k$ antisymmetric matrix (since each entry $K(x_i, x_j)$ is a $2 \times 2$ block). Determinantal random point processes is a special case of the Pfaffian processes, corresponding to the matrix kernel of the form

$$K(x, y) = \begin{pmatrix} 0 & \tilde{K}(x, y) \\ -\tilde{K}(y, x) & 0 \end{pmatrix}$$

where $\tilde{K}$ is a scalar kernel. The most well known examples of the Pfaffian random point processes, that cannot be reduced to determinantal form are $\beta = 1$ and $\beta = 4$ polynomial ensembles of random matrices and their limits (in the bulk and at the edge of the spectrum), as the size of a matrix goes to infinity.

# Diagrammatic Techniques in Perturbation Theory

**G Gentile**, Università degli Studi "Roma Tre", Rome, Italy

## Introduction

Consider the dynamical system on $\mathbb{R}^d$ described by the equation

$$\dot{u} = \frac{\mathrm{d}u}{\mathrm{d}t} = G(u) + \varepsilon F(u) \qquad [1]$$

where $F, G : \mathcal{S} \subset \mathbb{R}^d \to \mathbb{R}^d$ are analytic functions and $\varepsilon$ a real (small) parameter. Suppose also that for $\varepsilon = 0$ a solution $u_0 : \mathbb{R} \to \mathcal{S}$ (for some initial condition $u_0(0) = \bar{u}$) is known.

We look for a solution of [1] which is a perturbation of $u_0$, that is, for a solution $u$ which can be written in the form $u = u_0 + U$, with $U = O(\varepsilon)$ and $U(0) = \bar{U} \equiv u(0) - \bar{u}$. Then we consider the variational equation

$$\dot{U} = M(t)U + \Phi(t), \quad M_{ij}(t) = \partial_{u_i} G_j(u_0(t)) \qquad [2]$$

where $\Phi(t) = \tilde{\Phi}(u_0(t), U)$, with $\tilde{\Phi}(u_0, U) = G(u_0 + U) - G(u_0) - \partial_u G(u_0)U + \varepsilon F(u_0 + U)$. By defining the Wronskian matrix $W$ as the solution of the matrix equation $\dot{W} = M(t)W$ such that $W(0) = \mathbb{1}$ (the columns of $W$ are given by $d$ independent solutions of the linear equation $\dot{u} = M(t)u$), we can write

$$U(t) = W(t)\bar{U} + W(t)\int_0^t \mathrm{d}\tau W^{-1}(\tau)\Phi(\tau) \qquad [3]$$

If we expect the solution $U$ to be of order $\varepsilon$, we can try to write it as a Taylor series in $\varepsilon$, that is,

$$U(t) = \sum_{k=1}^{\infty} \varepsilon^k U^{(k)} \qquad [4]$$

and, by inserting [4] into [3] and equating the coefficients with the same Taylor order, we obtain

$$U^{(k)}(t) = W(t)\bar{U}^{(k)} + W(t)\int_0^t \mathrm{d}\tau\, W^{-1}(\tau)\Phi^{(k)}(\tau) \qquad [5]$$

where $\Phi^{(k)}(t)$ is defined as

$$\Phi^{(1)}(t) = F(u_0(t))$$

$$\Phi^{(k)}(t) = \sum_{p=2}^{\infty} \frac{1}{p!}\frac{\partial^p G}{\partial u^p}(u_0(t)) \sum_{k_1+\cdots+k_p=k} U^{(k_1)}\cdots U^{(k_p)} + \sum_{p=1}^{\infty}\frac{1}{p!}\frac{\partial^p F}{\partial u^p}(u_0(t)) \times \sum_{k_1+\cdots+k_p=k-1} U^{(k_1)}\cdots U^{(k_p)} \quad k \geq 2 \qquad [6]$$

Hence $\Phi^{(k)}(t)$ depends only on coefficients of orders strictly less than $k$. In this way, we obtain an algorithm useful for constructing the solution recursively, so that the problem is solved, up to (substantial) convergence problems.

## Historical Excursus

The study of a system like [1] by following the strategy outlined above can be hopeless if we do not make some further assumptions on the types of motions we are looking for.

We shall see later, in a concrete example, that the coefficients $U^{(k)}(t)$ can increase in time, in a $k$-dependent way, thus preventing the convergence of the series for large $t$. This is a general feature of this class of problems: if no care is taken in the choice of the initial datum, the algorithm can provide a reliable description of the dynamics only for a very short time.

However, if one looks for solutions having a special dependence on time, things can work better. This happens, for instance, if one looks for quasiperiodic solutions, that is, functions which depend on time through the variable $\psi = \omega t$, with $\omega \in \mathbb{R}^N$ a vector with rationally independent components, that is such that $\omega \cdot \nu \neq 0$ for all $\nu \in \mathbb{Z}^N \setminus \{0\}$ (the dot denotes the standard inner product, $\omega \cdot \nu = \omega_1\nu_1 + \cdots + \omega_N\nu_N$). A typical problem of interest is: what happens to a quasiperiodic solution $u_0(t)$ when a perturbation $\varepsilon F$ is added to the unperturbed vector field $G$, as in [1]? Situations of this type arise when considering perturbations of integrable systems: a classical example is provided by planetary motion in celestial mechanics.

Perturbation series such as [4] have been extensively studied by astronomers in order to obtain a more accurate description of the celestial motions compared to that following from Kepler's theory (in which all interactions between planets are neglected and the planets themselves are considered as points). In particular, we recall the works of Newcomb and Lindstedt (series such as [4] are now known as Lindstedt series). At the end of the nineteenth century, Poincaré showed that the series describing quasiperiodic motions are well defined up to any perturbation order $k$ (at least if the perturbation is a trigonometric polynomial), provided that the components of $\omega$ are assumed to be rationally independent: this means that, under this condition, the coefficients $U^{(k)}(t)$ are defined for all $k \in \mathbb{N}$. However, Poincaré also showed that, in general, the series are divergent; this is due to the fact that, as seen later, in the perturbation series small divisors $\omega \cdot \nu$ appear, which, even if they do not vanish, can be arbitrarily close to zero.

The convergence of the series can be proved indeed (more generally for analytic perturbations, or even those that are differentiably smooth enough) by assuming on $\omega$ a stronger nonresonance condition, such as the Diophantine condition

$$|\omega \cdot \nu| > \frac{C_0}{|\nu|^\tau} \quad \forall \nu \in \mathbb{Z}^N \setminus \{0\} \qquad [7]$$

where $|\nu| = |\nu_1| + \cdots + |\nu_N|$, and $C_0$ and $\tau$ are positive constants. We note that the set of vectors satisfying [7] for some positive constant $C_0$ have full measure in $\mathbb{R}^N$ provided one takes $\tau > N - 1$.

Such a result is part of the Kolmogorov–Arnold–Moser (KAM) theorem, and it was first proved by Kolmogorov in 1954, following an approach quite different fom the one described here. New proofs were given in 1962 by Arnol'd and by Moser, but only very recently, in 1988, Eliasson gave a proof in which a bound $C^k$ is explicitly derived for the coefficients $U^{(k)}(t)$, again implying convergence for $\varepsilon$ to be small enough.

Eliasson's work was not immediately known widely, and only after publication of papers by Gallavotti and by Chierchia and Falcolini, in which Eliasson's ideas were revisited, did his work become fully appreciated. The study of perturbation series [4] employs techniques very similar to those typical of a very different field of mathematical physics, the quantum field theory, even if such an analogy was stressed and used to full extent only in subsequent papers.

The techniques have so far been applied to a wide class of problems of dynamical systems: a list of original results is given at the end.

## A Paradigmatic Example

Consider the case $\mathcal{S} = \mathcal{A} \times \mathbb{T}^N$, with $\mathcal{A}$ an open subset of $\mathbb{R}^N$, and let $\mathcal{H}_0 : \mathcal{A} \to \mathbb{R}$ and $f : \mathcal{A} \times \mathbb{T}^N \to \mathbb{R}$ be two analytic functions. Then consider the Hamiltonian system with Hamiltonian $\mathcal{H}(A,\alpha) = \mathcal{H}_0(A) + \varepsilon f(A,\alpha)$. The corresponding equations describe a dynamical system of the form [1], with $u = (A,\alpha)$, which can be written explicitly:

$$\begin{cases} \dot{A} = -\varepsilon \partial_\alpha f(A,\alpha) \\ \dot{\alpha} = \partial_A \mathcal{H}_0(A) + \varepsilon \partial_A f(A,\alpha) \end{cases} \qquad [8]$$

Suppose, for simplicity, $\mathcal{H}_0(A) = A^2/2$ and $f(A,\alpha) = f(\alpha)$, where $A^2 = A \cdot A$. Then, we obtain for $\alpha$ the following closed equation:

$$\ddot{\alpha} = -\varepsilon \partial_\alpha f(\alpha) \qquad [9]$$

while $A$ can be obtained by direct integration once [9] has been solved. For $\varepsilon = 0$, [9] gives trivially $\alpha = \alpha_0(t) \equiv \alpha_0 + \omega t$, where $\omega = \partial_A \mathcal{H}_0(A_0) = A_0$ is

called the rotation (or frequency) vector. Hence, for $\varepsilon = 0$ all solutions are quasiperiodic. We are interested in the preservation of quasiperiodic solutions when $\varepsilon \neq 0$.

For $\varepsilon \neq 0$, we can write, as in [3],

$$\alpha = \alpha_0(t) + a(t), \quad a(t) = \sum_{k=1}^{\infty} \varepsilon^k a^{(k)}(t) \qquad [10]$$

where $a^{(k)}$ is determined as the solution of the equation

$$a^{(k)} = t\bar{A}^{(k)} + \bar{a}^{(k)}(t) - \int_0^t \mathrm{d}\tau \int_0^\tau \mathrm{d}\tau' [\partial_\alpha f(\alpha(\tau'))]^{(k-1)} \qquad [11]$$

with $[\partial_\alpha f(\alpha(\tau'))]^{(k-1)}$ expressed as in [6].

The quasiperiodic solutions with rotation vector $\omega$ could be written as a Fourier series, by expanding

$$a^{(k)}(t) = \sum_{\nu \in \mathbb{Z}^N} \mathrm{e}^{\mathrm{i}\nu\cdot\omega t} a_\nu^{(k)} \qquad [12]$$

with $\omega$ as before. If the series [10], with the Taylor coefficients as in [12], exists, it will describe a quasiperiodic solution analytic in $\varepsilon$, and in such a case we say that it is obtained by continuation of the unperturbed one with rotation vector $\omega$, that is $\alpha_0(t)$.

Suppose that the integrand $[\partial_\alpha f(\alpha(\tau'))]^{(k-1)}$ in [11] has vanishing average. Then the integral over $\tau'$ in [11] produces a quasiperiodic function, which in general has a nonvanishing average, so that the integral over $\tau$ produces a quasiperiodic function plus a term linear in $t$. If we choose $\bar{A}^{(k)}$ in [11] so as to cancel out exactly the term linear in time, we end up with a quasiperiodic function. In Fourier space, an explicit calculation gives, for all $\nu \neq 0$,

$$a_\nu^{(1)} = \frac{1}{(\omega\cdot\nu)^2}\mathrm{i}\nu f_\nu$$
$$a_\nu^{(k)} = \frac{1}{(\omega\cdot\nu)^2}\sum_{p=1}^{\infty}\sum_{\substack{k_1+\cdots+k_p=k-1\\ \nu_0+\nu_1+\cdots+\nu_p=\nu}} \frac{(\mathrm{i}\nu_0)^{p+1}}{p!} a_{\nu_1}^{(k_1)}\ldots a_{\nu_p}^{(k_p)}$$
$$k \geq 2 \qquad [13]$$

which again is suitable for an iterative construction of the solution. The coefficients $a_0^{(k)}$ are left undetermined, and we can fix them (arbitrarily) as identically vanishing.

Of course, the property that the integrand in [11] has zero average is fundamental; otherwise, terms increasing as powers of $t$ would appear (the so-called secular terms). Indeed, it is easy to realize that, if this happened, to order $k$ terms proportional to $t^{2k}$ could be present, thus requiring, at best, $|\varepsilon| < |t|^{-2}$ for convergence up to time $t$. This would exclude *a fortiori* the possibility of quasiperiodic solutions.

The aforementioned property of zero average can be verified only if the rotation vector is nonresonant, that is, if its components are rationally independent or, more particularly, if the Diophantine condition [7] is satisfied. Such a result was first proved by Poincaré, and it holds irrespective of how the parameters $\bar{a}^{(k)}$ appearing in [11] are fixed. This reflects the fact that quasiperiodic motions take place on invariant surfaces (KAM tori), which can be parameterized in terms of the angle variables $\alpha(t)$, so that the values $\bar{a}^{(k)}$ contribute to the initial phases, and the latter can be arbitrarily fixed.

The recursive equations [13] can be suitably studied by introducing a diagrammatic representation, as explained below.

## Graphs and Trees

A (connected) graph $\mathbb{G}$ is a collection of points, called vertices, and lines connecting all of them. We denote with $V(\mathbb{G})$ and $L(\mathbb{G})$ the set of vertices and the set of lines, respectively. A path between two vertices is a minimal subset of $L(\mathbb{G})$ connecting the two vertices. A graph is planar if it can be drawn in a plane without graph lines crossing.

A tree is a planar graph $\mathbb{G}$ containing no closed loops (cycles); in other words, it is a connected acyclic graph. One can consider a tree $\mathbb{G}$ with a single special vertex $\mathrm{v}_0$: this introduces a natural partial ordering on the set of lines and vertices, and one can imagine that each line carries an arrow pointing toward the vertex $\mathrm{v}_0$. We can add an extra oriented line $\ell_0$ connecting the special vertex $\mathrm{v}_0$ to another point which will be called the root of the tree; the added line will be called the root line. In this way, we obtain a rooted tree $\theta$ defined by $V(\theta) = V(\mathbb{G})$ and $L(\theta) = L(\mathbb{G}) \cup \ell_0$. A labeled tree is a rooted tree $\theta$ together with a label function defined on the sets $V(\theta)$ and $L(\theta)$.

Two rooted trees which can be transformed into each other by continuously deforming the lines in the plane in such a way that the latter do not cross each other (i.e., without destroying the graph structure) will be said to be equivalent. This notion of equivalence can also be extended to labeled trees, simply by considering equivalent two labeled trees if they can be transformed into each other in such a way that the labels also match.

Given two vertices $\mathrm{v}, \mathrm{w} \in V(\theta)$, we say that $\mathrm{w} \prec \mathrm{v}$ if $\mathrm{v}$ is on the path connecting $\mathrm{w}$ to the root line. One

can identify a line with the vertices it connects; given a line $\ell = (\mathrm{v}, \mathrm{w})$, one says that $\ell$ enters v and exits w. For each vertex v, we define the branching number as the number $p_\mathrm{v}$ of lines entering v.

The number of unlabeled trees with $k$ vertices can be bounded by the number of random walks with $2k$ steps, that is, by $4^k$.

The labels are as follows: with each vertex v we associate a mode label $\nu_\mathrm{v} \in \mathbb{Z}^N$, and with each line we associate a momentum $\nu_\ell \in \mathbb{Z}^N$, such that the momentum of the line leaving the vertex v is given by the sum of the mode labels of all vertices preceding v (with v being included): if $\ell = (\mathrm{v}', \mathrm{v})$ then $\nu_\ell = \sum_{\mathrm{w} \preceq \mathrm{v}} \nu_\mathrm{w}$. Note that for a fixed unlabeled tree the branching labels are uniquely determined, and, for a given assignment of the mode labels, the momenta of the lines are also uniquely determined.

Define

$$V_\mathrm{v} = \frac{(\mathrm{i}\nu_\mathrm{v})^{p_\mathrm{v}+1}}{p_\mathrm{v}!} f_{\nu_\mathrm{v}}, \qquad g_\ell = \frac{1}{(\omega \cdot \nu_\ell)^2} \qquad [14]$$

where the tensor $V_\mathrm{v}$ is referred to as the node factor of v and the scalar $g_\ell$ as the propagator of the line $\ell$. One has $|f_\nu| \le F\,\mathrm{e}^{-\kappa|\nu|}$, for suitable positive constants $F$ and $\kappa$, by the analyticity assumption. Then one can check that the coefficients $a_\nu^{(k)}$, defined in [12], for $\nu \neq 0$, can be expressed in terms of trees as

$$a_\nu^{(k)} = \sum_{\theta \in \Theta_\nu^{(k)}} \mathrm{Val}(\theta)$$
$$\mathrm{Val}(\theta) = \left( \prod_{\mathrm{v} \in V(\theta)} V_\mathrm{v} \right) \left( \prod_{\ell \in L(\theta)} g_\ell \right) \qquad [15]$$

where $\Theta_\nu^{(k)}$ denotes the set of all inequivalent trees with $k$ vertices and with momentum $\nu$ associated with the root line, while the coefficients $a_0^{(k)}$ can be fixed $a_0^{(k)} = 0$ for all $k \ge 1$, by the arbitrariness of the initial phases previously remarked. The property that $[\partial_\alpha f(\alpha(\tau'))]^{(k-1)}$ in [11] has zero average for all $k \ge 1$ implies that for all lines $\ell \in L(\theta)$ one has $g_\ell = (\omega \cdot \nu_\ell)^{-2}$ only for $\nu_\ell \neq 0$, whereas $g_\ell = 1$ for $\nu_\ell = 0$, so that the numerical values $\mathrm{Val}(\theta)$ are well defined for all trees $\theta$. If $a_0^{(k)} = 0$ for all $k \ge 1$, then $\nu_\ell \neq 0$ for all $\ell \in L(\theta)$.

The proof of [15] can be performed by induction on $k$. Alternatively, we can start from the recursive definition [13], whereby the trees naturally arise in the following way.

Represent graphically the coefficient $a_\nu^{(k)}$ as in Figure 1; to keep track of the labels $k$ and $\nu$, we assign $k$ to the black bullet and $\nu$ to the line. For $k = 1$, the black bullet is meant as a grey vertex (like the ones appearing in Figure 3).

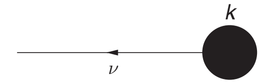

**Figure 1** Graphical representation of $a_\nu^{(k)}$.

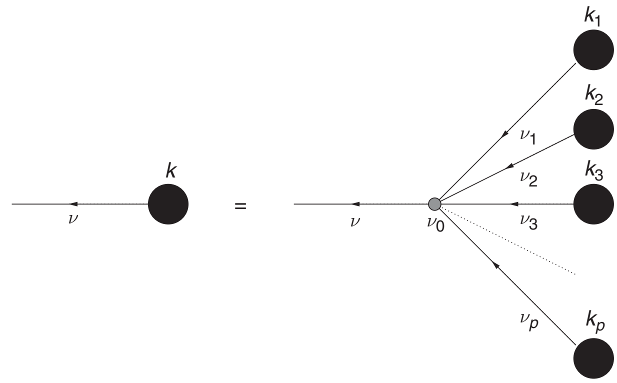

**Figure 2** Graphical representation of the recursive equation [13].

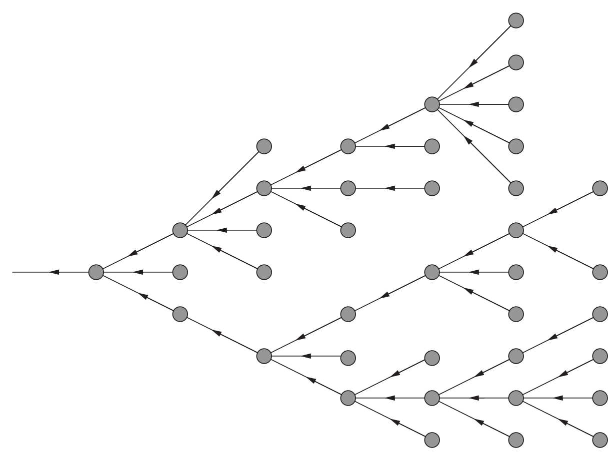

**Figure 3** An example of tree to be summed over in [15] for $k = 39$. The labels are not explicitly shown. The momentum of the root line is $\nu$, so that the mode labels satisfy the constraint $\sum_{v \in V(\theta)} \nu_v = \nu$.

Then recursive equation [13] can be graphically represented as the diagram in Figure 2, provided that we associate with the (grey) vertex $\mathrm{v}_0$ the node factor $V_{\mathrm{v}_0}$, with $\nu_{\mathrm{v}_0} = \nu_0$ and $p_{\mathrm{v}_0} = p$ denoting the number of lines entering $\mathrm{v}_0$, and with the lines $\ell_i$, $i = 1, \ldots, p$, entering $\mathrm{v}_0$ the momenta $\nu_{\ell_i}$, respectively. Of course, the sums over $p$ and over the possible assignments of the labels $\{k_i\}_{i=1}^p$ and $\{\nu_i\}_{i=0}^p$ are understood. Each black bullet on the right-hand side of Figure 2, together with its exiting line looks like the diagram on the left-hand side, so that it represents $a_{\nu_i}^{(k_i)}$, $i = 1, \ldots, p$. Note that Figure 2 has to be interpreted in the following way: if one associates with the diagram as drawn in the right-hand side a numerical value (as

described above) and one sums all the values over the assignments of the labels, then the resulting quantity is precisely $a_\nu^{(k)}$.

The (fundamental) difference between the black bullets on the right- and left-hand sides is that the labels $k_i$ of the latter are strictly less than $k$, hence we can iterate the diagrammatic decomposition simply by expressing again each $a_{\nu_i}^{(k_i)}$ as $a_\nu^{(k)}$ in [13], and so on, until one obtains a tree with $k$ grey vertices and no black bullets; see Figure 3, where the labels are not explicitly written. This corresponds to the tree expansion [15].

Any tree appearing in [15] is an example of what physicists call a Feynman graph, while the diagrammatic rules one has to follow in order to associate to the tree $\theta$ its right numerical value $\mathrm{Val}(\theta)$ are usually called the Feynman rules for the model under consideration. Such a terminology is borrowed from quantum field theory.

## Multiscale Analysis and Clusters

Suppose we replace [9] with $\alpha = \varepsilon\partial_\alpha f(\alpha)$, so that no small divisors appear (that is, $g_\ell = 1$ in [14]). Then convergence is easily proved for $\varepsilon$ small enough, since (by using the identity $\sum_{\mathrm{v}\in V(\theta)} p_\mathrm{v} = k-1$ and the inequality $\mathrm{e}^{-x}x^k/k! \le 1$ for all $x \in \mathbb{R}_+$ and all $k \in \mathbb{N}$), one finds

$$\prod_{\mathrm{v}\in v(\theta)} |V_\mathrm{v}| \le \left(\frac{4^2 F}{\kappa^2}\right)^k \mathrm{e}^{-\kappa|\nu|/4} \left(\prod_{\mathrm{v}\in v(\theta)} \mathrm{e}^{-\kappa|\nu_\mathrm{v}|/4}\right) \qquad [16]$$

and the sum over the mode labels can be performed by using the exponential decay factors $\mathrm{e}^{-\kappa|\nu_\mathrm{v}|/4}$, while the sum over all possible unlabeled trees gives $4^k$. In particular, analyticity in $t$ follows.

Of course, the interesting case is when the propagators are present. In such a case, even if no division by zero occurs, as $\omega\cdot\nu_\ell \neq 0$ (by the assumed Diophantine condition [13] and the absence of secular terms discussed previously), the quantities $\omega\cdot\nu_\ell$ in [14] can be very small.

Then we can introduce a scale $h$ characterizing the size of each propagator: we say that a line $\ell$ has scale $h_\ell = h \ge 0$ if $\omega\cdot\nu_\ell$ is of order $2^{-h}C_0$ and scale $h_\ell = -1$ if $\omega\cdot\nu_\ell$ is greater than $C_0$ (of course, a more formal definition can be easily envisaged, for which the reader is referred to the original papers). Then, we can bound $|\omega\cdot\nu_\ell| \ge 2^{-h}C_0$ for any $\ell \in L(\theta)$, and write

$$\prod_{\ell\in L(\theta)} |g_\ell| \le C_0^{-2k} \prod_{h=0}^{\infty} 2^{2hN_h(\theta)}$$
$$\le C_0^{-2k} 2^{2h_0 k} \exp\left(\sum_{h=h_0}^{\infty} 2\log 2\, hN_h(\theta)\right) \qquad [17]$$

where $N_h(\theta)$ is the number of lines in $L(\theta)$ with scale $h$ and $h_0$ is a (so far arbitrary) positive integer. The problem is then reduced to that of finding an estimate for $N_h(\theta)$.

To identify which kinds of tree are the source of problems, we introduce the notion of a cluster and a self-energy graph. A cluster $T$ with scale $h_T$ is a connected set of nodes linked by a continuous path of lines with the same scale label $h_T$ or a lower one and which is maximal, namely all the lines not belonging to $T$ but connected to it have scales higher than $h_T$ and at least one line in $T$ has scale $h_T$. An inclusion relation is established between clusters, in such a way that the innermost clusters are the clusters with lowest scale, and so on. Each cluster $T$ can have an arbitrary number of lines coming into it (entering lines), but only one or zero lines coming out from it (exiting line): lines of $T$ which either enter or exit $T$ are called external lines. A cluster $T$ with only one entering line $\ell_T^2$ and with one exiting line $\ell_T^1$ such that one has $\nu_{\ell_T^1} = \nu_{\ell_T^2}$ will be called a self-energy graph (SEG) or resonance. In such a case, the line $\ell_T^1$ is called a resonant line. Examples of clusters and SEGs are suggested by the bubbles in Figure 4; the mode labels are not represented, whereas the scales of the lines are explicitly written.

If $S_h(\theta)$ is the number of SEGs whose resonant lines have scales $h$, then $N_h^*(\theta) = N_h(\theta) - S_h(\theta)$ will denote the number of nonresonant lines with scale $h$.

A fundamental result, known as Siegel–Bryuno lemma, shows that, for some positive constant $c$, one has

$$N_h^*(\theta) \le 2^{h/\tau} c \sum_{\mathrm{v}\in V(\theta)} |\nu_\mathrm{v}| \qquad [18]$$

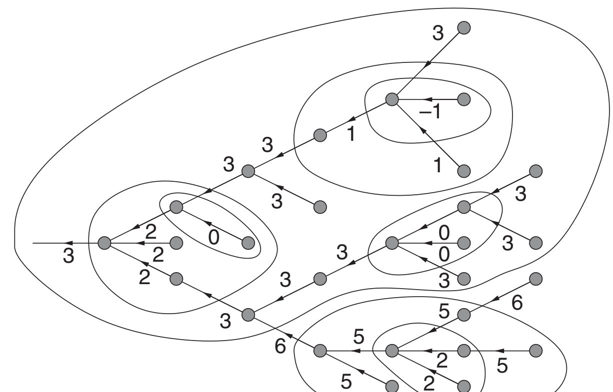

**Figure 4** Examples of clusters and SEGs. Note that the tree itself is a cluster (with scale 6), and each of the two clusters with one entering and one exiting lines is a SEG only if the momenta of its external lines are equal to each other.

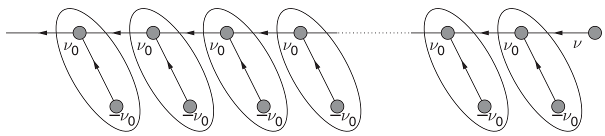

**Figure 5** Example of tree whose value grows like a factorial.

which, if inserted into [17] instead of $N_h(\theta)$, would give a convergent series; then $h_0$ should be chosen in such a way that the sum of the series in [17] is less than, say, $\kappa\sum_{v\in V(\theta)}|\nu_v|/8$.

The bound [18] is a very deep one, and was originally proved by Siegel for a related problem (Siegel's problem), in which, in the formalism followed here, SEGs do not occur; such a bound essentially shows that accumulation of small divisors is possible only in the presence of SEGs. A possible tree with $k$ vertices whose value can be proportional to some power of $k!$ is represented in Figure 5, where a chain of $(k-1)/2$ SEGs, $k$ odd, is drawn with external lines carrying a momentum $\nu$ such that $\omega\cdot\nu \approx C_0|\nu|^{-\tau}$.

In order to take into account the resonant lines, we have to add a factor $(\omega\cdot\nu_\ell)^{-2}$ for each resonant line $\ell$. It is a remarkable fact that, even if there are trees whose value cannot be bounded as a constant to the power $k$, there are compensations (that is, partial cancellations) between the values of all trees with the same number of vertices, such that the sum of all such trees admits a bound of this kind.

The cancellations can be described graphically as follows. Consider a tree $\theta$ with a SEG $T$. Then take all trees which can be obtained by shifting the external lines of $T$, that is, by attaching such lines to all possible vertices internal to $T$, and sum together the values of all such trees. An example is given in Figure 6. The corresponding sum turns out to be proportional to $(\omega\cdot\nu)^2$, if $\nu$ is the momentum of the resonant line of $T$, and such a factor compensates exactly the propagator of this line. The argument above can be repeated for all SEGs: this requires a little care because there are SEGs which are inside some other SEGs. Again, for details and a more formal discussion, the reader is referred to original papers.

The conclusion is that we can take into account the resonant lines: this simply adds an extra constant raised to the power $k$, so that an overall estimate $C^k$, for some $C>0$, holds for $U^{(k)}(t)$, and the convergence of the series follows.

## Other Examples and Applications

The discussion carried out so far proves a version of the KAM theorem, for the system described by [9], and it is inspired by the original papers by Eliasson (1996) and, mostly, by Gallavotti (1994).

Here we list some problems in which original results have been proved by means of the diagrammatic techniques described above, or by some variants of them. These are discussed in the following.

The first generalization one can think of is the problem of conservation in quasi-integrable systems of resonant tori (that is, invariant tori whose frequency vectors have rationally dependent components). Even if most of such tori disappear as an effect of the perturbation, some of them are conserved as lower-dimensional tori, which, generically, become of either elliptic or hyperbolic or mixed type according to the sign of $\varepsilon$ and the perturbation. With techniques extending those described here (introducing also, in particular, a suitable resummation procedure for divergent series), this has been done by Gallavotti and Gentile; see Gallavotti *et al.* (2004) and Gallavotti and Gentile (2005) for an account.

An expansion like the one considered so far can be envisaged also for the motions occurring on the stable and unstable manifolds of hyperbolic lower-dimensional tori for perturbations of Hamiltonians describing a system of rotators (as in the previous case) plus $n$ pendulum-like systems. In such a case, the function $G(u)$ has a less simple form. For $n=1$, one can look for solutions which depend on time through two variables, $\psi=\omega t$ and $x=e^{-gt}$, with $(\omega,g)\in\mathbb{R}^{N+1}$, and $\omega$ Diophantine as before and $g$ related to the timescale of the pendulum. This has been worked out by Gallavotti (1994), and then used by Gallavotti *et al.* (1999) to study a class of three-timescale systems, in order to obtain a lower

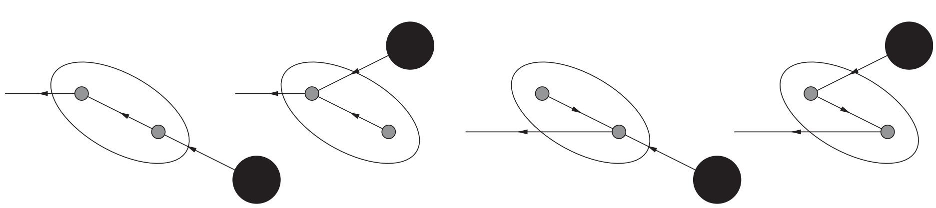

**Figure 6** Example of SEGs whose values have to be summed together in order to produce the cancellation discussed in the text. The mode labels are all fixed.

bound on the homoclinic angles (i.e., the angles between the stable and unstable manifolds of hyperbolic tori which are preserved by the perturbation). The formalism becomes a little more involved, essentially because of the entries of the Wronskian matrix appearing in [5]. In such a case, the unperturbed solution $u_0(t)$ corresponds to the rotators moving linearly with rotation vector $\omega$ and the pendulum moving along its separatrix; a nontrivial fact is that if $g_0$ denotes the Lyapunov exponent of the pendulum in the absence of the perturbation, then one has to look for an expansion in $x = e^{-gt}$ with $g = g_0 + O(\varepsilon)$, because the perturbation changes the value of such an exponent.

The same techniques have also been applied to study the relation of the radius of convergence of the standard map, an area-preserving diffeomorphism from the cylinder to itself, which has been widely studied in the literature since the original papers by Greene and by Chirikov, both appeared in 1979, with the arithmetical properties of the rotation vector (which is, in this case, just a number). In particular, it has been proved that the radius of convergence is naturally interpolated through a function of the rotation number known as Bryuno function (which has been introduced by Yoccoz as the solution of a suitable functional equation completely independent of the dynamics); see Berretti and Gentile (2001) for a review of results of this and related problems.

Also the generalized Riccati equation $\dot{u} - iu^2 - 2if(\omega t) + i\varepsilon^2 = 0$, where $\omega \in \mathbb{T}^d$ is Diophantine and $f$ is an analytic periodic function of $\psi = \omega t$, has been studied with the diagrammatic technique by Gentile (2003). Such an equation is related to two-level quantum systems (as first used by Barata), and existence of quasiperiodic solutions of the generalized Riccati equation for a large measure set $\mathcal{E}$ of values of $\varepsilon$ can be exploited to prove that the spectrum of the corresponding two-level system is pure point for those values of $\varepsilon$; analogously, one can prove that, for fixed $\varepsilon$, one can impose some further nonresonance conditons on $\omega$, still leaving a full measure set, in such a way that the spectrum is pure point. (We note, in addition, that, technically, such a problem is very similar to that of studying conservation of elliptic lower-dimensional tori with one normal frequency.)

Finally we mention a problem of partial differential equations, where, of course, the scheme described above has to be suitably adapted: this is the study of periodic solutions for the nonlinear wave equation $u_{tt} - u_{xx} + mu = \varphi(u)$, with Dirichlet boundary conditions, where $m$ is a real parameter (mass) and $\varphi(u)$ is a strictly nonlinear analytic odd function. Gentile and Mastropietro (2004) reproduced the result of Craig and Wayne for the existence of periodic solutions for a large measure set of periods, and, in a subsequent paper by the same authors with Procesi (2005), an analogous result was proved in the case $m = 0$, which had previously remained an open problem in literature.

# Dimer Problems

**R Kenyon**, University of British Columbia, Vancouver, BC, Canada

## Definitions

The dimer model arose in the mid-twentieth century as an example of an exactly solvable statistical mechanical model in two dimensions with a phase transition. It is used to model a number of physical processes: free fermions in 1 dimension, the two-dimensional Ising model, and various other two-dimensional statistical-mechanical models at restricted parameter values, such as the 6- and 8-vertex models and $O(n)$ models. A number of observable quantities such as the "height function" and densities of motifs have been shown to have conformal invariance properties in the scaling limit (when the lattice spacing tends to zero).

Recently, the model is also used as an elementary model of crystalline surfaces in $\mathbb{R}^3$.

A dimer covering, or perfect matching, of a graph is a set of edges ("dimers") which covers every vertex exactly once. In other words, it is a pairing of adjacent vertices (see Figure 1a which is a dimer covering of an $8 \times 8$ grid). Dimer coverings of a grid are sometimes represented as domino tilings, that is, tilings with $2 \times 1$ rectangles (Figure 1b). The dimer model is the study of the set of dimer coverings of a graph. Typically, the underlying graph is taken to be a regular lattice in two dimensions, for example, the square grid or the honeycomb lattice, or a finite part of such a lattice.

Dimer coverings of the honeycomb graph are in bijection with tilings of plane regions with 60° rhombi, also known as lozenges (see Figure 2). These tilings in turn are projections of piecewise-linear surfaces in $\mathbb{R}^3$ composed of unit squares in the 2-skeleton of $\mathbb{Z}^3$. So one can think of honeycomb dimer coverings as modeling discrete surfaces in $\mathbb{R}^3$. These surfaces are monotone in the sense that the orthogonal projection to the plane $P_{111} = \{(x, y, z) | x + y + z = 0\}$ is injective.

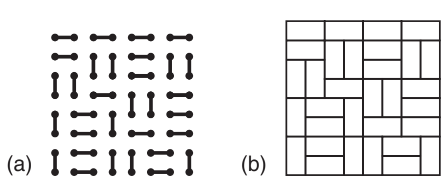

**Figure 1** A dimer covering of a grid and the corresponding domino tiling.

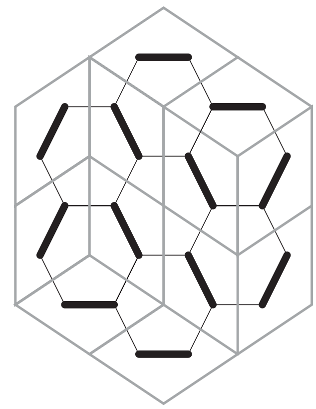

**Figure 2** Honeycomb dimers (solid) and the corresponding "lozenge" tilings (gray).

Other models related to the dimer model are:

- The spanning tree model on planar graphs. The set of spanning trees on a planar graph is in bijection with the set of dimer coverings on an associated bipartite planar graph. Conversely, dimer coverings of a bipartite planar graph are in bijection with directed spanning trees on an associated graph.
- The Ising model on a planar graph with zero external field can be modeled with dimers on an associated planar graph.
- Plane partitions (three-dimensional versions of integer partitions). Viewing a plane partition along the (1, 1, 1)-direction, one sees a lozenge tiling of the plane.
- Annihilating random walks in one dimension can be modeled with dimers on an associated planar graph.
- The monomer-dimer model, where one allows a certain density of holes (monomers) in a dimer covering. This model is unsolved at present, although some partial results have been obtained.

### Gibbs Measures

The most general setting in which the dimer model can be solved is that of an arbitrary planar graph with energies on the edges. We define here the corresponding measure.

Let $G = (V, E)$ be a graph and $\mathcal{M}(G)$ the set of dimer coverings of $G$. Let $\mathcal{E}$ be a real-valued function on the edges of $G$, with $\mathcal{E}(e)$ representing the energy associated to a dimer on the bond $e$. One defines the energy of a dimer covering as the sum of the energies of those bonds covered with dimers.

The partition function of the model on $(G, \mathcal{E})$ is then the sum

$$Z = \sum_{C \in \mathcal{M}(G)} e^{-\mathcal{E}(C)/kT}$$

where the sum is over dimer coverings. In what follows we will take $kT = 1$ for simplicity. Note that $Z$ depends on both $G$ and $\mathcal{E}$.

The partition function is well defined for a finite graph and defines the Gibbs measure, which is by definition the probability measure $\mu = \mu_{\mathcal{E}}$ on the set $\mathcal{M}(G)$ of dimer coverings satisfying $\mu(C) = (1/Z)e^{-\mathcal{E}(C)}$ for a covering $C$.

For an infinite graph $G$ with fixed energy function $\mathcal{E}$, a Gibbs measure on $\mathcal{M}(G)$ is by definition any measure which is a limit of the Gibbs measures on a sequence of finite subgraphs which fill out $G$. There may be many Gibbs measures on an infinite graph, since this limit typically depends on the sequence of finite graphs. When $G$ is an infinite periodic graph (and $\mathcal{E}$ is periodic as well), it is natural to consider translation-invariant Gibbs measures; one can show that in the case of a bipartite, periodic planar graph the translation-invariant and ergodic Gibbs measures form a two-parameter family – see Theorem 3 below.

For a translation-invariant Gibbs measure $\nu$ which is a limit of Gibbs measures on an increasing sequence of finite graphs $G_n$, one can define the partition function per vertex of $\nu$ to be the limit

$$Z = \lim_{n \to \infty} Z(G_n)^{1/|G_n|}$$

where $|G_n|$ is the number of vertices of $G_n$. The free energy, or surface tension, of $\nu$ is $-\log Z$.

## Combinatorics

### Partition Function

One can compute the partition function for dimer coverings on a finite planar graph $G$ as the Pfaffian (square root of the determinant) of a certain antisymmetric matrix, the Kasteleyn matrix. The Kasteleyn matrix is an oriented adjacency matrix of $G$, indexed by the vertices $V$: orient the edges of a graph embedded in the plane so that each face has an odd number of clockwise oriented edges. Then define $K = (K_{vv'})$ with

$$K_{vv'} = \pm e^{-\mathcal{E}(vv')}$$

if $G$ has an edge $vv'$, with a sign according to the orientation of that edge, and $K_{vv'} = 0$ if $v, v'$ are not adjacent. We then have the following result of Kasteleyn:

**Theorem 1** $Z = |\mathrm{Pf}(K)| = \sqrt{|\det K|}$.

Here $\mathrm{Pf}(K)$ denotes the Pfaffian of $K$.

Such an orientation of edges (which always exists for planar graphs) is called a Kasteleyn orientation; any two such orientations can be obtained from one another by a sequence of operations consisting of reversing the orientations of all edges at a vertex.

If $G$ is a bipartite graph, that is, the vertices can be colored black and white with no neighbors having the same color, then the Pfaffian of $K$ is the determinant of the submatrix whose rows index the white vertices and columns index the black vertices. For bipartite graphs, instead of orienting the edges one can alternatively multiply the edge weights by a complex number of modulus 1, with the condition that the alternating product around each face (the first, divided by the second, times the third, as so on) is real and negative.

For nonplanar graphs, one can compute the partition function as a sum of Pfaffians; for a graph embedded on a surface of Euler characteristic $\chi$, this requires in general $2^{2-\chi}$ Pfaffians.

### Local Statistics

The inverse of the Kasteleyn matrix can be used to compute the local statistics, that is, the probability that a given set of edges occurs in a random dimer covering (random with respect to the Gibbs measure $\mu$).

**Theorem 2** *Let $S = \{(v_1, v_2), \ldots, (v_{2k-1}, v_{2k})\}$ be a set of edges of $G$. The probability that all these edges occur in a $\mu$-random covering is*

$$\Pr(S) = \left(\prod_{i=1}^{k} K_{v_{2i-1}, v_{2i}}\right) \mathrm{Pf}_{2k \times 2k}((K^{-1})_{v_i, v_j})$$

Again, for bipartite graphs the Pfaffian can be made into a determinant.

### Heights

**Bipartite graphs** Suppose $G$ is a bipartite planar graph. A 1-form on $G$ is simply a function on the set of oriented edges which is antisymmetric with respect to reversing the edge orientation: $f(-e) = -f(e)$ for an edge $e$. A 1-form can be identified with a flow: just flow by $f(e)$ along oriented edge $e$. The divergence of the flow $f$ is then $d^* f$. Let $\Omega$ be the space of flows on edges of $G$, with divergence 1 at each white vertex and divergence –1 at each black vertex, and such that the flow along each edge from white to black is in [0, 1]. From a dimer covering $M$ one can construct such a flow $\omega(M) \in \Omega$: just flow

one unit along each dimer, and zero on the remaining edges. The set $\Omega$ is a convex polyhedron in $\mathbb{R}^E$ and its vertices can be seen to be exactly the dimer coverings.

Given any two flows $\omega_1, \omega_2 \in \Omega$, their difference is a divergence-free flow. Its dual $(\omega_1 - \omega_2)^*$ (or conjugate flow) defined on the planar dual of $G$ is therefore the gradient of a function $h$ on the faces of $G$, that is, $(\omega_1 - \omega_2)^* = \mathrm{d}h$, where $h$ is well defined up to an additive constant.

When $\omega_1$ and $\omega_2$ come from dimer coverings, $h$ is integer valued, and is called the height difference of the coverings. The level sets of the function $h$ are just the cycles formed by the union of the two matchings. If we fix a "base point" covering $\omega_0$ and a face $f_0$ of $G$, we can then define the height function of any dimer covering (with flow $\omega$) to be the function $h$ with value zero at $f_0$ and which satisfies $\mathrm{d}h = (\omega - \omega_0)^*$.

**Nonbipartite graphs** On a nonbipartite planar graph the height function can be similarly defined modulo 2. Fix a base covering $\omega_0$; for any other covering $\omega$, the superposition of $\omega_0$ and $\omega$ is a set of cycles and doubled edges of $G$; the function $h$ is constant on the complementary components of these cycles and changes by 1 mod 2 across each cycle. We can think of the height modulo 2 as taking two values, or spins, on the faces of $G$, and the dimer chains are the spin-domain boundaries. In particular, dimers on a nonbipartite graph model can in this way model the Ising model on an associated dual planar graph.

## Thermodynamic Limit

By periodic planar graph we mean a graph $G$, with energy function on edges, for which translations by elements of $\mathbb{Z}^2$ or some other rank-2 lattice $\Gamma \subset \mathbb{R}^2$ are isomorphisms of $G$ preserving the edge energies, and such that the quotient $G/\mathbb{Z}^2$ is a finite graph. Without loss of generality we can take $\Gamma = \mathbb{Z}^2$. The standard example is $G = \mathbb{Z}^2$ with $\mathcal{E} \equiv 0$, which we refer to as "dimers on the grid." However, other examples display different global behaviors and so it is worthwhile to remain in this generality.

For a periodic planar graph $G$, an ergodic probability measure on $\mathcal{M}(G)$ is one which is translation invariant (the measure of a set is the same as any $\mathbb{Z}^2$-translate of that set) and whose invariant subsets have measure 0 or 1.

We will be interested in probability measures which are both ergodic and Gibbs (we refer to them as ergodic Gibbs measures, dropping the term "probability"). When $G$ is bipartite, there are multiple ergodic Gibbs measures (see Theorem 3 below). When $G$ is nonbipartite, it is conjectured that there is a single ergodic Gibbs measure.

In the remainder of this section we assume that $G$ is bipartite, and assume also that the $\mathbb{Z}^2$-action preserves the coloring of the edges as black and white (simply pass to an index-2 sublattice if not).

For integer $n > 0$ let $G_n = G/n\mathbb{Z}^2$, a finite graph on a torus (in other words, with periodic boundary conditions). For a dimer covering $M$ of $G_n$, we define $(h_x, h_y) \in \mathbb{Z}^2$ to be the horizontal and vertical height change of $M$ around the torus, that is, the net flux of $\omega(M) - \omega_0$ across a horizontal, respectively vertical, cut around the torus (in other words, $h_x, h_y$ are the horizontal and vertical periods around the torus of the 1-form $\omega(M) - \omega_0$). The characteristic polynomial $P(z, w)$ of $G$ is by definition

$$P(z, w) = \sum_{M \in \mathcal{M}(G_1)} \mathrm{e}^{-\mathcal{E}(M)} z^{h_x} w^{h_y} (-1)^{h_x h_y}$$

here the sum is over dimer coverings $M$ of $G_1 = G/\mathbb{Z}^2$, and $h_x, h_y$ depend on $M$. The polynomial $P$ depends on the base point $\omega_0$ only by a multiplicative factor involving a power of $z$ and $w$. From this polynomial most of the large-scale behavior of the ergodic Gibbs measures can be extracted.

The Gibbs measure on $G_n$ converges as $n \to \infty$ to the (unique) ergodic Gibbs measure $\mu$ with smallest free energy $F = -\log Z$. The unicity of this measure follows from the strict concavity of the free energy of ergodic Gibbs measures as a function of the slope, see below. The free energy $F$ of the minimal free energy measure is

$$F = -\frac{1}{(2\pi \mathrm{i})^2} \int_{S^1 \times S^1} \log P(z, w) \frac{\mathrm{d}z}{z} \frac{\mathrm{d}w}{w}$$

that is, minus the Mahler measure of $P$.

For any translation-invariant measure $\nu$ on $\mathcal{M}(G)$, the average slope $(s, t)$ of the height function for $\nu$-almost every tiling is by definition the expected horizontal and vertical height change over one fundamental domain, that is, $s = \mathbb{E}[h(f + (1, 0)) - h(f)]$ and $t = \mathbb{E}[h(f + (0, 1)) - h(f)]$ where $f$ is any face. This quantity $(s, t)$ lies in the Newton polygon of $P(z, w)$ (the convex hull in $\mathbb{R}^2$ of the set of exponents of monomials of $P$). In fact, the points in the Newton polygon are in bijection with the ergodic Gibbs measures on $\mathcal{M}(G)$:

**Theorem 3** *When $G$ is a periodic bipartite planar graph, any ergodic Gibbs measure has average slope $(s, t)$ lying in $N(P)$. Moreover, for every point $(s, t) \in N(P)$ there is a unique ergodic Gibbs measure $\mu(s, t)$ with that average slope.*

In particular, this gives a complete description of the set of all ergodic Gibbs measures. The ergodic Gibbs measure $\mu(s,t)$ of slope $(s,t)$ can be obtained as the limit of the Gibbs measures on $G_n$, when one conditions the configurations to have a particular slope approximating $(s,t)$.

### Ronkin Function and Surface Tension

The Ronkin function of $P$ is a map $R:\mathbb{R}^2 \to \mathbb{R}$ defined for $(B_x, B_y) \in \mathbb{R}^2$ by

$$R(B_x, B_y) = \frac{1}{(2\pi i)^2} \int_{S^1 \times S^1} \log P(z e^{B_x}, w e^{B_y}) \frac{dz}{z} \frac{dw}{w}$$

The Ronkin function is convex and its graph is piecewise linear on the complement of the amoeba $\mathbb{A}(P)$ of $P$, which is the image of the zero set $\{(z,w) \in \mathbb{C}^2 \mid P(z,w)=0\}$ under the map $(z,w) \mapsto (\log|z|, \log|w|)$ (see Figures 3 and 4 for an example).

The free energy $F(\mu(s,t))$ of $\mu(s,t)$, as a function of $(s,t) \in N(P)$, is the Legendre dual of the Ronkin function of $P(z,w)$: we have

$$F(\mu(s,t)) = R(B_x, B_y) - sB_x - tB_y$$

where

$$s = \frac{\partial R(B_x, B_y)}{\partial B_x}, \qquad t = \frac{\partial R(B_x, B_y)}{\partial B_y}$$

The continuous map $\nabla R:\mathbb{R}^2 \to N(P)$ which takes $(B_x, B_y)$ to $(s,t)$ is injective on the interior of $\mathbb{A}(P)$, collapses each bounded complementary component of $\mathbb{A}(P)$ to an integer point in the interior of $N(P)$, and collapses each unbounded complementary component of $\mathbb{A}(P)$ to an integer point on the boundary of $N(P)$.

Under the Legendre duality, the facets in the graph of the Ronkin function (i.e., maximal regions on which $R$ is linear) give points of nondifferentiability of the free energy $F$, as defined on $N(P)$. We refer to these points of nondifferentiability as "cusps." Cusps occur only at integer slopes $(s,t)$ (see Figure 5 for the free energy associated to the Ronkin function in Figure 4).

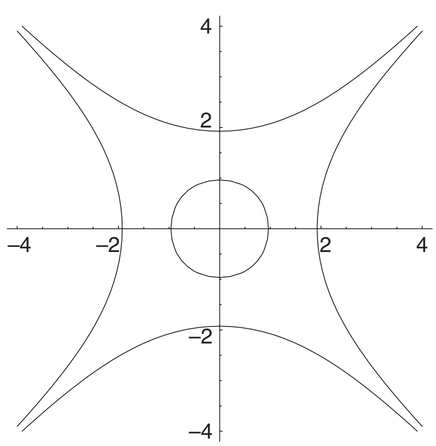

**Figure 3** The amoeba of $P(z,w)=5+z+1/z+w+1/w$, which is the characteristic polynomial for dimers on the periodic "square-octagon" lattice.

**Figure 4** Minus the Ronkin function of $P(z,w)=5+z+1/z+w+1/w$.

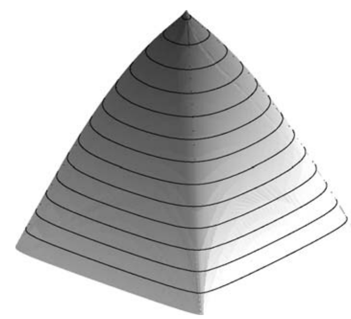

**Figure 5** (Negative of) the free energy for dimers on the square-octagon lattice.

By Theorem 3, the coordinates $(B_x, B_y)$ can also be used to parametrize the set of Gibbs measures $\mu(s,t)$ (but only those with slope $(s,t)$ in the interior of $N(P)$ or on the corners of $N(P)$ and boundary integer points). This parametrization is not one-to-one since when $(B_x, B_y)$ varies in a complementary component of the amoeba, the measure $\mu(s,t)$ does not change. On the interior of the amoeba the parametrization is one-to-one.

The remaining Gibbs measures, whose slopes are on the boundary of $N(P)$, can be obtained by taking limits of $(B_x, B_y)$ along the "tentacles" of the amoeba.

### Phases

The Gibbs measures $\mu(s,t)$ can be partitioned into three classes, or phases, according to the behavior of the fluctuations of the height function. If we measure the height at two distant points $x_1$ and $x_2$ in $G$, the average height difference, $\mathbb{E}[h(x_1)-h(x_2)]$, is a linear function of $x_1 - x_2$ determined by the average slope of the measure. The height fluctuation is defined to be the random variable $h(x_1)-h(x_2)-\mathbb{E}[h(x_1)-h(x_2)]$. This random variable depends on

the two points and we are interested in its behavior when $x_1$ and $x_2$ are far apart.

We say $\mu(s,t)$ is

1. "Frozen" if the height fluctuations are bounded almost surely.
2. "Rough" (or "liquid") if the covariance in the height function $\mathbb{E}[h(x_1)h(x_2)] - \mathbb{E}[h(x_1)]\mathbb{E}[h(x_2)]$ is unbounded as $|x_1 - x_2| \to \infty$.
3. "Smooth" (or "gaseous") if the covariance of the height function is bounded but the height fluctuations are unbounded.

The height fluctuations can be related to the decay of the entries of $K^{-1}$, which are in turn related to the decay of the Fourier coefficients of $1/P$. In particular, we have

**Theorem 4** *The measure $\mu(s,t)$ is respectively frozen, rough, or smooth according to whether $(B_x, B_y) = (\nabla R)^{-1}(s,t)$ is in the closure of an unbounded complementary component of $\mathbb{A}(p)$, in the interior of $\mathbb{A}(P)$, or in the closure of a bounded component of $\mathbb{A}(P)$.*

The characteristic polynomials $P$ which occur in the dimer model are not arbitrary: their algebraic curves $\{P = 0\}$ are all of a special type known as Harnack curves, which are characterized by the fact that the map from the zero-set of $P$ in $\mathbb{C}^2$ to its amoeba in $\mathbb{R}^2$ is at most two-to-one. In fact:

**Theorem 5** *By varying the edge energies all Harnack curves can be obtained as the characteristic polynomial of a planar dimer model.*

### Local Statistics

In the thermodynamic limit (on a periodic planar graph), local statistics of dimer coverings for the Gibbs measure of minimal free energy can be obtained from the limit of the inverse of the Kasteleyn matrix on the finite toroidal graphs $G_n$. This in turn can be computed from the Fourier coefficients of $1/P$.

As an example, let $G$ be the square grid $\mathbb{Z}^2$ and take $\mathcal{E} = 0$ (which corresponds to the uniform measure on configurations for finite graphs). An appropriate choice of signs for the Kasteleyn matrix is to put weights $1, -1$ on alternate horizontal edges and $i, -i$ on alternate vertical edges in such a way that around each white vertex the weights are cyclically $1, i, -1, -i$. For this choice of signs we have

$$K^{-1}_{(0,0),(x,y)} = \frac{1}{(2\pi)^2}\int_0^{2\pi}\int_0^{2\pi}\frac{\mathrm{e}^{-\mathrm{i}(\theta x+\phi y)}\mathrm{d}\theta\,\mathrm{d}\phi}{2\sin\theta + 2i\sin\phi}$$

This integral can be evaluated explicitly (see Figure 6 for values of $K^{-1}_{(0,0),(x,y)}$ near the origin; by

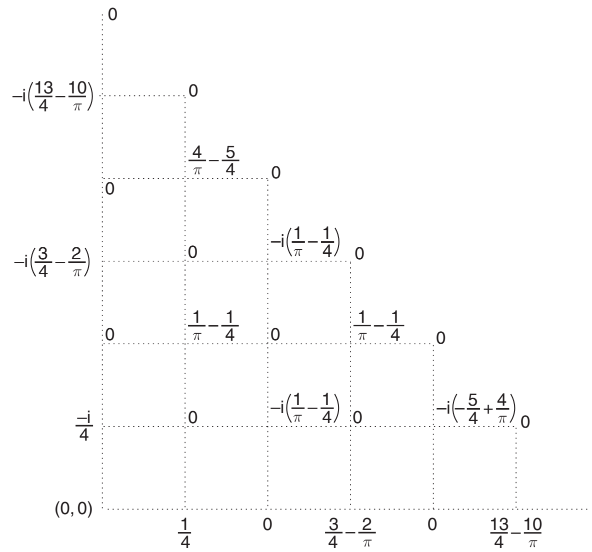

**Figure 6** Values of $K^{-1}$ on $Z^2$ with zero energies.

translation invariance $K^{-1}_{(x',y'),(x,y)} = K^{-1}_{(0,0),(x-x',y-y')}$) and values in other quadrants can be obtained by $K^{-1}_{(0,0),(x,y)} = -\mathrm{i}K^{-1}_{(0,0),(-y,x)}$).

As a sample computation, using Theorem 2, the probability that the dimer covering the origin points to the right and, simultaneously, the one covering $(0,1)$ points upwards is

$$K_{(0,0),(1,0)}K_{(0,2),(0,1)}\det\begin{pmatrix} K^{-1}_{(0,0),(1,0)} & K^{-1}_{(0,0),(0,1)} \\ K^{-1}_{(0,2),(1,0)} & K^{-1}_{(0,2),(0,1)}\end{pmatrix}$$

$$= 1\cdot(-\mathrm{i})\cdot\det\begin{pmatrix}\frac{1}{4} & \frac{-\mathrm{i}}{4} \\ -\frac{1}{4}+\frac{1}{\pi} & \frac{\mathrm{i}}{4}\end{pmatrix} = \frac{1}{4\pi}$$

Another computation which follows is the decay of the edge covariances. If $e_1, e_2$ are two edges at distance $d$, then $\Pr(e_1 \& e_2) - \Pr(e_1)\Pr(e_2)$ decays quadratically in $1/d$, since $K^{-1}((0,0),(x,y))$ decays like $1/(|x| + |y|)$.

## Scaling Limits

The scaling limit of the dimer model is the limit when the lattice spacing tends to zero.

Let us define the scaling limit in the following way. Let $\epsilon\mathbb{Z}^2$ be the square grid scaled by $\epsilon$, so the lattice mesh size is $\epsilon$. Fix a Jordan domain $U \subset \mathbb{R}^2$ and consider for each $\epsilon$ a subgraph $U_\epsilon$ of $\epsilon\mathbb{Z}^2$, bounded by a simple polygon, which tends to $U$ as $\epsilon \to 0$. We are interested in limiting properties of random dimer coverings of $U_\epsilon$, in the limit as $\epsilon \to 0$, for example, the fluctuations of the height function and edge densities.

The limit depends on the (sequence of) boundary conditions, that is, on the exact choice of approximating regions $U_\epsilon$. By changing $U_\epsilon$ one can change the limiting rescaled height function along the boundary. It is conjectured that the limit of the height function along the boundary of $U_\epsilon$ (scaled by $\epsilon \ldots$ and assuming this limit exists) determines essentially all of the limiting behavior in the interior, in particular the limiting local statistics.

Therefore, let $u$ be a real-valued continuous function on the boundary of $U$. Consider a sequence of subgraphs $U_\epsilon$ of $\epsilon\mathbb{Z}^2$, as $\epsilon \to 0$ as above, and whose height function along the boundary, when scaled by $\epsilon$, is approximating $u$. We discuss the limit of the model in this setting.

### Crystalline Surfaces

The height function allows us to view dimer coverings as random surfaces in $\mathbb{R}^3$: to a dimer covering of $G$, one associates the graph of its height function, extended in a piecewise linear fashion over the edges and faces of the dual $G^*$. These surfaces are then piecewise linear random surfaces, which resemble crystal surfaces in the sense that microscopically (on the scale of the lattice) they are rough, whereas their long-range behavior is smooth and facetted, as we now describe.

In the scaling limit, boundary conditions as described in the last paragraph of the previous section are referred to as "wire-frame" boundary conditions, since the graph of the height function can be thought of as a (random) surface spanning the wire frame defined by its boundary values.

In the scaling limit, there is a law of large numbers which says that the Gibbs measure on random surfaces (which is unique since we are dealing with a finite graph) concentrates, for fixed wire-frame boundary conditions, on a single surface $S_0$. That is, as the lattice spacing $\epsilon$ tends to zero, with probability tending to 1 the random surface lies close to a limiting surface $S_0$. The surface $S_0$ is the unique surface which minimizes the total surface tension, or free energy, for its fixed boundary values, that is, minimizes the integral over the surface of the $F(\mu(s,t))$, where $(s,t)$ is the slope of the surface at the point being integrated over. Existence and unicity of the minimizer follow from the strict convexity of the free energy/surface tension as a function of the slope.

At a point where the free energy has a cusp, the crystal surface $S_0$ will in general have a facet, that is, a region on which it is linear. Outside of the facets, one expects that $S_0$ is analytic, since the free energy is analytic outside the cusps.

### Fluctuations

While the scaled height function $\epsilon h$ in the scaling limit converges to its mean value $h_0$ (whose graph is the surface $S_0$), the fluctuations of the unrescaled height function $h - (1/\epsilon)h_0$ will converge in law to a random process on $U$.

In the simplest setting, that of honeycomb dimers with $\mathcal{E} \equiv 0$, and in the absence of facets, the height fluctuations converge to a continuous Gaussian process, the image of the Gaussian free field on the unit disk $\mathbb{D}$ under a certain diffeomorphism $\Phi$ (depending on $h_0$) of $\mathbb{D}$ to $U$.

In the particular case $h_0 = 0$, $\Phi$ is the Riemann map from $\mathbb{D}$ to $U$ and the law of the height fluctuations is just the Gaussian free field on $U$ (defined to be the Gaussian process whose covariance kernel is the Dirichlet Green's function). The conformal invariance of the Gaussian free field is the basis for a number of conformal invariance properties of the honeycomb dimer model.

### Densities of Motifs

Another observable of interest is the density field of a motif. A motif is a finite collection of edges, taken up to translation. For example, consider, for the square grid, the "L" motif consisting of a horizontal domino and a vertical domino aligned to form an "L," which we showed above to have a density $1/4\pi$ in the thermodynamic limit. The probability of seeing this motif at any given place is $1/4\pi$. However, in the scaling limit one can ask about the fluctuations of the occurrences of this motif: in a large ball around a point $x$, what is the distribution of $N_L - A/4\pi$, where $N_L$ is the number of occurrences of the motif, and $A$ is the area of the ball? These fluctuations form a random field, since there is a long-range correlation between occurrences of the motif.

It is known that on $\mathbb{Z}^2$, for the minimal free energy ergodic Gibbs measure, the rescaled density field

$$\frac{1}{\sqrt{A}}\left(N_L - \frac{A}{4\pi}\right)$$

converges as $\epsilon \to 0$ weakly to a Gaussian random field which is a linear combination of a directional derivative of the Gaussian free field and an independent white noise. A similar result holds for other motifs.

The joint distribution of densities of several motifs can also be shown to be Gaussian.

# Dirac Fields in Gravitation and Nonabelian Gauge Theory

**J A Smoller**, University of Michigan, Ann Arbor, MI, USA

## Introduction

In this article we describe some recent results (Finster *et al.* 1999a,b, 2000 a–c, 2002a) concerning the existence of both particle-like, and black hole solutions of the coupled Einstein–Dirac–Yang–Mills (EDYM) equations. We show that there are stable globally defined static, spherically symmetric solutions. We also show that for static black hole solutions, the Dirac wave function must vanish identically outside the event horizon. The latter result indicates that the Dirac particle (fermion) must either enter the black hole or tend to infinity.

The plan of the article is as follows. The next section describes the background material. It is followed by a discussion of the coupled EDYM equations for static, spherically symmetric particle-like and black hole solutions. The final section of the article is devoted to a discussion of these results.

## Background Material

### Einstein's Equations

We begin by describing the Einstein equation for the gravitational field (for more details, see, e.g., Adler *et al.* (1975)). We first note Einstein's hypotheses of general relativity (GR):

(E1) The gravitational field is the metric $g_{ij}$ in $3+1$ spacetime dimensions. The metric is assumed to be symmetric.
(E2) At each point in spacetime, the metric can be diagonalized as diag(–1,1,1,1).
(E3) The equations which describe the gravitational field should be covariant; that is, independent of the choice of coordinate system.

The hypothesis (E1) is Einstein's brilliant insight, whereby he "geometrizes" the gravitational field. (E2) means that there are inertial frames at each point (but not globally), and guarantees that special relativity (SR) is included in GR, while (E3) implies that the gravitational field equations must be tensor equations; that is, coordinates are an artifact, and physics should not depend on the choice of coordinates.

### Einstein's Equations of GR

The metric $g_{ij}=g_{ij}(x), i,j=0,1,2,3, x=(x^0,x^1,x^2,x^3)$, $x^0=ct$ ($c$=speed of light, $t$=time), is the metric tensor defined on four-dimensional spacetime. Einstein's equations are ten (tensor) equations for the unknown metric $g_{ij}$ (gravitational field), and take the form

$$R_{ij}-\tfrac{1}{2}Rg_{ij}=\sigma T_{ij} \qquad [1]$$

where the left-hand side $G_{ij}=R_{ij}-\frac{1}{2}Rg_{ij}$ is the Einstein tensor and depends only on the geometry, $\sigma=8\pi G/c^4$, where $G$ is Newton's gravitational constant, while $T_{ij}$, the energy–momentum tensor, represents the source of the gravitational field, and encodes the distribution of matter. (The word "matter" in GR refers to everything which can produce a gravitational field, including elementary particles, electromagnetic or Yang–Mills (YM) fields. From the Bianchi identities in geometry (cf. Adler *et al.* (1975)), the (covariant) divergence of the Einstein tensor, $G_{ij}$, vanishes identically, namely

$$G^j_{i,j}=0$$

so, on solutions of Einstein's equations,

$$T^j_{i,j}=0$$

and this in turn expresses the conservation of energy and momentum. The quantities which comprise the Einstein tensor are given as follows: first, from the metric tensor $g_{ij}$, we form the Levi-Civita connection $\Gamma^k_{ij}$ defined by:

$$\Gamma^k_{ij}=\frac{1}{2}g^{k\ell}\left(\frac{\partial g_{\ell j}}{\partial x^i}-\frac{\partial g_{i\ell}}{\partial x^j}-\frac{\partial g_{ij}}{\partial x^\ell}\right)$$

where ($4\times 4$ matrix) $[g^{k\ell}]=[g_{k\ell}]^{-1}$, and summation convention is employed; namely, an index which appears as both a subscript and a superscript is to be summed from 0 to 3. With the aid of $\Gamma^k_{ij}$, we can

construct the celebrated Riemann curvature tensor $R^i_{qk\ell}$:

$$R^i_{qk\ell} = \frac{\partial \Gamma^i_{q\ell}}{\partial x^k} - \frac{\partial \Gamma^i_{qk}}{\partial x^\ell} + \Gamma^i_{pk}\Gamma^p_{q\ell} - \Gamma^i_{p\ell}\Gamma^p_{qk}$$

Finally, the terms $R_{ij}$ and $R$ which appear in the Einstein tensor $G_{ij}$ are given by

$$R_{ij} = R^s_{isj}$$

(the Ricci tensor), and

$$R = g^{ij}R_{ij}$$

is the scalar curvature.

From the above definitions, one sees at once the enormous complexity of the Einstein equations. For this reason, one usually seeks solutions which have a high degree of symmetry, and in what follows, in this section, we shall only consider static, spherically symmetric solutions; that is, solutions which depend only on $r = |x| = \sqrt{(x^1)^2 + (x^2)^2 + (x^3)^2}$. In this case, the metric $g_{ij}$ takes the form

$$\mathrm{d}s^2 = -T(r)^2\mathrm{d}t^2 + A(r)^{-1}\mathrm{d}r^2 + r^2\mathrm{d}\Omega^2 \qquad [2]$$

where $\mathrm{d}\Omega^2 = \mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\varphi^2$ is the standard metric on the unit 2-sphere, $r,\theta,\varphi$ are the usual spherical coordinates, and $t$ denotes time.

### Black Hole Solutions

Consider the problem of finding the gravitational field outside a ball of mass $M$ in $\mathbb{R}^3$; that is, there is no matter exterior to the ball. Solving Einstein's equations $G_{ij}{}' = 0$ gives the famous Schwarzschild solution (1916):

$$\mathrm{d}s^2 = -\left(1 - \frac{2m}{r}\right)c^2\mathrm{d}t^2 + \left(1 - \frac{2m}{r}\right)^{-1}\mathrm{d}r^2 + r^2\mathrm{d}\Omega^2 \qquad [3]$$

where $m = GM/c^2$. Since $2m$ has the dimensions of length, it is called the Schwarzschild radius. Observe that when $r = 2m$, the metric is singular; namely, $g_{tt} = 0$ and $g_{rr} = \infty$. By transforming the metric [2] to the so-called Kruskal coordinates (cf. Adler *et al.* (1975)), one observes that the Schwarzschild sphere $r = 2m$ has the physical characteristics of a black hole: light and nearby particles can enter the region $r < 2m$, nothing can exit this region, and there is an intrinsic (nonremovable) singularity at the center $r = 0$.

For the general metric [2], we define a black hole solution of Einstein's equations to be a solution which satisfies, for some $\rho > 0$,

$$A(\rho) = 0, \quad A(r) > 0 \text{ if } r > \rho$$

$\rho$ is called the radius of the black hole, or the event horizon.

### Yang–Mills Equations

The YM equations generalize Maxwell's equations. To see how this comes about, we first write Maxwell's equations in an invariant way. Thus, let $A$ denote a scalar-valued 1-form:

$$A = A_i\mathrm{d}x^i, \quad A_i \in \mathbb{R}$$

which is called the electromagnetic potential (by physicists), or a connection (by geometers). The electromagnetic field (curvature) is the 2-form

$$F = \mathrm{d}A$$

In local coordinates,

$$F = F_{ij}\mathrm{d}x^i \wedge \mathrm{d}x^j, \quad F_{ij} = \frac{\partial A_j}{\partial x^i} - \frac{\partial A_i}{\partial x^j}$$

In this framework, Maxwell's equations are given by

$$\mathrm{d}^\star F = 0, \qquad \mathrm{d}F = 0 \qquad [4]$$

where $\star$ is the Hodge star operator, mapping 2-forms to 2-forms (in $\mathbb{R}^4$), and is defined by

$$({}^\star F)_{k\ell} = \tfrac{1}{2}\sqrt{|g|}\varepsilon_{ijk\ell}F^{ij}$$

where $g = \det(g_{ij})$ and $\varepsilon_{ijk\ell}$ is the completely antisymmetric symbol defined by $\varepsilon_{ijk\ell} = \mathrm{sgn}(ijk\ell)$. As usual, indices are raised (or lowered) via the metric, so that, for example,

$$F^{ij} = g^{\ell i}g^{mj}F_{jm}$$

It is important to notice that ${}^\star F$ depends on the metric. Note also that Maxwell's equations are linear equations for the $A_i$'s.

The YM equations generalize Maxwell's equations and can be described as follows. With each YM field (described below) is associated a compact Lie group $G$ called the gauge group. For such $G$, we denote its Lie algebra by $\mathfrak{g}$, defined to be the tangent space at the identity of $G$. Now let $A$ be a $\mathfrak{g}$-valued 1-form

$$A = A_i\mathrm{d}x^i$$

where each $A_i$ is in $\mathfrak{g}$. In this case, the curvature 2-form is defined by

$$F = \mathrm{d}A + A \wedge A$$

or, in local coordinates,

$$F_{ij} = \frac{\partial A_j}{\partial x^i} - \frac{\partial A_i}{\partial x^j} + [A_i, A_j]$$

The commutator $[A_i, A_j] = 0$ if $G$ is an abelian group, but is generally nonzero if $G$ is a matrix group. In this framework, the YM equations can be written in the form $d^\star F = 0$, where now d is an appropriately defined covariant exterior derivative. For Maxwell's equations, the gauge group $G = U(1)$ (the circle group $\{e^{i\theta}: \theta \in \mathbb{R}\}$) so $\mathfrak{g}$ is abelian and we recover Maxwell's equations from the YM equations. Observe that if $G$ is nonabelian, then the YM equations $d^\star F = 0$ are nonlinear equations for the connection coefficients $A_i$.

### The Dirac Equation in Curved Spacetime

The Dirac equation is a generalization of Schrödinger's equation, in a relativistic setting (Bjorken and Drell 1964). It thus combines quantum mechanics with the theory of relativity. In addition, the Dirac equation also describes the intrinsic "spin" of fermions and, for this reason, solutions of the Dirac equation are often called spinors.

The Dirac equation can be written as

$$(G - m)\Psi = 0 \qquad [5]$$

where $G$ is the Dirac operator, $m$ is the mass of the Dirac particle (fermion), and $\Psi$ is a complex-valued 4-vector called the wave function, or spinor. The Dirac operator $G$ is of the form

$$G = iG^j(x)\frac{\partial}{\partial x^j} + B(x) \qquad [6]$$

where $G^j$ as well as $B$ are $4 \times 4$ matrices, $m$ is the (rest) mass of the fermion, and $i = \sqrt{-1}$. The Dirac equation is thus a linear equation for the spinors. The $G^j$ (called Dirac matrices) and the Lorentzian metric $g_{ij}$ are related by

$$g^{jk} I = \tfrac{1}{2}\{G^j, G^k\} \qquad [7]$$

where $\{G^j, G^k\}$ is the anticommutator

$$\{G^j, G^k\} = G^j G^k + G^k G^j$$

Thus, the Dirac matrices depend on the underlying metric in four-dimensional spacetime.

Suppose that $H$ is a spacelike hypersurface in $\mathbb{R}^4$, with future-directed normal vector $\nu = \nu(x)$, and let $d\mu$ be the invariant measure on $H$ induced by the metric $g_{ij}$. We define a scalar product on solutions $\Psi, \Phi$ of the Dirac equation by

$$\langle \Psi | \Phi \rangle = \int_H \bar{\Psi} G^j \Phi \nu_j \, d\mu \qquad [8]$$

This scalar product is positive definite, and because of current conservation (cf. Finster (1988))

$$\nabla_j \bar{\Psi} G^j \Phi = 0$$

it is also independent of $H$. By generalizing the expression (due to Dirac), $\bar{\Psi}\gamma^0\Psi = |\Psi|^2$, in Minkowski space, where $\gamma^0$ and $\bar{\Psi}$, the adjoint spinors, are defined by

$$\gamma^0 = \begin{pmatrix} \mathbf{1} & 0 \\ 0 & -\mathbf{1} \end{pmatrix}, \qquad \bar{\Psi} = \Psi^* \gamma^0$$

where $*$ denotes complex conjugation, and $\mathbf{1}$ is the $2 \times 2$ identity matrix, the quantity $\bar{\Psi} G^j \Psi \nu_j$ is interpreted as the probability density of the Dirac particle. We normalize solutions of the Dirac equation by requiring

$$\langle \Psi | \Psi \rangle = 1 \qquad [9]$$

## Spherically Symmetric EDYM Equations

In the remainder of this article we assume that all fields are spherically symmetric, so they depend only on the variable $r = |x|$. In this case, the Lorentzian metric in polar coordinates $(t, r, \theta, \varphi)$ takes the form [2]. The Dirac wave function can be (Finster *et al.* 2000b) described by two real functions, $(\alpha(r), \beta(r))$, and the potential $W(r)$ corresponds to the magnetic component of an SU(2) YM field. As shown in Finster *et al.* (2000b), the EDYM equations are

$$\sqrt{A}\alpha' = \frac{w}{r}\alpha - (m + \omega T)\beta \qquad [10]$$

$$\sqrt{A}\beta' = (-m + \omega T)\alpha - \frac{w}{r}\beta \qquad [11]$$

$$rA' = 1 - A - \frac{1}{e^2}\frac{(1 - w^2)^2}{r^2} - 2\omega T^2(\alpha^2 + \beta^2) - \frac{2}{e^2}Aw'^2 \qquad [12]$$

$$2rA'\frac{T'}{T} = -1 + A + \frac{1}{e^2}\frac{(1 - w^2)^2}{r^2} + 2mT(\alpha^2 - \beta^2) - 2\omega T^2(\alpha^2 + \beta^2) + 4\frac{T}{r}w\alpha\beta - \frac{2}{e^2}Aw'^2 \qquad [13]$$

$$rAw'' = -(1 - w^2)w + e^2 rT\alpha\beta - r^2\frac{A'T - 2AT'}{2T}w' \qquad [14]$$

Equations [10] and [11] are the Dirac equations, [12] and [13] are the Einstein equations, and [14] is

the YM equation. The constants $m, \omega$, and $e$ denote, respectively, the rest mass of the Dirac particle, its energy, and the YM coupling constant.

### Nonexistence of Black Hole Solutions

Let the surface $r = \rho > 0$ represent a black hole event horizon:

$$A(\rho) = 0, \quad A(r) > 0 \text{ if } r > \rho \qquad [15]$$

In this case, the normalization condition [9] is replaced by

$$\int_{r_0}^{\infty} (\alpha^2 + \beta^2) \frac{\sqrt{T}}{A}\, dr < \infty, \quad \text{for every } r_0 > \rho \qquad [16]$$

In addition, we assume that the following global conditions hold:

$$\lim_{r\to\infty} r\big(1 - A(r)\big) = M < \infty \qquad [17]$$

(finite mass),

$$\lim_{r\to\infty} T(r) = 1 \qquad [18]$$

(gravitational field is asymptotically flat Minkowskian), and

$$\lim_{r\to\infty} \big(w(r)^2, w'(r)\big) = (1, 0) \qquad [19]$$

(the YM field is well behaved).

Concerning the event horizon $r = \rho$, we make the following regularity assumptions:

1. The volume element $\sqrt{|\det g_{ij}|} = |\sin\theta| r^2 A^{-1} T^{-2}$ is smooth and nonzero on the horizon; that is,

$$T^{-2}A^{-1},\ T^2 A \in C^1([\rho, \infty))$$

2. The strength of the YM field $F_{ij}$ is given by

$$\operatorname{tr}(F_{ij}F^{ij}) = \frac{2Aw'^2}{r^4} + \frac{(1 - w^2)^2}{r^4}$$

(cf. Bartnik and McKinnon 1988). We assume that this scalar is bounded near the horizon; that is, outside the event horizon and near $r = \rho$, assume that

$$w \text{ and } Aw'^2 \text{ are bounded} \qquad [20]$$

3. The function $A(r)$ is monotone increasing outside of and near the event horizon.

As discussed in Finster *et al.* (1999a), if assumption 1 or 2 were violated, then an observer freely falling into the black hole would feel strong forces when crossing the horizon. Assumption 3 is considerably weaker than the corresponding assumption in Finster *et al.* (1999b), where, indeed, it was assumed that the function $A(r)$ obeyed a power law $A(r) = c(r-\rho)^s + \mathcal{O}((r-\rho)^{s+1})$, with positive constants $c$ and $s$, for $r > \rho$.

The main result in this subsection is the following theorem:

**Theorem 1** *Every black hole solution of the EDYM equations [10]–[14] satisfying the regularity conditions 1–3 cannot be normalized and coincides with a Bartnik–McKinnon (BM) black hole of the corresponding Einstein–Yang–Mills (EYM) equations; that is, the spinors $\alpha$ and $\beta$ must vanish identically outside the event horizon.*

**Remark** Smoller and Wasserman (1998) proved that any black hole solution of the EYM equations that has finite mass (i.e., that satisfies [17]) must be one of the BM black hole solutions (Bartnik and McKinnon 1988) whose existence was first demonstrated in Smoller *et al.* (1993). Thus, amending the EYM equations by taking quantum-mechanical effects into account – in the sense that both the gravitational and YM fields can interact with Dirac particles – does not yield any new types of black hole solutions.

The present strategy in proving this theorem is to assume that we have a black hole solution of the EDYM equations [10]–[18] satisfying assumptions 1–3, where the spinors do not vanish identically outside of the black hole. We shall show that this leads to a contradiction. The proof is broken up into two cases: either $A^{-1/2}$ is integrable or nonintegrable near the event horizon. We shall only discuss the proof for the case when $A^{-1/2}$ is integrable near the event horizon, leaving the alternate case for the reader to view in Finster *et al.* (2000a).

If $A^{-1/2}$ is integrable, then one shows that there are positive constants $c, \varepsilon$ such that

$$c \le \alpha^2(r) + \beta^2(r) \le \frac{1}{c}, \quad \text{if} \quad \rho < r < \rho + \varepsilon \qquad [21]$$

Indeed, multiplying [10] by $\alpha$, and [11] by $\beta$ and adding gives an estimate of the form

$$\sqrt{A}(\alpha^2 + \beta^2)' \le \kappa(\alpha^2 + \beta^2)$$

Upon dividing by $\sqrt{A}(\alpha^2 + \beta^2)$ and integrating from $r > \rho$ to $\rho + \varepsilon$ gives

$$|\log(\alpha^2 + \beta^2)(\rho + \varepsilon) - \log(\alpha^2 + \beta^2)(r)| \le \text{const.}$$

from which the desired result follows. Next, from [12] and [13],

$$r(AT^2)' = 4 - \omega T^4(\alpha^2 + \beta^2) + T^3\left[2m(\alpha^2 - \beta^2) + \frac{4w}{r}\alpha\beta\right] - \frac{4}{e^2}(Aw')^2T^2 \qquad [22]$$

Using assumption 2 together with the last theorem, we see that the coefficients of $T^4, T^3$, and $T^2$ on the right-hand side of [21] are bounded near $\rho$, and from assumption 1 the left-hand side of [21] is bounded near $\rho$. Since assumption 1 implies $T(r) \to \infty$ as $r \searrow \rho$, we see that $\omega = 0$. Since $\omega = 0$, the Dirac equations simplify and we can show that $\alpha\beta$ is a positive decreasing function which tends to 0 as $r \to \infty$. Then the YM equation can be written in the form

$$r^2(Aw')' = -w(1-w)^2 + e^2\frac{r(T\sqrt{A})\alpha\beta}{\sqrt{A}} + r^2\frac{(AT^2)'}{2AT^2}(Aw') \qquad [23]$$

From assumption 2, $Aw'^2$ is bounded so $A^2w'^2 \to 0$ as $r \searrow \rho$. Thus, from [22] we can write, for $r$ near $\rho$,

$$(Aw')'(r) \geq c_1 + \frac{c_2}{\sqrt{A(r)}}$$

where $c_1$ and $c_2$ are positive constants. Using this inequality, we can show that for $r$ near $\rho$,

$$A(r) = (r - \rho)B(r)$$

where $0 < \lim_{r \searrow \rho} B(r) < \infty$. It follows that $A(\rho) = 0$ and $A'(\rho) > 0$. Thus, the Einstein metric has the same qualitative features as the Schwarzschild metric near the event horizon. Hence, the metric singularity can be removed via a Kruskal transformation (Adler *et al.* 1975). In these Kruskal coordinates, the YM potential is continuous and bounded (as is easily verified). As a consequence, the arguments in Finster *et al.* (2000c) go through and show that the spinors must vanish identically outside the horizon. For this, one must note that continuous zero-order terms in the Dirac operator are irrelevant for the derivation of the matching conditions in Finster *et al.* 2000c, section 2.4). Thus, the matching conditions (equations (2.31), (2.34) of Finster *et al.* (2000c)) are valid without changes in the presence of our YM field. Using conservation of the (electromagnetic) Dirac current and its positivity in timelike directions, the arguments in Finster *et al.* (2000c, section 4) all carry over. This completes the proof.

We have thus proved that the only black hole solutions of our EDYM equations are the BM black holes; that is, the spinors must vanish identically. In other words, the EDYM equations do not admit normalizable black hole solutions. Thus, in the presence of quantum-mechanical Dirac particles, static and spherically symmetric black hole solutions do not exist. Another interpretation of these our result is that Dirac particles can only either disappear into the black hole or escape to infinity. These results were proved under very weak regularity assumptions on the form of the event horizon (see assumptions 1–3).

## Particle-Like Solutions

By a particle-like (bound state) solution of the (SU(2)) EDYM equations, we mean a smooth solution of eqns [10]–[14], which is defined for all $r \geq 0$, and satisfies condition [9], which explicitly becomes

$$\int_0^r (\alpha^2 + \beta^2)\frac{\sqrt{T}}{A}\,dr = 1 \qquad [24]$$

In addition, we demand that [17]–[19] also hold. It is easily shown that, near $r = 0$, we must have

$$w(r) = 1 - \frac{\lambda}{2}r^2 + \mathcal{O}(r^2) \qquad [25]$$

where $\lambda$ is a real parameter. From this, via a Taylor expansion, one finds that

$$\begin{aligned} \alpha(r) &= \alpha_1 r + \mathcal{O}(r^3) \\ \beta(r) &= \tfrac{1}{2}(\omega T_0 - m)\alpha_1 r^2 + \mathcal{O}(r^3) \end{aligned} \qquad [26]$$

$$A(r) = 1 + \mathcal{O}(r^2), \quad T(r) = T_0 + \mathcal{O}(r^2) \qquad [27]$$

with two parameters $\alpha_1$ and $T_0 > 0$. Using linearity of the Dirac equation, we can always assume that $\alpha_1 > 0$.

Under all realistic conditions, the coupling of Dirac particles to the YM field (describing the weak or strong interactions) is much stronger than the coupling to the gravitational field. Thus, we are particularly intrested in the case of weak gravitational coupling. As shown in Finster *et al.* (2000b), the gravitational field is essential for the formation of bound states. However, for arbitrarily weak gravitational coupling, we can hope to find bound states. It is even conceivable that these bound-state solutions might have a well-defined limit when the gravitational coupling tends to zero, if we let the YM coupling go to infinity at the same time. Our idea is that this limiting case might yield a system of equations which is simpler than the full EDYM system, and can thus serve as a physically interesting starting point for the analysis of the coupled

interactions described by the EDYM equations. Expressed in dimensionless quantities, we shall thus consider the limits

$$m^2\kappa \to 0 \quad \text{and} \quad e^2 \to \infty \qquad [28]$$

That is, we ask whether weak gravitational coupling can give rise to bound states. Using numerical methods, we find particle-like solutions which are stable, even for arbitrarily weak gravitational coupling.

Now assuming that [27] holds (weak gravitational coupling), so that $(A, T) \approx (1, 1)$, then we find that the Dirac equations have a meaningful limit only under the assumptions that $\alpha$ converges and that

$$m\beta(r) \to \hat{\beta}(r), \quad m^2(T(r) - 1) \to \varphi \qquad [29]$$
$$m(\omega - m) \to E$$

with two real functions $\hat{\beta}, \varphi$ and a real parameter $E$. Multiplying [29] with $m$ and taking the limits [28] as well as $A, T \to 1$, the Dirac equations become

$$\alpha' = \frac{w}{r}\alpha - 2\hat{\beta} \qquad [30]$$

$$\hat{\beta}' = (E + \varphi)\alpha - \frac{w}{r}\hat{\beta} \qquad [31]$$

We next consider the YM equation [14]. The last term in [14] drops out in the limit of weak gravitational coupling [27]. The second summand converges only under the assumption that

$$\frac{e^2}{m} \to q \qquad [32]$$

with $q$ a real parameter, playing the role of an "effective" coupling constant. Together with [27], this implies that $m \to \infty$. The YM equations thus have the limit

$$r^2 w'' = -(1 - w)^2 w + qr\alpha\hat{\beta} \qquad [33]$$

In order to get a well-defined and nontrivial limit of the Einstein equations [13] and [14], we need to assume that the parameter $m^3\kappa$ has a finite, nonzero limit. Since this parameter has the dimension of inverse length, we can arrange by a scaling of our coordinates that

$$m^3\kappa \to 1 \qquad [34]$$

We differentiate the $T$-equation [13] with respect to $r$ and substitute [12]. Taking the limits [28] and [33], a straightforward calculation yields the equation

$$r^2\Delta\varphi = -\alpha^2 \qquad [35]$$

where $\Delta = r^{-2}\partial_r(r^2\partial_r)$ is the radial Laplacian in Euclidean $\mathbb{R}^3$. Indeed, this equation can be regarded as Newton's equation with the Newtonian potential $\varphi$. Thus, the limiting case [34] for the gravitational field corresponds to taking the Newtonian limit. Finally, the normalization condition [16] reduces to

$$\int_0^\infty \alpha(r)^2 \, dr = 1 \qquad [36]$$

The boundary conditions [17]–[19], [24]–[26] are transformed into

$$w(r) = 1 - \frac{\lambda}{2}r^2 + \mathcal{O}(r^3), \quad \lim_{r\to\infty} w(r) = \pm 1 \qquad [37]$$

$$\alpha(r) = \alpha_1 r + \mathcal{O}(r^3), \quad \hat{\beta}(r) = \mathcal{O}(r^3) \qquad [38]$$

$$\varphi(r) = \varphi_0 + \mathcal{O}(r^3), \quad \lim_{r\to\infty} \varphi(r) < \infty \qquad [39]$$

with the three parameters $\lambda, \alpha_1$, and $\varphi_0$. We point out that the limiting system contains only one coupling constant $q$. According to [31] and [33], $q$ is in dimensionless form given by

$$e^2 m^2 \kappa \to q \qquad [40]$$

Hence, in dimensionless quantities, the limit [17] describes the situation where the gravitational coupling goes to zero, while the YM coupling constant goes to infinity like $e^2 \sim (m^2\kappa)^{-1}$. Therefore, this limiting case is called the reciprocal coupling limit (RCL). The reciprocal coupling system is given by eqns [29], [30], [32], and [34] together with the normalization conditions [35] and the boundary conditions [36]–[38]. According to [28], the parameter $E$ coincides up to a scaling factor with $\omega - m$, and thus has the interpretation as the (properly scaled) energy of the Dirac particle. As in Newtonian mechanics, the potential $\varphi$ is determined only up to a constant $\mu \in \mathbb{R}$; namely, the reciprocal limit equations are invariant under the transformation

$$\varphi \to \varphi + \mu, \qquad E \to E - \mu \qquad [41]$$

To simplify the connection between the EDYM equations, and the RCL equations, we introduce a parameter $\varepsilon$ in such a way that as $\varepsilon \to 0$, EDYM $\to$ RCL; namely,

$$\varepsilon = \frac{m^2\kappa}{e^2}$$

Notice that $\varepsilon$ describes the relative strength of gravity versus the YM interaction. For realistic physical situations, the gravitational coupling is weak; namely, $m^2\kappa \ll 1$, but the YM coupling constant is of order $1 : e^2 \sim 1$. So we investigate the parameter range $\varepsilon \ll 1, q \sim 0$. These form the starting points for the numeric below.

We seek stable bound states for weak gravitational coupling. For this purpose, we consider the total binding energy

$$B = M - m \qquad [42]$$

where $M$ is the ADM mass defined by [17] and $m$ is the rest mass of the Dirac particle. $B$ is thus the amount of energy set free when the binding is broken. If $B < 0$, then energy is needed to break up the binding. According to Lee (1987), a solution is stable if $B < 0$. In order to find solutions of the RCL equations with $B < 0$, Lee's treatment and a new two-parameter shooting method (Finster *et al.* 2000b) can be used. Stable solutions of these RCL equations then follow (see Finster *et al.* (2000b) for details).

We now turn to the full EDYM equations. Here are the key steps of our method:

1. Find solutions which are small perturbations of the limiting (RCL) solutions.
2. Trace these solutions by gradually changing the coupling constants.
3. This should yield a one-parameter family of solutions which are "far" from the known limiting solutions.

The point is that we use the RCL solutions as a starting point for numerics, and we "continue" these solutions to solutions of the full EDYM equations.

To be somewhat more specific, we see that if we fix $\varepsilon$ and $q$, we have two parameters:

$$\alpha_1 = \alpha'(0) \quad \text{and} \quad E = \omega - m$$

and two conditions at $\infty$:

$$\alpha^2 + \beta^2 \to 0, \qquad w^2 \to 1$$

We consider the EDYM equations with weaker side conditions

$$0 < \lambda^2 \equiv \int_0^\infty (\alpha^2 + \beta^2)\frac{\sqrt{T}}{A}\,\mathrm{d}r < \infty$$
$$0 < \tau = \lim_{r\to\infty} T(r) < \infty$$
$$\lim_{r\to\infty} w^2(r) = 1$$
$$\rho = \lim_{r\to\infty} r(1 - A(r)) < \infty$$

Then we rescale these solutions to obtain the true side conditions via the transformations

$$\tilde{\alpha}(r) = \sqrt{\tau}\lambda^{-2}\alpha(\lambda^{-2}r)$$
$$\tilde{\beta}(r) = \sqrt{\tau}\lambda^{-2}\beta(\lambda^{-2}r)$$
$$\tilde{A}(r) = A(\lambda^{-2}r), \quad \tilde{T}(r) = \tau^{-1}T(\lambda^{-2}r)$$
$$\tilde{m} = \lambda^{-2}m, \quad \tilde{\omega} = \tau\lambda^{-2}\omega$$
$$\tilde{\kappa} = \lambda^6\kappa, \quad \tilde{e}^2 = \lambda^2 e^2$$

## Discussion

In this article we have considered the SU(2) EDYM equations. Our first result shows that the only black hole solutions of these equations are the BM black holes; that is, the spinors must vanish identically outside of the black hole. In other words, the EDYM equations do not admit normalizable black hole solutions. Thus, as mentioned earlier, this result indicates that the Dirac particle either enters the black hole or escapes to infinity. Two recent publications (Finster *et al.* 2002a,b) we consider the Cauchy problem for a massive Dirac equation in a charged, rotating-black-hole geometry (the non-extreme Kerr–Newman black hole), with compactly supported initial data outside the black hole. We prove that, in this case, the probability that the Dirac particle lies in any compact set tends to zero as $t \to \infty$. This means that the Dirac particle indeed either enters the black hole or tends to infinity. We also show that the wave function decays at a rate $t^{-5/6}$ on any compact set outside of the event horizon.

For particle-like solutions of the SU(2) EDYM equations, we find stable bound states for arbitrarily weak gravitational coupling. This shows that as weak as the gravitational interaction is, it has a regularizing effect on the equations. The stability of particle-like solutions of the EDYM equations is in sharp contrast to the EYM equations, where the particle-like solutions are all unstable (Straumann and Zhou 1990).

# Dirac Operator and Dirac Field

**S N M Ruijsenaars**, Centre for Mathematics and Computer Science, Amsterdam, The Netherlands

## Introduction

The Dirac equation arose in the early days of quantum mechanics, inspired by the problem of taking special relativity into account in the quantum mechanical description of a freely moving electron. From the outset, however, Dirac looked for an equation that also accomodated the electron spin and that could be modified to include interaction with an external electromagnetic field. The equation he discovered satisfies all of these requirements. On the other hand, when it is rewritten in Hamiltonian form, the spectrum of the resulting Dirac operator includes not only the desired interval $[mc^2, \infty)$ (where $m$ is the electron mass and $c$ the speed of light), but also an interval $(-\infty, -mc^2]$.

Dirac himself already considered this negative part of the spectrum as unphysical, since no such negative energies had been observed and their presence would entail instability of the electron. This physical flaw of the "first-quantized" description of a relativistic electron led to the introduction of "second quantization," as encoded in quantum field theory. In the field-theoretic version of the Dirac theory, the unphysical negative energies are obviated by a prescription that originated in Dirac's hole theory.

Specifically, Dirac postulated that the negative-energy states of his equation were occupied by a sea of unobservable particles, the Pauli principle forbidding an occupancy greater than one. In this heuristic picture, the annihilation of a negative-energy electron yields a hole in the sea, observable as a new type of positive-energy particle with the same mass, but opposite charge. This led Dirac to predict that the electron should have an oppositely charged partner.

His prediction was soon confirmed experimentally, the partner of the negatively charged electron showing up as the positively charged positron. More generally, all electrically charged particles (not only spin-1/2 particles described by the Dirac equation) have turned out to have oppositely charged antiparticles. Furthermore, some electrically neutral particles also have distinct antiparticles.

Returning to the second-quantized Dirac theory, this involves a Dirac quantum field in which the creation/annihilation operators of negative-energy states are replaced by annihilation/creation operators of positive-energy holes, resp. The hole theory substitution therefore leads to a Hilbert space (called Fock space) that accomodates an arbitrary number of particles and antiparticles with the same mass and opposite charge.

Soon after the introduction of the Dirac equation (which dates from 1928), it turned out that the number of particles and antiparticles is not conserved in a high-energy collision. Such creation and annihilation processes admit a natural description in the Fock spaces associated with relativistic quantum field theories. The very comprehensive mathematical description of real-world elementary particle phenomena that is now called the standard model arose some 30 years ago, and has been abundantly confirmed by experiment ever since. It involves

various relativistic quantum fields with nonlinear interactions. The Dirac quantum field is an essential ingredient, inasmuch as it is used to describe all spin-1/2 particles and antiparticles in the model (including quarks, electrons, neutrinos etc.).

After this survey (which is not only very brief, but also biased toward the physical concepts at issue), the contents of this article will be sketched. The free Dirac equation associated with the physical Minkowski spacetime $\mathbb{R}^4$ is first detailed. The exposition and notation are slightly unconventional in some respects. This is because we are partly preparing the ground for a mathematically precise account of the second-quantized version of the free Dirac theory. For example, momentum space (as opposed to position space) is emphasized, since the variable $\boldsymbol{x}$ in the Dirac equation does not have a clear physical significance and should be discarded in the Hilbert space formulation of the second-quantized Dirac field. The latter acts on a Fock space of multi-particle and -antiparticle wave functions depending on momentum and spin variables, and the spacetime dependence of the Dirac field is solely a consequence of relativistic covariance. (In particular, the variable $\boldsymbol{x}$ in the Dirac field $\Psi(t, \boldsymbol{x})$ should not be viewed as the position of particles and antiparticles created and annihilated by the field.)

To be sure, there is much more to the Dirac theory than its free first- and second-quantized versions for Minkowski spacetime $\mathbb{R}^4$. The primary purpose here is, however, to present these foundational versions in some detail. A much more sketchy account of further developments can be found in subsequent sections. First, the one-particle theory is reconsidered. Generalizations of the free theory to arbitrary dimensions and Euclidean settings are sketched and interactions with external fields are described, touching on various aspects and applications.

The next focus is on relations with index theory that arise when the massless Euclidean Dirac operator is generalized to geometric settings, namely $l$-dimensional Riemannian manifolds allowing a spin structure. We illustrate the general Atiyah–Singer index theory for the Dirac framework with some simple examples for $l=1$ (Toeplitz operators) and $l=2$ (the manifold $S^1 \times S^1$).

More information on the many-particle Dirac theory appears in the final section. Brief remarks on the Dirac field in interaction with other quantized fields are followed by an elaboration of the far simpler situation of the Dirac field interacting with external fields. Among the $S$-operators corresponding to such fields there is a special class of unitary matrix multipliers; the external field then vanishes for $t < 0$ and equals the pure gauge field corresponding to the unitary matrix for $t \geq 0$. Specializing to an even spacetime dimension and choosing special "kink" type unitaries, the associated Fock-space quadratic forms can be made to converge to the free Dirac field.

As mentioned already, Dirac's second quantization procedure was invented to get rid of the unphysical negative energies of the first-quantized (one-particle) theory. It is an amazing fact that the resulting formalism for the simplest case (namely the massless Dirac operator in a two-dimensional spacetime) can be exploited for quite different purposes. In particular, this setting can be tied in with various soliton equations and the representation theory of certain infinite-dimensional groups and Lie algebras. In conclusion, some of these applications are briefly sketched, namely the construction of special solutions to the Kadomtsev–Petviashvili (KP) equation (including the KP solitons and finite-gap solutions) and special representations of Kac–Moody and Virasoro algebras.

## The Free One-Particle Dirac Equation in $\mathbb{R}^4$

The free time-dependent Dirac equation is a linear hyperbolic evolution equation for a function $\Psi(t, \boldsymbol{x})$ on spacetime $\mathbb{R}^4$ with values in $\mathbb{C}^4$. It involves four $4 \times 4$ matrices $\gamma^\mu$, $\mu = 0, 1, 2, 3$, satisfying the $\gamma$-algebra

$$\gamma^\mu\gamma^\nu + \gamma^\nu\gamma^\mu = 2g^{\mu\nu}\mathbf{1}_4, \quad g = \mathrm{diag}(1, -1, -1, -1) \quad [1]$$

Using the Pauli matrices

$$\sigma_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \sigma_2 = \begin{pmatrix} 0 & -\mathrm{i} \\ \mathrm{i} & 0 \end{pmatrix}$$
$$\sigma_3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \quad [2]$$

one can choose for example

$$\gamma^0 = \begin{pmatrix} 0 & \mathbf{1}_2 \\ \mathbf{1}_2 & 0 \end{pmatrix}, \quad \gamma^k = \begin{pmatrix} 0 & -\sigma_k \\ \sigma_k & 0 \end{pmatrix}$$
$$k = 1, 2, 3 \quad [3]$$

Now the free Dirac equation reads

$$(\mathrm{i}\hbar\gamma^0\partial_t + \mathrm{i}\hbar c\gamma \cdot \nabla - mc^2\mathbf{1}_4)\Psi(t, \boldsymbol{x}) = 0 \quad [4]$$

where $\hbar$ is Planck's constant, $c$ the speed of light, and $m$ the particle mass. Using from now on units so that $\hbar = c = 1$, this can be abbreviated as

$$\left(\mathrm{i}\sum_{\mu=0}^{3}\gamma^{\mu}\partial_{\mu} - m\right)\Psi(x) = 0, \quad x = (x^0, x^1, x^2, x^3)$$
$$\partial_\mu = \partial/\partial x^\mu, \quad \mu = 0, 1, 2, 3 \qquad [5]$$

The relativistic invariance of this equation can be understood as follows. First, since the equation does not explicitly involve the spacetime coordinates, it is invariant under spacetime translations. (If $\Psi(t, \boldsymbol{x})$ solves [5], then also $\Psi(t - a_0, \boldsymbol{x} - \boldsymbol{a})$ is a solution for all $(a_0, \boldsymbol{a}) \in \mathbb{R}^4$.) Second, it is invariant under Lorentz transformations (rotations and boosts). Indeed, if $\Psi(x)$ is a solution and $L \in \mathrm{SO}(1,3)$, then $S(L)\Psi(L^{-1}x)$ solves [5] too, where $S(L)$ denotes a (suitably normalized) matrix satisfying

$$S(L)^{-1}\gamma^{\mu}S(L) = \sum_{\nu=0}^{3} L^{\mu}{}_{\nu}\gamma^{\nu} \qquad [6]$$

(The matrices $\gamma^{\mu\prime}$ on the right-hand side of [6] satisfy the $\gamma$-algebra [1]. From this, the existence of a representation $S(L)$ of SO(1, 3) satisfying [6] is readily deduced.)

As a consequence, the Poincaré group (inhomogeneous Lorentz group) acts in a natural way on the space of solutions to the time-dependent Dirac equation, expressing its independence of the choice of inertial frame. For quantum mechanical purposes, however, one needs to choose a frame and use the associated time variable to rewrite the equation as a Hilbert space evolution equation.

The relevant Hilbert space $\check{\mathcal{H}}$ is the space of four-component functions that are square integrable over space,

$$\check{\mathcal{H}} = L^2(\mathbb{R}^3, \mathrm{d}\boldsymbol{x}) \otimes \mathbb{C}^4 \qquad [7]$$

To obtain a self-adjoint Hamiltonian on $\check{\mathcal{H}}$, one multiplies [5] by $\gamma^0$ and introduces the Hermitian matrices

$$\beta = \gamma^0, \qquad \alpha^k = \gamma^0\gamma^k, \quad k = 1, 2, 3 \qquad [8]$$

Then, one obtains the Schrödinger type equation

$$\mathrm{i}\frac{\mathrm{d}}{\mathrm{d}t}\psi = \check{H}\psi \qquad [9]$$

where $\check{H}$ is the Dirac operator,

$$\check{H} = -\mathrm{i}\alpha\cdot\nabla + \beta m \qquad [10]$$

Under Fourier transformation,

$$\mathcal{F} : \check{\mathcal{H}} \to L^2(\mathbb{R}^3, \mathrm{d}\boldsymbol{p}) \otimes \mathbb{C}^4$$
$$\psi(\boldsymbol{x}) \mapsto \phi(\boldsymbol{p}) = (2\pi)^{-3/2}\int_{\mathbb{R}^3} \mathrm{d}\boldsymbol{x}\ \exp(-\mathrm{i}\boldsymbol{x}\cdot\boldsymbol{p})\psi(\boldsymbol{x}) \qquad [11]$$

eqn [9] turns into

$$\mathrm{i}\frac{\mathrm{d}}{\mathrm{d}t}\phi = D(\boldsymbol{p})\phi, \quad D(\boldsymbol{p}) = \boldsymbol{\alpha}\cdot\boldsymbol{p} + \beta m \qquad [12]$$

The matrix $D(\boldsymbol{p})$ is Hermitian and has square $E_p^2\mathbf{1}_4$, where $E_p$ is the relativistic energy,

$$E_p = (\boldsymbol{p}\cdot\boldsymbol{p} + m^2)^{1/2} \qquad [13]$$

corresponding to a momentum $\boldsymbol{p}$. Now, we have

$$U_{\mathrm{C}}\overline{D(-\boldsymbol{p})} = -D(\boldsymbol{p})U_{\mathrm{C}} \qquad [14]$$

where $U_{\mathrm{C}}$ is the charge conjugation matrix,

$$U_{\mathrm{C}} = \mathrm{i}\gamma^2 \qquad [15]$$

Hence, the four eigenvalues of $D(\boldsymbol{p})$ are given by $E_p$, $E_p$, $-E_p$, and $-E_p$. Therefore, the matrices

$$P_{\pm}(\boldsymbol{p}) = \frac{1}{2}\left(\mathbf{1}_4 \pm \frac{D(\boldsymbol{p})}{E_p}\right) \qquad [16]$$

are projections on the positive and negative spectral subspaces of $D(\boldsymbol{p})$.

As orthonormal base for the positive-energy subspace, we can now choose

$$w_{+,j}(\boldsymbol{p}) = \left(\frac{2E_p}{E_p + m}\right)^{1/2} P_+(\boldsymbol{p})b_j, \quad j = 1, 2 \qquad [17]$$

where

$$b_1 = \frac{1}{\sqrt{2}}\begin{pmatrix}1\\0\\1\\0\end{pmatrix}, \quad b_2 = \frac{1}{\sqrt{2}}\begin{pmatrix}0\\1\\0\\1\end{pmatrix} \qquad [18]$$

Next, setting

$$w_{-,j}(\boldsymbol{p}) = U_{\mathrm{C}}\overline{w_{+,j}}(\boldsymbol{p}), \quad j = 1, 2 \qquad [19]$$

an orthonormal base $w_{-,1}(-\boldsymbol{p})$, $w_{-,2}(-\boldsymbol{p})$ for the negative-energy subspace of $D(\boldsymbol{p})$ is obtained; cf. [14].

The upshot is that the time-independent Dirac equation

$$\check{H}\psi = E\psi \qquad [20]$$

gives rise to bounded eigenfunctions

$$\begin{aligned} e_{+,j}(\boldsymbol{x},\boldsymbol{p}) &= (2\pi)^{-3/2}\exp(\mathrm{i}\boldsymbol{x}\cdot\boldsymbol{p})w_{+,j}(\boldsymbol{p}), \quad j=1,2 \\ e_{-,j}(\boldsymbol{x},\boldsymbol{p}) &= (2\pi)^{-3/2}\exp(-\mathrm{i}\boldsymbol{x}\cdot\boldsymbol{p})w_{-,j}(\boldsymbol{p}), \quad j=1,2 \end{aligned} \qquad [21]$$

with eigenvalues $E=E_p$ and $E=-E_p$, resp. Clearly, they are not square-integrable, but they can be used as the kernel of a unitary transformation between $\check{\mathcal{H}}$ (7) and the Hilbert space

$$\begin{aligned} \mathcal{H} &= \mathcal{H}_+ \oplus \mathcal{H}_- = P_+\mathcal{H} \oplus P_-\mathcal{H} \\ \mathcal{H}_+, \mathcal{H}_- &= L^2(\mathbb{R}^3, \mathrm{d}\boldsymbol{p}) \otimes \mathbb{C}^2 \end{aligned} \qquad [22]$$

Specifically, we have

$$\begin{aligned} &W : \mathcal{H} \to \check{\mathcal{H}} \\ &f(\boldsymbol{p}) = (f_+(\boldsymbol{p}), f_-(\boldsymbol{p})) \\ &\mapsto \psi(\boldsymbol{x}) = \sum_{\delta=+,-}\sum_{j=1,2}\int_{\mathbb{R}^3}\mathrm{d}\boldsymbol{p}\, e_{\delta,j}(\boldsymbol{x},\boldsymbol{p})f_{\delta,j}(\boldsymbol{p}) \end{aligned} \qquad [23]$$

which entails

$$(W^{-1}\psi)_{\delta,j}(\boldsymbol{p}) = \int_{\mathbb{R}^3}\mathrm{d}\boldsymbol{x}\,\overline{e_{\delta,j}}(\boldsymbol{x},\boldsymbol{p})\cdot\psi(\boldsymbol{x}) \qquad [24]$$

(Here and throughout this article, a bar denotes complex conjugation.)

From the above, it is clear that the Dirac Hamiltonian $\check{H}$ acting on the Hilbert space $\check{\mathcal{H}}$ is unitarily equivalent to the multiplication operator on $\mathcal{H}$ [22] given by

$$(Hf)_\delta(\boldsymbol{p}) = \delta E_p f_\delta(\boldsymbol{p}), \quad \delta=+,- \qquad [25]$$

Indeed, $W$ is a diagonalizing transformation for $\check{H}$, the relation

$$H = W^{-1}\check{H}W \qquad [26]$$

yielding an explicit realization of the spectral theorem.

Using the same notational convention, the momentum, charge conjugation, parity, and time-reversal operators on $\check{\mathcal{H}}$, given by

$$(\check{P}_k\psi)(\boldsymbol{x}) = -\mathrm{i}\partial_k\psi(\boldsymbol{x}) \qquad [27]$$

$$(\check{C}\psi)(\boldsymbol{x}) = U_C\bar{\psi}(\boldsymbol{x}) \qquad [28]$$

$$(\check{P}\psi)(\boldsymbol{x}) = U_P\psi(-\boldsymbol{x}), \quad U_P = \gamma^0 \qquad [29]$$

$$(\check{T}\psi)(\boldsymbol{x}) = U_T\bar{\psi}(\boldsymbol{x}), \quad U_T = \gamma^1\gamma^3 \qquad [30]$$

transform into the operators

$$(P_kf)_\delta(\boldsymbol{p}) = \delta p_k f_\delta(\boldsymbol{p}), \quad \delta=+,- \qquad [31]$$

$$(Cf)_\delta(\boldsymbol{p}) = \bar{f}_{-\delta}(\boldsymbol{p}), \quad \delta=+,- \qquad [32]$$

$$(Pf)_\delta(\boldsymbol{p}) = \delta f_\delta(-\boldsymbol{p}), \quad \delta=+,- \qquad [33]$$

$$(Tf)_\delta(\boldsymbol{p}) = \mathrm{i}\sigma_2\bar{f}_\delta(-\boldsymbol{p}), \quad \delta=+,- \qquad [34]$$

Note that $P_k$, $P$, and $T$ leave the positive- and negative-energy subspaces $\mathcal{H}_+$ and $\mathcal{H}_-$ invariant, whereas $C$ interchanges them.

To conclude this section, we describe some salient features of the unitary representation of the (identity component of the) Poincaré group on $\mathcal{H}$, which follows from the representation on solutions to [5] already sketched. The spacetime translations over $a \in \mathbb{R}^4$ are represented by the unitary operator $\exp(-\mathrm{i}a_0H + \mathrm{i}\boldsymbol{a}\cdot\boldsymbol{P})$; explicitly,

$$\begin{aligned} &(\exp(-\mathrm{i}a_0H + \mathrm{i}\boldsymbol{a}\cdot\boldsymbol{P})f)_\delta(\boldsymbol{p}) \\ &\quad = \exp(-\mathrm{i}\delta(a_0E_p - \boldsymbol{a}\cdot\boldsymbol{p}))f_\delta(\boldsymbol{p}), \quad \delta=+,- \end{aligned} \qquad [35]$$

The representation of the Lorentz group involves unitary $2\times2$ matrices $U(k, A)$, where $k$ is an arbitrary 4-vector satisfying $k^\mu k_\mu = 1$ and $A$ the matrix in SL(2, $\mathbb{C}$) representing $L \in$ SO(1, 3). (Recall that SL(2, $\mathbb{C}$) can be viewed as a 2-fold cover of SO(1, 3).) In particular, $U(k, A)$ does not depend on $k$ for rotations,

$$U(k, A) = A^*, \quad \forall A \in \mathrm{SU}(2) \qquad [36]$$

(Here and henceforth, we use $*$ to denote the Hermitian adjoint of matrices and operators.) For boosts, however, there is dependence on the vector $k$, which is the image of the vector (1, **0**) under the boost. We refrain from a more detailed description of $U(k, A)$, as this would carry us too far afield.

The unitary SO(1, 3) representation leaves the decomposition $\mathcal{H} = P_+\mathcal{H} \oplus P_-\mathcal{H}$ invariant. On the positive-energy subspace $\mathcal{H}_+$, it is given by

$$(U(L)f)_+(\boldsymbol{p}) = \left(\frac{p_0^L}{p_0}\right)^{1/2} U\left(\frac{p}{m}, A\right)^* f_+(\boldsymbol{p}^L) \qquad [37]$$

where

$$p = (E_p, \boldsymbol{p}), \quad p^L = L^{-1}p \qquad [38]$$

On $\mathcal{H}_-$, it is given by the complex-conjugate representation,

$$(U(L)f)_-(\boldsymbol{p}) = \left(\frac{p_0^L}{p_0}\right)^{1/2} U\left(\frac{p}{m}, A\right)^{\mathrm{t}} f_-(\boldsymbol{p}^L) \qquad [39]$$

just as for the spacetime translations, cf. [35]. (The superscript t is used to denote the transpose matrix.) This feature is crucial for the second-quantized Dirac theory, which is discussed next.

## The Free Dirac Field in $\mathbb{R}^4$

The free Dirac field is an operator-valued distribution on a Fock space that describes an arbitrary number of spin-1/2 particles and antiparticles in terms of momentum space wave functions. Since spin-1/2 particles are fermions (which encodes the Pauli exclusion principle), an $M$-particle wave function $F^{+,\dots,+}_{j_1,\dots,j_M}(\boldsymbol{p}_1,\dots,\boldsymbol{p}_M)$ (where $j_l \in \{1, 2\}$ is the spin index) is antisymmetric under any interchange of a pair $(j_i, \boldsymbol{p}_i)$ and $(j_k, \boldsymbol{p}_k)$. Likewise, $N$-antiparticle wave functions $F^{-,\dots,-}_{k_1,\dots,k_N}(\boldsymbol{q}_1,\dots,\boldsymbol{q}_N)$ are antisymmetric. But a wave function $F^{+-}_{j,k}(\boldsymbol{p},\boldsymbol{q})$ describing a particle–antiparticle pair need not have any symmetry property, since a particle and an antiparticle can be distinguished by their charge.

The relevant Fock space is therefore the tensor product of two antisymmetric Fock spaces built over the one-particle and one-antiparticle spaces $L^2(\mathbb{R}^3, \mathrm{d}\boldsymbol{p}) \otimes \mathbb{C}^2$. For later purposes, it is important to view these spaces as the summands $\mathcal{H}_+$ and $\mathcal{H}_-$ of the space $\mathcal{H}$ from the previous section. Thus, the arena for the free Dirac field is the Hilbert space

$$\mathcal{F}_a(\mathcal{H}) \simeq \mathcal{F}_a(\mathcal{H}_+) \otimes \mathcal{F}_a(\mathcal{H}_-) \qquad [40]$$

where, for example,

$$\mathcal{F}_a(\mathcal{H}) = (\mathbb{C} \oplus \mathcal{H} \oplus (\mathcal{H} \otimes \mathcal{H})_a \oplus \cdots)^- \qquad [41]$$

where the bar denotes the completion of the infinite direct sum in the obvious inner product. The tensor $(1, 0, 0, \dots)$ is viewed as the vacuum (the "filled Dirac sea") and denoted by $\Omega$.

To get around in Fock space, one employs the creation and annihilation operators $c^{(*)}(f), f \in \mathcal{H}$. The creation operator $c^*(f), f \in \mathcal{H}$, is defined by linear and continuous extension of its action on the vacuum $\Omega$ and on elementary antisymmetric tensors, recursively given by

$$\begin{aligned} &c^*(f)\Omega = f, \quad c^*(f)f_1 = f \wedge f_1, \dots \\ &\quad c^*(f)f_1 \wedge \cdots \wedge f_N = f \wedge f_1 \wedge \cdots \wedge f_N, \dots \end{aligned} \qquad [42]$$

Its adjoint, the annihilation operator $c(f)$, satisfies

$$\begin{aligned} &c(f)\Omega = 0, \quad c(f)f_1 = (f, f_1)\Omega, \dots \\ &c(f)f_1 \wedge \cdots \wedge f_N = \sum_{j=1}^{N} (-)^{j-1}(f, f_j) \\ &\qquad \times f_1 \wedge \cdots \wedge \widehat{f_j} \wedge \cdots \wedge f_N, \dots \end{aligned} \qquad [43]$$

Accordingly, the operators $c^{(*)}(f)$ satisfy the canonical anticommutation relations (CARs) over $\mathcal{H}$,

$$\begin{aligned} &\{c(f), c(g)\} = 0, \\ &\quad \{c(f), c^*(g)\} = (f, g), \quad \forall f, g \in \mathcal{H} \end{aligned} \qquad [44]$$

where $\{A, B\}$ denotes the anticommutator $AB + BA$. (From this, one readily deduces that $c^{(*)}(f)$ is bounded with norm $\|f\|$.)

Next, recalling the direct sum decomposition [22], a notation change

$$c^{(*)}(P_+f) \to a^{(*)}(P_+f), \quad c^{(*)}(P_-f) \to b^{(*)}(P_-f) \qquad [45]$$

is made, thus indicating that $a^{(*)}$ and $b^{(*)}$ should be viewed as the creation/annihilation operators of particles and antiparticles, resp. Since $\mathcal{H}_+$ and $\mathcal{H}_-$ are copies of $L^2(\mathbb{R}^3, \mathrm{d}\boldsymbol{p}) \otimes \mathbb{C}^2$, a given function $(f_1(\boldsymbol{p}), f_2(\boldsymbol{p}))$ in the latter space can occur both as an argument of $a^{(*)}(\cdot)$ and of $b^{(*)}(\cdot)$; it can also be viewed as a smearing function for unsmeared quantities $a_j^{(*)}(\boldsymbol{p})$ and $b_j^{(*)}(\boldsymbol{p})$, $j = 1, 2$, that are often referred to as operators as well (even though they are only quadratic forms). Thus, one has, for example,

$$\begin{aligned} b^*(f) &= \sum_{j=1}^{2} \int_{\mathbb{R}^3} \mathrm{d}\boldsymbol{p}\, b_j^*(\boldsymbol{p}) f_j(\boldsymbol{p}) \\ b(f) &= \sum_{j=1}^{2} \int_{\mathbb{R}^3} \mathrm{d}\boldsymbol{p}\, b_j(\boldsymbol{p}) \bar{f}_j(\boldsymbol{p}) \end{aligned} \qquad [46]$$

As explained shortly, the smeared time-zero Dirac field takes the form

$$\Phi(f) = a(P_+f) + b^*(KP_-f), \quad f \in \mathcal{H} \qquad [47]$$

Here and below, $K$ denotes complex conjugation on $\mathcal{H}$, $\mathcal{H}_+$, and $\mathcal{H}_-$. Just as the operators $c^{(*)}(f)$, the operators $\Phi^{(*)}(f)$ satisfy the CARs over $\mathcal{H}$,

$$\begin{aligned} &\{\Phi(f), \Phi(g)\} = 0 \\ &\{\Phi(f), \Phi^*(g)\} = (f, g), \quad \forall f, g \in \mathcal{H} \end{aligned} \qquad [48]$$

as is readily verified using [44]–[45]. But this $\Phi$-representation is not unitarily equivalent to the $c$-representation [44]. This becomes clear in particular from the consideration of a crucial type of CAR automorphism that is considered next.

To this end, we fix a unitary operator $U$ on $\mathcal{H}$. Then it is plain that the operators

$$\tilde{c}^{(*)}(f) = c^{(*)}(Uf) \qquad [49]$$

$$\tilde{\Phi}^{(*)}(f) = \Phi^{(*)}(Uf) \qquad [50]$$

also satisfy the CARs. The CAR-algebra automorphism $c^{(*)}(f) \mapsto \tilde{c}^{(*)}(f)$ can be unitarily implemented in $\mathcal{F}_a(\mathcal{H})$, since one has

$$\tilde{c}^{(*)}(f) = \Gamma(U)c^{(*)}(f)\Gamma(U^*) \qquad [51]$$

where $\Gamma(U)$ denotes the Fock-space product operator corresponding to $U$. Thus, for example,

$$\begin{aligned} &\Gamma(U)\Omega = \Omega, \quad \Gamma(U)f = Uf, \ldots \\ &\quad \Gamma(U)f_1 \wedge \cdots \wedge f_N = Uf_1 \wedge \cdots \wedge Uf_N, \ldots \end{aligned} \qquad [52]$$

For the CAR automorphism $\Phi^{(*)}(f) \mapsto \tilde{\Phi}^{(*)}(f)$ this is not true, however. Rewriting it in terms of the annihilation and creation operators $a^{(*)}$ and $b^{(*)}$ via [47], it amounts to a linear transformation (Bogoliubov transformation), whose unitary implementability has been clarified several decades ago. To be specific, the necessary and sufficient condition for unitary implementability is that the off-diagonal parts

$$U_{+-} = P_+ U P_-, \qquad U_{-+} = P_- U P_+ \qquad [53]$$

in the $2 \times 2$ matrix decomposition of operators on $\mathcal{H}$ be Hilbert–Schmidt operators. Therefore, no problem arises when $U$ is diagonal with respect to this decomposition. Indeed, in that case one can choose as unitary implementer the product operator

$$\tilde{\Gamma}(U) = \Gamma(U_{++}) \otimes \Gamma(KU_{--}K) \qquad [54]$$

(cf. the tensor product structure [40] of $\mathcal{F}_a(\mathcal{H})$).

In particular, the automorphism

$$\Phi(f) \mapsto \Phi(\mathrm{e}^{\mathrm{i}tH}f) \qquad [55]$$

where $H$ is the free diagonalized Dirac Hamiltonian [25], is implemented by the operator

$$\tilde{\Gamma}(\mathrm{e}^{\mathrm{i}tH}) = \Gamma(\mathrm{e}^{\mathrm{i}tE}) \otimes \Gamma(\mathrm{e}^{\mathrm{i}tE}) \qquad [56]$$

where $E$ denotes multiplication by $E_p$ on $\mathcal{H}_+$ and $\mathcal{H}_-$. The change of CAR representation, therefore, entails that the unphysical negative energies of the one-particle theory are replaced by positive energies of antiparticles. Hence, we obtain a mathematically precise version of Dirac's hole theory substitution $b_j(\boldsymbol{p}) \to b_j^*(\boldsymbol{p})$, $b_j^*(\boldsymbol{p}) \to b_j(\boldsymbol{p})$.

More generally, if one chooses for $U$ the Poincaré group representation (given by [35] and [37]–[39]), then the Fock-space implementer [54] is the tensor product of two product operators with the same action on $\mathcal{F}_a(L^2(\mathbb{R}^3, \mathrm{d}\boldsymbol{p}) \otimes \mathbb{C}^2)$. Observe that this is also true for the Fock-space version $\tilde{\Gamma}(T) = \Gamma(T)$ of the time-reversal operator [34]. By contrast, the Fock-space parity operator $\tilde{\Gamma}(P) = \Gamma(P)$ gives rise to two product operators with slightly different actions, cf. [33]. Accordingly, particles and antiparticles have opposite parity.

The map

$$\Phi(f) \mapsto \Phi(Cf)^* \qquad [57]$$

also yields a CAR automorphism. It is unitarily implemented by the Fock-space charge-conjugation operator

$$\mathcal{C} = \Gamma\left(\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}\right) \qquad [58]$$

which interchanges particles and antiparticles. Notice that $\mathcal{C}$ is unitary, whereas $C$ is antiunitary.

It remains to establish the precise relation of the above to the customary free Dirac field $\Psi(t, \boldsymbol{x})$. This is a quadratic form on $\mathcal{F}_a(\mathcal{H})$ given by

$$\begin{aligned} \Psi(t, \boldsymbol{x}) = (2\pi)^{-3/2} \int_{\mathbb{R}^3} \mathrm{d}\boldsymbol{p} \sum_{j=1,2} \Big( a_j(\boldsymbol{p}) w_{+,j}(\boldsymbol{p}) \mathrm{e}^{-\mathrm{i}E_p t + \mathrm{i}\boldsymbol{p}\cdot\boldsymbol{x}} \\ + b_j^*(\boldsymbol{p}) w_{-,j}(\boldsymbol{p}) \mathrm{e}^{\mathrm{i}E_p t - \mathrm{i}\boldsymbol{p}\cdot\boldsymbol{x}} \Big) \end{aligned} \qquad [59]$$

(Its expectation $\langle F_1, \Psi(t, \boldsymbol{x}) F_2 \rangle$ is, for example, well defined for $F_1$, $F_2$ in the dense subspace of $\mathcal{F}_a(\mathcal{H})$ that consists of vectors with finitely many particles and antiparticles and wave functions in Schwartz space.) It satisfies the time-dependent Dirac equation

$$\mathrm{i}\partial_t \Psi = (-\mathrm{i}\alpha \cdot \nabla + \beta m)\Psi \qquad [60]$$

in the sense of quadratic forms. Furthermore, smearing it with a function $\overline{\psi}(\boldsymbol{x})$ in the Hilbert space $\check{\mathcal{H}}$ (7), we obtain

$$\begin{aligned} &\int_{\mathbb{R}^3} \mathrm{d}\boldsymbol{x} \overline{\psi}(\boldsymbol{x}) \cdot \Psi(t, \boldsymbol{x}) \\ &\quad = \Phi(\mathrm{e}^{\mathrm{i}tH} W^{-1} \psi) \\ &\quad = \tilde{\Gamma}(\mathrm{e}^{\mathrm{i}tH}) \Phi(W^{-1}\psi) \tilde{\Gamma}(\mathrm{e}^{-\mathrm{i}tH}) \quad \psi \in \check{\mathcal{H}} \end{aligned} \qquad [61]$$

As announced, the time evolution of the free Dirac field is, therefore, given by the unitary one-parameter group [56], whose generator (the second-quantized Dirac Hamiltonian) has spectrum $\{0\} \cup [m, \infty)$.

The Dirac field $\Psi(t, \boldsymbol{x})$ can also be smeared with a test function $F(t, \boldsymbol{x})$ in the Schwartz space $S(\mathbb{R}^4)^4$, yielding a bounded operator

$$\Psi(F) = \int_{\mathbb{R}^4} \mathrm{d}x F(x) \cdot \Psi(x) \qquad [62]$$

Then one obtains the relativistic covariance relation

$$\tilde{\Gamma}(U(a, L)) \Psi(F) \tilde{\Gamma}(U(a, L))^* = \Psi(F^{a,L}) \qquad [63]$$

where

$$F^{a,L}(x) = S(L^{-1})^t F(L^{-1}(x - a)) \qquad [64]$$

and $U(a, L)$ denotes the Poincaré group representation on $\mathcal{H}$, cf. [35] and [37]–[39]. Likewise, one gets the inversion formulas

$$\tilde{\Gamma}(I)\Psi(F)\tilde{\Gamma}(I)^* = \Psi(F_I), \quad I = P, T \qquad [65]$$

with

$$F_P(t, \boldsymbol{x}) = U_P^t F(t, -\boldsymbol{x}), \quad F_T(t, \boldsymbol{x}) = U_T^t \bar{F}(-t, \boldsymbol{x}) \qquad [66]$$

while the Fock-space charge-conjugation operator [58] transforms the Dirac field as

$$\mathcal{C}\Psi(F)\mathcal{C} = \Psi(F_C)^* \qquad [67]$$

with

$$F_C(x) = U_C^t \bar{F}(x) \qquad [68]$$

Finally, let us consider the global U(1) gauge transformations $f \mapsto e^{i\phi} f$, where $\phi \in \mathbb{R}$ and $f \in \mathcal{H}$. They can be implemented by

$$\tilde{\Gamma}(e^{i\phi}) = \Gamma(e^{i\phi}) \otimes \Gamma(e^{-i\phi}) \qquad [69]$$

and one has

$$\tilde{\Gamma}(e^{i\phi})\Psi(F)\tilde{\Gamma}(e^{i\phi})^* = \Psi(F_\phi) \qquad [70]$$

with

$$F_\phi(x) = e^{-i\phi} F(x) \qquad [71]$$

The generator $Q$ of the one-parameter group $\phi \mapsto \tilde{\Gamma}(e^{i\phi})$ is the charge operator: on wave functions describing $N_+$ particles and $N_-$ antiparticles, it has eigenvalue $N_+ - N_-$.

## More on the One-Particle Dirac Theory

Even for the free one-particle setting, the account given earlier is far from complete. To begin with, the free Dirac equation admits a specialization to massless particles. In the Weyl representation of the $\gamma$-algebra adopted above, the choice $m = 0$ entails that the $\boldsymbol{p}$-space equation [12] decouples into two $2 \times 2$ equations for spinors that can be labeled by their chirality ("handedness"). This refers to their eigenvalue with respect to the chirality matrix

$$\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3 = \begin{pmatrix} \mathbf{1}_2 & 0 \\ 0 & -\mathbf{1}_2 \end{pmatrix} \qquad [72]$$

and this notion derives from the noninvariance of the separate $2 \times 2$ equations under parity. (A positive-chirality spinor is mapped to a negative-chirality spinor under the parity operator $\check{P}$ (33) and vice versa.) Since the weak interaction breaks parity symmetry, the two $2 \times 2$ equations (often called Weyl equations) do have physical relevance. Indeed, the associated quantum fields are a crucial ingredient of the standard model.

Next, we point out that it is possible to switch to a representation in which the gamma matrices are real. This so-called Majorana representation is convenient (but not indispensable) in the description of neutral spin-1/2 particles. By definition, such particles are equal to their antiparticles, so that the second-quantized formalism of the previous section must be adapted: one needs the neutral CAR algebra over $\mathcal{H}$ (also known as self-dual CAR).

For various purposes, it is important to formulate the free Dirac equation for a spacetime whose spatial dimension is arbitrary. Then one needs, first of all, gamma matrices satisfying the (Minkowski) Clifford algebra relations

$$\gamma^\mu\gamma^\nu + \gamma^\nu\gamma^\mu = 2g^{\mu\nu}\mathbf{1}_\Lambda, \quad g = \mathrm{diag}(1, -\mathbf{1}_n) \qquad [73]$$

where $n$ is the space dimension and the minimal size $\Lambda \times \Lambda$ of the gamma matrices is to be determined.

Clearly, for $n = 1$ and $n = 2$, one can take $\Lambda = 2$, choosing, for example,

$$\gamma^0 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \gamma^1 = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$$
$$\gamma^2 = \begin{pmatrix} i & 0 \\ 0 & -i \end{pmatrix} \qquad [74]$$

to fulfill [73]. For $n = 4$, one can take $\Lambda = 4$, just as for $n = 3$, supplementing [1] with the matrix $i\gamma^5$, cf. [72].

More generally, for $n = 2N - 1$ and $n = 2N$, one can take $\Lambda = 2^N$ in [73]. Indeed, a representation on the $2^N$-dimensional fermion Fock space $\mathcal{F}_a(\mathbb{C}^N)$ (cf. [41]) is readily constructed using the creation and annihilation operators described in the previous section. Once this has been taken care of, most of the discussion on the free one-particle Dirac equation in $\mathbb{R}^4$ can be easily generalized. Of special importance in this regard is the straightforward adaptation of the formulas [7]–[26], which form the foundation for the second-quantized version. Indeed, the discussion of the last section applies nearly verbatim for arbitrary spacetime dimension.

In several applications, the so-called Euclidean version of the free Dirac theory in spacetime dimension $n + 1$ is important. Basically, this version is obtained upon replacing $i\partial_0$ by $\partial_{n+1}$ in the Dirac equation, a substitution that changes the character of the equation from hyperbolic to elliptic. Provided that the mass vanishes, the Euclidean Dirac equation admits a reinterpretation as a time-independent zero-eigenvalue Weyl equation in a Minkowski spacetime of dimension $n + 2$. (This equation is often called the zero-mode equation.)

Let us now turn to the description of the interaction with an external electromagnetic potential $A_\mu(t, \boldsymbol{x})$. This can be taken into account via the minimal substitution,

$$\partial_\mu \to \partial_\mu + \mathrm{i}eA_\mu \qquad [75]$$

also known as the covariant derivative, in the time-dependent Dirac equation [5].

For the electron in the Coulomb field of a nucleus of charge $Ze$, one has

$$A_k = 0,\ k = 1,2,3, \quad A_0 = -\frac{Ze}{4\pi|\boldsymbol{x}|} \qquad [76]$$

and the time-independent equation

$$\left(-\mathrm{i}\boldsymbol{\alpha}\cdot\nabla + \beta m - \frac{Ze^2}{4\pi|\boldsymbol{x}|}\right)\psi = E\psi \qquad [77]$$

can be solved explicitly. This leads to a bound-state spectrum that is more accurate than its nonrelativistic counterpart. In particular, one finds that energy levels that are degenerate in the nonrelativistic theory split up into slightly different levels. The resulting fine structure of the Dirac levels can be understood as a consequence of the coupling between the spin of the electron and its orbital motion.

In spite of this better agreement with the experimental levels, the physical interpretation of the Dirac electron in a Coulomb field is enigmatic. This is not only because of the persistence of the negative-energy states of the free theory (which turn into scattering states), but also because of unphysical properties of the position operator. More general time-independent external fields (such as step potentials $A_0(\boldsymbol{x})$ with a step height larger than $2m$) can cause transitions between positive- and negative-energy states (Klein paradox). This phenomenon is enhanced when time dependence is allowed. In particular, any external field that is given by functions in $C_0^\infty(\mathbb{R}^4)$ leads to a scattering operator $S$ on the one-particle space $\mathcal{H}$ [22] that has nonzero off-diagonal parts $S_{\pm\mp}$. Hence, a positive-energy wave packet scattering at such a time- and space-localized field has a nonzero probability to show up as a negative-energy wave packet.

When one tensors the one-particle space $\check{\mathcal{H}}$ with an internal symmetry space $\mathbb{C}^k$, one can also couple external Yang–Mills fields $A_\mu$ taking values in the $k \times k$ matrices via the substitution [75]. (From a geometric viewpoint, this can be rephrased as tensoring the spinor bundle with a vector bundle equipped with a connection $A$.) The generalization of this external gauge field coupling to a Minkowski spacetime or Euclidean space of arbitrary dimension is straightforward. An adaptation of the resulting interacting one-particle Dirac theory in arbitrary dimension to quite general geometric settings also yields a crucial starting point for index theory.

Before turning to the latter area, we conclude this section with another striking application of the one-particle framework, namely the massless Dirac equation in two spacetime dimensions with special external fields. Specifically, the relevant Dirac operator is of the form

$$\begin{pmatrix} \mathrm{i}\frac{\mathrm{d}}{\mathrm{d}x} & -\mathrm{i}q(x) \\ \mathrm{i}r(x) & -\mathrm{i}\frac{\mathrm{d}}{\mathrm{d}x} \end{pmatrix} \qquad [78]$$

where $r(x)$ and $q(x)$ are not necessarily real valued. (Note that this operator is in general not self-adjoint.) With suitable restrictions on $r$ and $q$, the direct and inverse scattering theory associated with the Dirac operator [78] can be applied to various nonlinear PDEs in two spacetime dimensions to solve their Cauchy problems in considerable detail. As a crucial special case, initial conditions yielding vanishing reflection give rise to soliton solutions for the pertinent equation.

The first example in this framework was found by Zakharov and Shabat (the nonlinear Schrödinger equation); with other choices of $r$ and $q$ several other soliton PDEs (including the sine-Gordon and modified Korteweg–de Vries equations) were handled by Ablowitz, Kaup, Newell, and Segur, who studied a quite general class of external fields $r$ and $q$.

## The Dirac Operator and Index Theory

Thus far, we have considered various versions of the Dirac operator associated with the spaces $\mathbb{R}^l$ for some $l \geq 1$. For applications in the area of index theory, however, one needs to generalize this base manifold. Indeed, one can define a Dirac operator for any $l$-dimensional oriented Riemannian manifold $\mathcal{M}$ that admits a spin structure. This is a lifting of the transition functions of the tangent bundle $T\mathcal{M}$ (which may be assumed to take values in $\mathrm{SO}(l)$) to the simply connected twofold cover $\mathrm{Spin}(l)$ (taking $l \geq 3$).

Choosing first $l = 2N + 1$, the spin group has a faithful irreducible representation on $\mathbb{C}^{2^N}$. Hence, one obtains a $\mathbb{C}^{2^N}$-bundle over $\mathcal{M}$, the spinor bundle. The Levi-Civita connection on $\mathcal{M}$ derived from the metric can now be lifted to a connection on the spinor bundle. From the covariant derivative corresponding to the spin connection and the

Clifford algebra generators $\gamma^1, \ldots, \gamma^l$, one can then construct a first-order elliptic differential operator that acts on sections of the spinor bundle. (For the case $\mathcal{M} = \mathbb{R}^{2N+1}$ with its Euclidean metric, this construction yields the massless positive-chirality Dirac operator acting on wave functions with $2^N$ components, as considered above.)

The massless Dirac operator thus obtained is self-adjoint as an operator on the $L^2$-space $\mathcal{H}$ associated with the spinor bundle, and it has infinite-dimensional positive and negative spectral subspaces $\mathcal{H}_+$ and $\mathcal{H}_-$. (In this section the check accent on position-space quantities is omitted.) Specializing to the case of compact $\mathcal{M}$, a continuous map from $\mathcal{M}$ to $\mathbb{C}^*$ gives rise to a Fredholm operator on $\mathcal{H}_+$, and more generally a continuous map from $\mathcal{M}$ to $\mathrm{GL}(k, \mathbb{C})$ yields a Fredholm operator on $\mathcal{H}_+ \otimes \mathbb{C}^k$.

For a smooth map, the Fredholm index of this operator can be written in terms of an integral over $\mathcal{M}$ involving certain closed differential forms. The value of this integral does not change when exact forms are added, since $\mathcal{M}$ has no boundary. Hence, one is dealing with de Rham cohomology classes. In this context, the class involved ("characteristic class") is determined by the Riemann curvature tensor of $\mathcal{M}$ and the topological ("winding") characteristics of the map.

The simplest example of this state of affairs arises for $l = 1$ and $\mathcal{M} = S^1$ with its obvious spin structure (periodic boundary conditions). Writing $\psi \in \mathcal{H} = L^2(S^1)$ as

$$\psi(z) = \sum_{n \in \mathbb{Z}} a_n z^n, \quad z \in S^1 \qquad [79]$$

the Dirac operator $H$ on $\mathcal{H}$ reads

$$H = z \frac{\mathrm{d}}{\mathrm{d}z} \qquad [80]$$

It has eigenfunctions $z^n, n \in \mathbb{Z}$. Thus, we may choose

$$(P_+\psi)(z) = \sum_{n \geq 0} a_n z^n, \quad (P_-\psi)(z) = \sum_{n < 0} a_n z^n \qquad [81]$$

As a consequence, the functions in $\mathcal{H}_+ (\mathcal{H}_-)$ are $L^2$-boundary values of holomorphic functions in $|z| < 1$ ($|z| > 1$). Operators of the form

$$T_\psi = P_+ M_\psi P_+ \qquad [82]$$

where $\psi$ is a continuous function on $S^1$ and $M_\psi$ denotes multiplication by $\psi$, are called Toeplitz operators. It is not hard to see that they are Fredholm (viewed as operators on $\mathcal{H}_+$), provided that $\psi$ does not vanish on $S^1$. (Recall a bounded operator $B$ is Fredholm if it has finite-dimensional kernel $K$ and cokernel $C$. Its Fredholm index is given by

$$\mathrm{index}(B) = \dim K - \dim C \qquad [83]$$

and is norm continuous and invariant under addition of a compact operator.) Assuming $\psi(S^1) \subset \mathbb{C}^*$ from now on, the curve $\psi(S^1)$ has a well-defined winding number $w(\psi)$ with respect to the origin. The equality

$$\mathrm{index}(T_\psi) = -w(\psi) \qquad [84]$$

between objects from the area of analysis on the left-hand side and from the areas of topology and geometry on the right-hand side is the simplest example of an Atiyah–Singer type index formula. When $\psi$ is not only continuous but also smooth, the index formula can be rewritten as

$$\mathrm{index}(T_\psi) = -\frac{1}{2\pi \mathrm{i}} \int_{S^1} \frac{\mathrm{d}\psi}{\psi} \qquad [85]$$

yielding a characteristic class version.

It should be noted that the operator $M_\psi$ on $\mathcal{H}$ has a bounded inverse $M_{1/\psi}$ when $0 \notin \psi(S^1)$, hence a trivially vanishing index. Therefore, the compression [82] involving the spectral projection of the Dirac operator is needed to get a nonzero index. Observe also that the equality [84] is quite easily verified for the case $\psi(z) = z^n$, since $T_\psi$ yields a power of the right ($n > 0$) or left ($n < 0$) shift on $P_+\mathcal{H} \simeq l^2(\mathbb{N})$.

We proceed to the case of even-dimensional manifolds, $l = 2N$. Then the fiber $\mathbb{C}^{2^N}$ of the spinor bundle splits into a direct sum of even and odd spinors, corresponding to two distinct representations of $\mathrm{Spin}(2N)$ on $\mathbb{C}^{2^{N-1}}$. (Here it is assumed that $N > 3$; recall the Lie algebra isomorphisms $\mathrm{so}(4) \simeq \mathrm{so}(3) \oplus \mathrm{so}(3)$ and $\mathrm{so}(6) \simeq \mathrm{su}(4)$.) With respect to this decomposition, the Dirac operator can be written as

$$H = \begin{pmatrix} 0 & \mathcal{D}^* \\ \mathcal{D} & 0 \end{pmatrix} \qquad [86]$$

where $\mathcal{D}$ and $\mathcal{D}^*$ are again first-order elliptic differential operators expressed in terms of Clifford algebra generators and the spin connection. Tensoring the spinor bundle with a vector bundle equipped with a connection $A$, one can define a Dirac operator on the tensor product which involves $A$ and takes the form

$$H_A = \begin{pmatrix} 0 & \mathcal{D}_A^* \\ \mathcal{D}_A & 0 \end{pmatrix} \qquad [87]$$

with respect to the even/odd spinor decomposition. Once more, the index of $\mathcal{D}_A$ (viewed as a Fredholm operator between two different Hilbert spaces) can be expressed as an integral over $\mathcal{M}$ involving characteristic classes that depend on the curvatures of the two connections.

Probably the simplest example of the constructions just sketched is given by the torus $\mathcal{M} = S^1 \times S^1$ with its flat metric. Employing the above coordinate and spin structure on $S^1$, one can take

$$\mathcal{H} = L^2(S^1 \times S^1) \otimes \mathbb{C}^2, \quad \mathcal{D} = z_1 \frac{\partial}{\partial z_1} + \mathrm{i} z_2 \frac{\partial}{\partial z_2} \qquad [88]$$

Since the curvature vanishes, the index theorem for this situation implies $\mathrm{index}(\mathcal{D}) = 0$. (Note that this is also plain from [88]: both kernel and cokernel of $\mathcal{D}$ are spanned by the constant sections.) On the other hand, when one tensors the spinor bundle with a line bundle with connection $A$, the index formula reads

$$\mathrm{index}(\mathcal{D}_A) = -\frac{1}{2\pi} \int_{S^1 \times S^1} F \qquad [89]$$

where $F$ is the curvature 2-form corresponding to $A$.

The Atiyah–Singer index theorem for Dirac operators has far-reaching applications. It can be used to derive other results in this area, such as the Gauss–Bonnet–Chern theorem, the Hirzebruch signature theorem, and (when $\mathcal{M}$ is a Kähler manifold) Riemann–Roch type theorems. From this, one can obtain information on various questions, such as the existence of positive scalar curvature metrics or zeros of vector fields on $\mathcal{M}$. Other applications include insights on topological invariants of manifolds obtained from "simple" manifolds (such as spheres and tori) by glueing or covering operations. This hinges on the additive properties of the index that are clear from its being given by an integral over the manifold. Conversely, the integrality of Fredholm indices can be used to deduce that certain rational cohomology classes are actually integral on manifolds that admit the structure that is required for the pertinent index theorem to apply, that certain manifolds do not admit such structures, since one knows that the relevant class is not integral, etc.

## More on the Dirac Field

As mentioned earlier, the free-field formalism can be easily generalized to an arbitrary spacetime dimension $d$. For $d > 4$, however, no renormalizable interacting quantum field models involving the Dirac field are known. For the physical case $d = 4$ the standard model involves various Dirac fields interacting with quantized gauge fields and Klein–Gordon fields. Although its perturbation theory is renormalizable, its mathematical existence is to date wide open.

It is far beyond the scope of this article to elaborate on the analytical difficulties of relativistic quantum field theories, let alone those associated with the standard model. Even for $d = 2$ and 3, a nonperturbative construction of interacting quantum field models involving the Dirac field is an extremely difficult enterprise. Apart from some rigorous results on certain self-interacting Dirac field models, the only interacting model that is reasonably well understood from the constructive field theory viewpoint is the Yukawa model for $d = 2$ and 3. This describes the interaction between the Dirac field $\Psi$ and a Klein–Gordon field $\phi$, the interaction term being formally given by $g(\Psi^* \gamma^0 \Psi)\phi$.

On the other hand, the interaction of the quantized Dirac field with external classical fields is much more easily understood and analytically controlled. As a bonus, within this context, one can make contact with various issues of physical and mathematical relevance. We now proceed to sketch the external-field framework and some of its applications.

Let us first consider the addition of an external field term $gV(t, \boldsymbol{x})$ to the free Dirac operator $\check{H}$ on

$$\check{\mathcal{H}} = L^2(\mathbb{R}^n, \mathrm{d}\boldsymbol{x}) \otimes \mathbb{C}^\Lambda \otimes \mathbb{C}^k \qquad [90]$$

We assume from now on that the coupling $g$ is real and that $V$ is a self-adjoint $k\Lambda \times k\Lambda$ matrix-valued function on spacetime $\mathbb{R}^{n+1}$ with matrix elements that are in $C_0^\infty(\mathbb{R}^{n+1})$. Then the (interaction picture) scattering operator $S$ exists. It is unitary and has off-diagonal Hilbert–Schmidt parts $S_{\pm\mp}$, so that a unitary Fock-space $S$-operator $\tilde{\Gamma}(S)$ implementing the Bogoliubov transformation generated by $S$ exists:

$$\tilde{\Gamma}(S)\Phi(f)\tilde{\Gamma}(S)^* = \Phi(Sf), \quad \forall f \in \mathcal{H} \qquad [91]$$

The arbitrary phase in $\tilde{\Gamma}(S)$ can be fixed by requiring that the vacuum expectation value of $\tilde{\Gamma}(S)$ be positive. More precisely, this number is generically nonzero and satisfies

$$|(\Omega, \tilde{\Gamma}(S)\Omega)| = \det(1 + T_S)^{-1/2} \qquad [92]$$

where $T_S$ is a positive trace class operator determined by $S$.

The vector $\tilde{\Gamma}(S)\Omega$ is a superposition of wave functions with an equal and arbitrary number of particles and antiparticles. More generally, the Fock-space $S$-operator $\tilde{\Gamma}(S)$ leaves the subspaces of $\mathcal{F}_a(\mathcal{H})$ with a fixed eigenvalue $q \in \mathbb{Z}$ of the charge operator $Q$ invariant, and can create and

annihilate an arbitrary number of particle–antiparticle pairs.

The unitary propagator $U(T_1, T_2)$ corresponding to $V(t, \boldsymbol{x})$ does not have Hilbert–Schmidt off-diagonal parts (unless the spacetime dimension is sufficiently small and special external fields are chosen). Even so, the diagonal parts are Fredholm with vanishing index, and the off-diagonal parts are compact. Omitting the ill-defined determinantal factor, these properties imply that one obtains a renormalized quadratic form $\tilde{\Gamma}_{\text{rcn}}(U(T_1, T_2))$ satisfying the implementing relation

$$\tilde{\Gamma}_{\text{rcn}}(U(T_1, T_2))\Phi(f) = \Phi(U(T_1, T_2)f)\tilde{\Gamma}_{\text{rcn}}(U(T_1, T_2)), \quad \forall f \in \mathcal{H} \qquad [93]$$

in the quadratic form sense.

The above unitary operators on $\mathcal{H}$ yield Fredholm diagonal parts whose indices vanish. (They are norm continuous in $g$ and reduce to the identity for $g = 0$.) This is why their Fock-space implementers leave the charge sectors invariant. Indeed, for a unitary operator $U$ on $\mathcal{H}$ with compact off-diagonal parts the implementer maps the charge-$q$ sector to the charge-$(q + q(U))$ sector, where

$$q(U) = \text{index}(U_{--}) \qquad [94]$$

Specializing to the case

$$n = 2N - 1, \quad \Lambda = 2\lambda, \quad \lambda = 2^{N-1} \qquad [95]$$

a unitary $(k\Lambda \times k\Lambda)$-matrix multiplier $\check{U}$ on $\check{\mathcal{H}}$ does not have compact off-diagonal parts in general. But when it is of the form

$$\check{U} = \begin{pmatrix} \mathbf{1}_\lambda \otimes u_+(\boldsymbol{x}) & 0 \\ 0 & \mathbf{1}_\lambda \otimes u_-(\boldsymbol{x}) \end{pmatrix} \qquad [96]$$

with respect to the chiral decomposition (the generalization of the $\gamma^5$-decomposition [72] to even spacetime dimension), then it suffices for compactness of the off-diagonal parts that the matrices $u_\pm(\boldsymbol{x}) \in \text{U}(k)$ are continuous and converge to $\mathbf{1}_k$ for $|\boldsymbol{x}| \to \infty$.

Viewing $\mathbb{R}^{2N-1}$ as arising from $S^{2N-1}$ via stereographic projection, the latter unitaries can be viewed as continuous maps from $S^{2N-1}$ to $\text{U}(k)$, reducing to $\mathbf{1}_k$ at the north pole. As such, they yield elements of the homotopy group $\pi_{2N-1}(\text{U}(k))$. By virtue of Bott's periodicity theorem, the latter group equals $\mathbb{Z}$ for $k \geq N$. Thus, the maps $u_\pm$ have a well-defined "winding number" $w(u_\pm) \in \mathbb{Z}$ for $k \geq N$. From the index formula

$$\text{index}(U_{--}) = w(u_+) - w(u_-) \qquad [97]$$

and [94] one now deduces that one can obtain implementers $\tilde{\Gamma}_{\text{rcn}}(U)$ effecting a nonzero charge change from unitary maps with nonzero winding number.

In particular, choosing $k = \lambda = 2^{N-1} \geq N$, there exist quite special "kink maps"

$$u_{\epsilon,\boldsymbol{a}}(\boldsymbol{x}) \in \text{U}(\lambda), \quad \epsilon > 0, \ \boldsymbol{a} \in \mathbb{R}^{2N-1} \qquad [98]$$

with winding number 1 and such that the quadratic form implementers of the unitary multiplication operators

$$\check{U}_{+,\epsilon,\boldsymbol{a}} = -\begin{pmatrix} \mathbf{1}_\lambda \otimes u_{\epsilon,\boldsymbol{a}}(\boldsymbol{x}) & 0 \\ 0 & \mathbf{1}_\lambda \otimes \mathbf{1}_\lambda \end{pmatrix}$$
$$\check{U}_{-,\epsilon,\boldsymbol{a}} = -\begin{pmatrix} \mathbf{1}_\lambda \otimes \mathbf{1}_\lambda & 0 \\ 0 & \mathbf{1}_\lambda \otimes u_{\epsilon,\mathbf{a}}(-\boldsymbol{x}) \end{pmatrix} \qquad [99]$$

converge to (a linear combination of the chiral components of) the free Dirac field $\Psi(0, \boldsymbol{a})$ as the kink size parameter $\epsilon$ goes to 0.

For the special case $N = 1$, one can take

$$u_{\epsilon,a}(x) = \frac{x - a - \text{i}\epsilon}{x - a + \text{i}\epsilon} \qquad [100]$$

and the off-diagonal parts of $U_{\pm,\epsilon,a}$ are actually Hilbert–Schmidt. Thus, the implementers can be chosen to be unitary operators. But to get convergence to the Dirac field components $\Psi(0, a)_\pm$ as $\epsilon \to 0$, the unitary implementers $\tilde{\Gamma}(U_{\pm,\epsilon,a})$ should be renormalized by a multiplicative factor.

For the $N = 1$ case, the unitary multipliers [96] give rise to loop groups. Indeed, requiring

$$\lim_{x \to \pm\infty} u_\delta(x) = \mathbf{1}_k, \quad \delta = +, - \qquad [101]$$

we are dealing with continuous maps $S^1 \to \text{U}(k)$. From the viewpoint of the Dirac theory, these groups are local gauge groups. The convergence to the Dirac field just sketched can be used to great advantage to clarify the structure of the corresponding Fock-space gauge groups. Their Lie algebras yield representations of Kac–Moody algebras, a topic which is considered shortly.

Before doing so, it should be pointed out that under some mild smoothness assumptions all of the above unitary matrix multipliers can also be viewed as $S$-operators associated with very special external fields. Indeed, the gauge-transformed Dirac operator

$$\check{H}_U = \check{U}^* \check{H} \check{U} \qquad [102]$$

is of the form

$$\check{H}_U = \check{H} + V(\boldsymbol{x}) \qquad [103]$$

where $V(\boldsymbol{x})$ is a self-adjoint $k\Lambda \times k\Lambda$ matrix on $\mathbb{R}^{2N-1}$ (a "pure gauge" field). If one now defines a time-dependent external field by

$$V(t, \boldsymbol{x}) = \begin{cases} V(\boldsymbol{x}), & t \geq 0 \\ 0, & t < 0 \end{cases} \qquad [104]$$

then $\check{U}$ equals the $S$-operator for $V(t, \boldsymbol{x})$. (Equivalently, $\check{U}$ is the $t \to \infty$ wave operator for the time-independent external field $V(\boldsymbol{x})$.)

To conclude this section we sketch some applications of the second-quantized Dirac formalism for the special case $N = 1$, $m = 0$, and positive chirality. Even though we could stick to the massless positive-chirality Dirac operator $-\mathrm{i}\,\mathrm{d}/\mathrm{d}x$ on the line, it is simpler and more natural to start from its counterpart on the circle already considered in the last section, cf. [80]. (Under the Cayley transform, the positive- and negative-energy subspaces of $-\mathrm{i}\,\mathrm{d}/\mathrm{d}x$ on $L^2(\mathbb{R})$ correspond to those of $z\mathrm{d}/\mathrm{d}z$ on $L^2(S^1)$, given by [81].) Letting $z = \mathrm{e}^{\mathrm{i}\theta}$, we then obtain

$$\begin{aligned} &\check{H} = -\mathrm{i}\,\mathrm{d}/\mathrm{d}\theta, \quad \check{\mathcal{H}} = L^2([0, 2\pi], \mathrm{d}\theta) \\ &\mathcal{H} = l^2(\mathbb{Z}), \quad \mathcal{H}_+ = l^2(\mathbb{N}), \quad \mathcal{H}_- = l^2(\mathbb{Z}_-) \end{aligned} \qquad [105]$$

and a corresponding Dirac field

$$\Psi(t, \theta) = (2\pi)^{-1/2} \left( \sum_{n=0}^{\infty} a_n \mathrm{e}^{-\mathrm{i}nt + \mathrm{i}n\theta} + \sum_{n=1}^{\infty} b_{-n}^* \mathrm{e}^{\mathrm{i}nt - \mathrm{i}n\theta} \right)$$
$$(t, \theta) \in \mathbb{R} \times [0, 2\pi] \qquad [106]$$

where

$$a_l = c(e_l),\ l \geq 0, \quad b_l = c(e_l),\ l < 0 \qquad [107]$$

and $\{e_l\}_{l \in \mathbb{Z}}$ is the canonical basis of $l^2(\mathbb{Z})$.

Consider now the group $\mathrm{GL}(\mathcal{H})$ of bounded operators on $\mathcal{H}$ with bounded inverses. The transformation

$$\begin{aligned} &\Phi^*(f) \mapsto \Phi^*(Gf), \quad \Phi(f) \mapsto \Phi(G^{-1*}f) \\ &f \in \mathcal{H}, \quad G \in GL(\mathcal{H}) \end{aligned} \qquad [108]$$

leaves the CAR [48] invariant. Provided that $G$ belongs to the subgroup

$$\begin{aligned} &G_2(\mathcal{H}) \\ &= \{G \in \mathrm{GL}(\mathcal{H}) \,|\, G_{\pm\mp} \text{ Hilbert–Schmidt}\} \end{aligned} \qquad [109]$$

there exists an implementer $\tilde{\Gamma}(G)$ on $\mathcal{F}_a(\mathcal{H})$:

$$\begin{aligned} &\tilde{\Gamma}(G)\Phi^*(f) = \Phi^*(Gf)\tilde{\Gamma}(G), \\ &\tilde{\Gamma}(G)\Phi(f) = \Phi(G^{-1*}f)\tilde{\Gamma}(G), \quad \forall f \in \mathcal{H} \end{aligned} \qquad [110]$$

In particular, the multiplication operator

$$\exp(h(x)), \quad h(x) = \sum_{k=1}^{\infty} x_k z^{-k}, \quad z = \mathrm{e}^{\mathrm{i}\theta} \qquad [111]$$

belongs to $G_2(\mathcal{H})$ provided the sequence $x_k$ vanishes sufficiently fast as $k \to \infty$. Thus, one obtains an implementer $\tilde{\Gamma}(\mathrm{e}^{h(x)})$, the so-called KP evolution operator. This designation is justified by the vacuum expectation value

$$\tau(x) = (\Omega, \tilde{\Gamma}(\mathrm{e}^{h(x)})\tilde{\Gamma}(G)\Omega), \quad G \in G_2(\mathcal{H}) \qquad [112]$$

being a tau-function solving the hierarchy of KP evolution equations in Hirota bilinear form, as first shown by Sato and his Kyoto school. For example, the KP equation itself,

$$u_{yy} = \partial_x\left(\tfrac{4}{3}u_t - 2uu_x - \tfrac{1}{3}u_{xxx}\right) \qquad [113]$$

has the bilinear form

$$\left(\frac{\partial^4}{\partial y_1^4} - 4\frac{\partial}{\partial y_1}\frac{\partial}{\partial y_3} + 3\frac{\partial^2}{\partial y_2^2}\right)\tau(x+y)\tau(x-y)\Big|_{y=0} = 0 \qquad [114]$$

the relation being given by

$$x_1 = x, \quad x_2 = y, \quad x_3 = t, \quad u = 2\partial_1^2 \ln \tau \qquad [115]$$

The class of solutions to [113] thus obtained includes not only the rational and soliton solutions (which correspond to choosing $\check{G}$ as multiplication by a rational function of $z = \mathrm{e}^{\mathrm{i}\theta}$ that does not vanish on $S^1$), but also the finite-gap solutions associated with compact Riemann surfaces. Moreover, for suitable subgroups of $G_2(\mathcal{H})$, one obtains tau-functions for related soliton hierarchies, including the Korteweg–de Vries, Boussinesq and Hirota–Satsuma hierarchies. Even though the class of solutions associated with $G_2(\mathcal{H})$ via the Dirac formalism is large, it should be noted that from the perspective of the Cauchy problem for the pertinent evolution equations the solutions are nongeneric, inasmuch as the initial data are real-analytic functions.

Finally, we consider Lie algebra representations related to the above special starting point [105] for the second-quantized Dirac framework. Assume that $\exp(tA)$ is a one-parameter group of bounded operators on $\mathcal{H}$ with generator $A$ in the Lie algebra of $G_2(\mathcal{H})$,

$$\begin{aligned} &g_2(\mathcal{H}) \\ &= \{A \text{ bounded} \,|\, A_{\pm\mp} \text{ Hilbert–Schmidt}\} \end{aligned} \qquad [116]$$

Then one can take

$$\tilde{\Gamma}(\exp(tA)) = \exp(t\mathrm{d}\tilde{\Gamma}(A)) \qquad [117]$$

where $\mathrm{d}\tilde{\Gamma}(A)$ is the Fock-space operator uniquely determined up to an additive constant by its commutation relation

$$[\mathrm{d}\tilde{\Gamma}(A), \Phi^*(f)] = \Phi^*(Af), \quad \forall f \in \mathcal{H} \qquad [118]$$

with the smeared Dirac field $\Phi^*(f)$. Fixing the constant by requiring

$$(\Omega, \mathrm{d}\tilde{\Gamma}(A)\Omega) = 0 \qquad [119]$$

the map $A \mapsto \mathrm{d}\tilde{\Gamma}(A)$ satisfies the Lie algebra relations

$$[\mathrm{d}\tilde{\Gamma}(A), \mathrm{d}\tilde{\Gamma}(B)] = \mathrm{d}\tilde{\Gamma}([A,B]) + C(A,B)\mathbf{1} \qquad [120]$$

so that the term

$$C(A,B) = \mathrm{tr}(A_{-+}B_{+-} - B_{-+}A_{+-}) \qquad [121]$$

encodes a central extension of the Lie algebra $g_2(\mathcal{H})$ [116].

The developments sketched in the previous paragraph are in fact independent of the specific form of the Hilbert space $\mathcal{H}$ and its $\mathcal{H}_+/\mathcal{H}_-$ decomposition. But the special feature of the choice [105] and its $S^1 \to \mathbb{R}$ analog is that the smeared Dirac current

$$\int_0^{2\pi} \mathrm{d}\theta\, \psi(\theta) : \Psi^*(0,\theta)\Psi(0,\theta) :, \quad \psi \in C^\infty(S^1) \qquad [122]$$

(where the double dots denote normal ordering – the replacement of terms involving $b_k b_l^*$ by $-b_l^* b_k$) is of the form $\mathrm{d}\tilde{\Gamma}(A_\psi)$ with $A_\psi \in g_2(\mathcal{H})$ determined by $\psi$. (For spacetime dimension $d > 2$, this is no longer true, as the Hilbert–Schmidt condition is violated.) Moreover, [120] reduces to

$$[\mathrm{d}\tilde{\Gamma}(A_\psi), \mathrm{d}\tilde{\Gamma}(A_\phi)] = C(A_\psi, A_\phi)\mathbf{1} \qquad [123]$$

with the central extension explicitly given by

$$C(A_\psi, A_\phi) = \frac{\mathrm{i}}{2\pi}\int_0^{2\pi} \mathrm{d}\theta\, \psi'(\theta)\phi(\theta) \qquad [124]$$

We have just sketched the details of the (simplest version of the) Dirac current algebra: the term [124] is commonly known as the Schwinger term, so that the central extension featuring in [120]–[121] may be viewed as a generalization. The above setup can also be slightly generalized so as to obtain representations of the Virasoro algebra, which is a central extension of the Lie algebra of polynomial vector fields on $S^1$. The general framework has a quite similar version for the neutral Dirac field (Majorana field), described in terms of the self-dual CAR algebra. In the neutral setting, one can construct the Neveu–Schwarz and Ramond representations of the Virasoro algebra, which are crucial in string theory.

Tensoring $\check{\mathcal{H}}$ with an internal symmetry space $\mathbb{C}^k$ and starting from the Lie algebra of rational maps $S^1 \to \mathrm{sl}(k, \mathbb{C})$, $z \mapsto M(z)$, with poles occurring solely at $z = 0$ and $z = \infty$ (regarded as multiplication operators on $L^2(S^1)^k$), the Fock-space counterparts obtained via the $\mathrm{d}\tilde{\Gamma}$-operation yield representations of the Kac–Moody Lie algebra $A^{(1)}_{k-1}$. Specifically, on the charge-0 sector of $\mathcal{F}_a(\mathcal{H})$, one obtains the so-called basic representation, whereas the charge-$q$ sectors with $q = 1, \ldots, k-1$, yield the fundamental representations. Using the neutral version of Dirac's second quantization, one can also obtain the basic and a fundamental representation of the Kac–Moody algebras $B^{(1)}_l$ (for $k = 2l+1$) and $D^{(1)}_l$ (for $k = 2l$).

# Dispersion Relations

**J Bros**, CEA/DSM/SPhT, CEA/Saclay, Gif-sur-Yvette, France

## Introduction

Dispersion relations constitute a basic chapter of mathematical physics which covers various types of classical and quantum scattering phenomena and illustrates in a typical way the importance of general principles in theoretical physics, among which causality plays a major role. Each such phenomenon is described in terms of a scattering amplitude $F(\omega)$, which is a complex-valued function of a frequency variable $\omega$; in quantum physics, this variable becomes an energy variable called $E$ (or $s$ in particle physics), as it follows from the fundamental de Broglie relation $E = \hbar\omega$. The real and imaginary parts of $F(\omega)$, which are called respectively the dispersive part $D(\omega)$ and the absorptive part $A(\omega)$ of $F$, have well-defined physical interpretations for all these phenomena; they represent quantities which are essentially accessible to measurements. The term dispersion relations refers to linear integral equations which relate the functions $D(\omega)$ and $A(\omega)$; such integral equations are always closely related to the Cauchy integral representation of a subjacent holomorphic function $\hat{F}(\omega^{(c)})$ of the complexified frequency (or energy) variable $\omega^{(c)}$. $\hat{F}(\omega^{(c)})$ is called the holomorphic scattering function or in short the scattering function, and the scattering amplitude appears as the boundary value of the latter, taken at positive real values of $\omega$ from the upper half-plane of $\omega^{(c)}$, namely

$$F(\omega) = \lim_{\varepsilon \to 0} \hat{F}(\omega + i\varepsilon), \quad \varepsilon > 0$$

Historically, the first relations of that type to be obtained were the Kramers–Krönig relations (1926), which concern the propagation of light in a dielectric medium. In this basic example, $F(\omega)$ represents the complex refractive index of the medium $n'(\omega) = n(\omega) + i\kappa(\omega)$ for a monochromatic wave with frequency $\omega$. The dispersive part $D(\omega)$ is the real refractive index $n(\omega)$, which is the inverse ratio of the phase velocity of the wave in the medium to its velocity $c$ in the vacuum: the fact that it depends on the frequency $\omega$ corresponds precisely to the phenomenon of dispersion of light in a dielectric medium. A slab of the latter thus appears as a prototype of a macroscopic scatterer. The absorptive part $A(\omega)$ is the rate of exponential damping $\kappa(\omega)$ of the wave, caused by the absorption of energy in the medium.

It has appeared much later that for many scattering phenomena, dispersion relations can be derived from an appropriate set of general physical principles. This means that inside a certain axiomatic framework these relations are model independent with respect to the detailed structure of the scatterer or to the detailed type of particle interaction in the quantum case.

In a very short and oversimplifying way, the following logical scheme holds. At first, one can say that any mathematical formulation of a physical principle of causality results in support-type properties with respect to a time variable $t$ of an appropriate "causal structural function" $R(t)$ of the physical system considered: typically, such a causal function should vanish for negative values of $t$. It follows that its Fourier transform $\tilde{R}$ admits an analytic continuation $\tilde{R}^{(c)}$ in the upper half-plane of the corresponding conjugate variable, interpreted as a frequency (or an energy in the quantum case): here is the general reason for the occurrence of complex frequencies and of holomorphic functions of such variables. In fact, the relevant holomorphic scattering function $\hat{F}(\omega^{(c)})$ always appears as generated by $\tilde{R}^{(c)}$ via some (more or less sophisticated) procedure: in the simplest case, $\hat{F}$ coincides with $\tilde{R}^{(c)}$ itself, but this is not so in general. Finally, the derivation of suitable analyticity and boundedness properties of $\hat{F}(\omega^{(c)})$ in a domain whose typical form is the upper half-plane, allows one to apply a Cauchy-type integral representation to this function; the dispersion relations directly follow from the latter.

The first part of this article aims to describe the most typical dispersion relations and their link with the Cauchy integral. It then presents two basic illustrations of these relations, which are: (1) in classical physics, the Kramers–Krönig relations mentioned above, and (2) in quantum physics, the dispersion relations for the forward scattering of equal-mass particles. The aim of the subsequent parts is to give as complete as possible accounts of the derivation of the relevant analyticity domains inside appropriate axiomatic frameworks which, respectively, contain the previous two examples. The simplest axiomatic framework is the one which governs all the phenomena of linear response: in the latter, the proof of analyticity and dispersion relations most easily follows the logical line sketched above. It will be presented together with its application to the derivation of

the Kramers–Krönig relations. The rest of the article is devoted to the derivation of the so-called crossing analyticity domains which are the relevant background of dispersion relations for the two-particle scattering (or collision) amplitudes in particle physics. This derivation relies on the general axiomatic framework of relativistic quantum field theory (QFT) (*see* Axiomatic Quantum Field Theory) and more specifically on the "analytic program in complex momentum space" of the latter. This framework, whose rigorous mathematical form has been settled around 1960, represents the safest conceptual approach for describing the particle collision processes in a range of energies which covers by far all those that can be produced and will be produced in the accelerators for several decades. A simple account of the field-theoretical axiomatic framework and of the logical line of the derivation of dispersion relations will be presented here for the simplest kinematical situations. A broader presentation of the analytic program including an extended class of analyticity properties for the general structure functions and (two-particle and multiparticle) collision amplitudes in QFT can also be found in this encyclopedia (*see* Scattering in Relativistic Quantum Field Theory: The Analytic Program). For brevity, we shall not treat here the derivation of dispersion relations in the framework of nonrelativistic potential theory. Concerning the latter, the interested reader can refer to the book by Nussenzweig (1972). A collection of old basic papers on field-theoretical dispersion relations can be found in the review book edited by Klein (1961). For a recent and well-documented review of the multiplicity of versions and applications of dispersion relations and their experimental checking, the reader can consult the article by Vernov (1996).

## Typical Dispersion Relations

The possibility of defining the scattering function $\hat{F}(\omega^{(c)})$ in the full upper half-plane and of exploiting the corresponding boundary value $F$ of $\hat{F}$ on the negative part as well as on the positive part of the real axis will depend on the framework of considered phenomena. For the moment, we do not consider the more general situations which also occur in particle physics and will be described later ("crossing domains" and "quasi-dispersion-relations").

In the simplest cases, the real and imaginary parts $D$ and $A$ of $F$ are extended to negative values of the variable $\omega$ via additional symmetry relations resulting from appropriate "reality conditions." As a typical and basic example, there occurs the symmetry relation $\overline{\hat{F}(\omega^{(c)})} = \hat{F}(-\overline{\omega^{(c)}})$, (with $\omega^{(c)}$ and $-\overline{\omega^{(c)}}$ in the upper half-plane) and correspondingly $D(\omega) = D(-\omega)$, $A(\omega) = -A(-\omega)$ on the reals; we shall call ($S$) this symmetry relation.

The simplest case of dispersion relations is then obtained when $D$ and $A$ are linked by the reciprocal Hilbert transformations:

$$D(\omega) = \frac{1}{\pi} P \int_{-\infty}^{+\infty} A(\omega') \frac{1}{\omega' - \omega}\, d\omega' \qquad [1a]$$

$$A(\omega) = -\frac{1}{\pi} P \int_{-\infty}^{+\infty} D(\omega') \frac{1}{\omega' - \omega}\, d\omega' \qquad [1b]$$

where $P$ denotes Cauchy's principal value, defined for any differentiable function $\varphi(x)$ (sufficiently regular at infinity) by

$$P \int_{-\infty}^{+\infty} \frac{\varphi(x)}{x}\, dx = \lim_{\varepsilon \to 0} \left[ \int_{-\infty}^{-\varepsilon} \varphi(x) \frac{dx}{x} + \int_{\varepsilon}^{+\infty} \varphi(x) \frac{dx}{x} \right] \qquad [2]$$

As a matter of fact, the pair of equations [1a], [1b] is equivalent to the following relation for $F \doteq D + iA$:

$$F(\omega) = \frac{1}{2i\pi} \int_{-\infty}^{+\infty} F(\omega') \lim_{\varepsilon \to 0} \frac{1}{\omega' - \omega - i\varepsilon}\, d\omega' \qquad [3]$$

The latter is obtained as a limiting case of the Cauchy formula

$$\hat{F}(\omega^{(c)}) = \frac{1}{2i\pi} \int_{-\infty}^{+\infty} \frac{F(\omega')}{\omega' - \omega^{(c)}}\, d\omega' \qquad [4]$$

expressing the fact that $\hat{F}$ is holomorphic and sufficiently decreasing at infinity in the upper half-plane $\mathcal{I}_+$ of the complex variable $\omega^{(c)}$ and that $F(\omega)$ is the boundary value of $\hat{F}(\omega^{(c)})$ on all the reals.

Finally, one checks that in view of the symmetry relation ($S$), the Hilbert integral relations between $D$ and $A$ given above reduce to the following dispersion relations:

$$D(\omega) = \frac{2}{\pi} P \int_{0}^{+\infty} A(\omega') \frac{\omega'}{\omega'^2 - \omega^2}\, d\omega' \qquad [5a]$$

$$A(\omega) = -\frac{2\omega}{\pi} P \int_{0}^{+\infty} D(\omega') \frac{1}{\omega'^2 - \omega^2}\, d\omega' \qquad [5b]$$

### Two Basic Examples

1. *The Kramers–Krönig relation in classical optics* It will be shown in the next part that the complex refractive index $n'(\omega) = n(\omega) + i\kappa(\omega)$ of a dielectric medium is the boundary value of a holomorphic

function $\hat{n}'(\omega^{(c)})$ in $\mathcal{I}_+$ satisfying the symmetry relation $(S)$, and such that the integral $\int_{-\infty}^{\infty} |\hat{n}'(\omega + i\eta) - 1|^2 \, d\omega$ is uniformly bounded for all $\eta > 0$.

It follows that all the previous relations are satisfied by the function $\hat{F}(\omega^{(c)}) = \hat{n}'(\omega^{(c)}) - 1$. In particular, the real refractive index $n(\omega)$ and the "extinction coefficient" $\beta(\omega) \doteq 2\omega\kappa(\omega)/c$ ($c$ being the velocity of light in the vacuum) are linked by the following Kramers–Krönig dispersion relation (corresponding to eqn [5a]):

$$n(\omega) - 1 = \frac{c}{2\pi} P \int \frac{\beta(\omega')}{\omega'^2 - \omega^2} \, d\omega' \qquad [6]$$

2. *Dispersion relation for the forward two-particle scattering amplitude in relativistic quantum physics* One considers the following collision phenomenon in particle physics. A particle $\Pi_2$ with mass $m$, called the target and sitting at rest in the laboratory, is collided by an identical particle $\Pi_1$ with relativistic energy $\omega$ larger than $m$ ($= mc^2$; in high-energy physics, one usually chooses units such that $c = 1$). After the collision, the particle $\Pi_1$ is scattered in all possible directions, $\theta$, of space, according to a certain quantum scattering amplitude $T_\theta(\omega)$, whose modulus is essentially the rate of probability for detecting $\Pi_1$ in the direction $\theta$. The forward scattering amplitude $T_0(\omega)$ corresponds to the detection of $\Pi_2$ in the forward longitudinal direction with respect to its incidence direction towards the target. Let us also assume that the particles carry no charge of any kind, so that each particle coincides with its "antiparticle." In that case, $T_0(\omega)$ is shown to be the boundary value of a scattering function $\hat{T}_0(\omega^{(c)})$ enjoying the following properties:

1. it is a holomorphic function in $\mathcal{I}_+$ satisfying the symmetry relation $(S)$;
2. its behavior at infinity in $\mathcal{I}_+$ is such that the integral

$$\int_{-\infty}^{\infty} \left| \frac{\hat{T}_0(\omega + i\eta)}{(\omega + i\eta)^2} \right|^2 d\omega$$

is uniformly bounded for all $\eta > 0$; and
3. under more specific assumptions on the mass spectrum of the subjacent theory, the "absorptive part" $A(\omega) \doteq \operatorname{Im} T_0(\omega)$ vanishes for $|\omega| < m$.

Then by applying eqn [5a] to the function $D(\omega) \doteq \operatorname{Re}[(T_0(\omega) - T_0(0))/\omega^2]$ (regular at $\omega = 0$), one obtains the following dispersion relation:

$$\operatorname{Re} T_0(\omega) = T_0(0) + \frac{2\omega^2}{\pi} P \int_m^{+\infty} A(\omega') \frac{1}{\omega'(\omega'^2 - \omega^2)} \, d\omega' \qquad [7]$$

**Remark** In view of (3), the scattering function $\hat{T}_0(\omega^{(c)})$ admits an analytic continuation as an even function of $\omega^{(c)}$ (still called $\hat{T}_0$) in the cut-plane $\boldsymbol{C}_m^{(\text{cut})} \doteq \boldsymbol{C} \backslash \{\omega \in \boldsymbol{R}; |\omega| \geq m\}$. In fact, in view of $(S)$ and (3), the boundary value $T_0$ of $\hat{T}_0$ satisfies the relation $T_0(\omega) = T_0(-\omega)$ in the real interval $\delta_m \doteq \{\omega \in \boldsymbol{R}; -m < \omega < m\}$. Let us then introduce the function $\hat{T}_0^-(\omega^{(c)}) \doteq \hat{T}_0(-\omega^{(c)})$ as a holomorphic function of $\omega^{(c)}$ in $\mathcal{I}_-$: one sees that the boundary values of $\hat{T}_0$ and $\hat{T}_0^-$ from the respective domains $\mathcal{I}_+$ and $\mathcal{I}_-$ coincide on $\delta_m$ and therefore admit a common analytic continuation throughout this real interval (in view of "Painlevé's lemma" or "one-dimensional edge-of-the-wedge theorem"). One also notes that in view of $(S)$ the extended function $\hat{T}_0$ satisfies the "reality condition" $\overline{\hat{T}_0(\omega^{(c)})} = \hat{T}_0(\overline{\omega^{(c)}})$ in $\boldsymbol{C}_m^{(\text{cut})}$. The fact that $\hat{T}_0$ is well defined as an even holomorphic function in the cut-plane $\boldsymbol{C}_m^{(\text{cut})}$ has been established in the general framework of QFT, as explained in the last part of this article.

## Phenomena of Linear Response: Causality and Dispersion Relations in the Classical Domain

The subsequent axiomatic framework and results (due to J S Toll (1952, 1956)) concern any physical system which exhibits the following type of phenomena: whenever it receives some excitation signal, called the input and represented by a real-valued function of time $f_{\text{in}}(t)$ with compact support, the system emits a response signal, called the output and represented by a corresponding real-valued function $f_{\text{out}}(t)$, in such a way that the following postulates are satisfied:

(P1) *Linearity*. To every linear combination of inputs $a_1 f_{\text{in},1} + a_2 f_{\text{in},2}$, there corresponds the output $a_1 f_{\text{out},1} + a_2 f_{\text{out},2}$.

(P2) *Reproductibility or time-translation invariance*. Let $\tau$ be a time-translation parameter taking arbitrary real values; to every "time-translated input" $f_{\text{in}}^{(\tau)}(t) \doteq f_{\text{in}}(t - \tau)$, there corresponds the output $f_{\text{out}}^{(\tau)}(t) \doteq f_{\text{out}}(t - \tau)$.

(P3) *Causality*. The effect cannot precede the cause, namely if $t_{\text{in}}$ and $t_{\text{out}}$ denote respectively the lower bounds of the supports of $f_{\text{in}}(t)$ and $f_{\text{out}}(t)$, then there always holds the inequality $t_{\text{in}} \leq t_{\text{out}}$.

(P4) *Continuity of the response*. There exists some continuity inequality which expresses the fact that a certain norm of the output is majorized by a corresponding norm of the input. The case of an $L_2$-norm inequality of the

form $|f_{\text{out}}| \leq |f_{\text{in}}|$ is particularly significant: when the norm $|f| \doteq [\int |f(t)|^2 \, \mathrm{d}t]^{1/2}$ is interpretable as an energy (for the output as well as for the input), it acquires the meaning of a "dissipation" property of the system.

The postulate of linear dependence (P1) of $f_{\text{out}}$ with respect to $f_{\text{in}}$ is obviously satisfied if the response is described by any general kernel $K(t, t')$ such that the following formula makes sense:

$$f_{\text{out}}(t) = \int_{-\infty}^{+\infty} K(t, t') f_{\text{in}}(t') \mathrm{d}t' \qquad [8]$$

Conversely, the existence of a distribution kernel $K$ can be established rigorously under the continuity assumption postulated in (P4) by using the Schwartz nuclear theorem. In full generality (see our comment in the next paragraph), the kernel $K(t, t')$ appears to be a tempered distribution in the pair of variables $(t, t')$ and the previous integral formula holds in the sense of distributions, which means that both sides of eqn [8] must be considered as tempered distributions (in $t$) acting on any smooth test-function $g(t)$ in the Schwartz space $\mathcal{S}$. (Note, for instance, that the trivial linear application $f_{\text{out}} = f_{\text{in}}$ is represented by the kernel $K(t, t') = \delta(t - t')$).

From the reproductibility postulate (P2), it follows that the distribution $K$ can be identified with a distribution of the single variable $\tau = t - t'$, namely $K(t, t') \doteq R(t - t')$. Moreover, the real-valuedness condition imposed to the pairs $(f_{\text{in}}, f_{\text{out}})$ entails that $R$ is real. Finally, the causality postulate (P3) implies that the support of the distribution $R$ is contained in the positive real axis, so that one can write, in the sense of distributions,

$$f_{\text{out}}(t) = \int_{-\infty}^{t} R(t - t') f_{\text{in}}(t') \mathrm{d}t' \qquad [9]$$

The convolution kernel $R(t - t')$ is typically what one calls in physics a "retarded kernel."

If we now introduce the frequency variable $\omega$, which is the conjugate of the time variable $t$, by the Fourier transformation

$$\tilde{f}(\omega) = \int_{-\infty}^{+\infty} f(t) \, \mathrm{e}^{\mathrm{i}\omega t} \, \mathrm{d}t$$

we see that the convolution equation [9] is equivalent to the following one:

$$\tilde{f}_{\text{out}}(\omega) = \tilde{R}(\omega) \tilde{f}_{\text{in}}(\omega) \qquad [10]$$

In the latter, the Fourier transform $\tilde{R}(\omega)$ of $R$ is a tempered distribution, which is the boundary value from the upper half-plane $\mathcal{I}_+$ of a holomorphic function $\tilde{R}^{(\text{c})}(\omega^{(\text{c})})$, called the Fourier–Laplace transform of $R$. $\tilde{R}^{(\text{c})}$ is defined for all $\omega^{(\text{c})} = \omega + \mathrm{i}\eta$, with $\eta > 0$, by the following formula in which the exponential is a good test-function for the distribution $R$ (since exponentially decreasing for $t \to +\infty$):

$$\tilde{R}^{(\text{c})}(\omega^{(\text{c})}) = \int_{0}^{+\infty} R(t) \mathrm{e}^{\mathrm{i}\omega^{(\text{c})} t} \, \mathrm{d}t \qquad [11]$$

More precisely, the tempered-distribution character of $R$ is strictly equivalent to the fact that $\tilde{R}^{(\text{c})}$ is of moderate growth both at infinity and near the reals in $\mathcal{I}_+$, namely that it satisfies a majorization of the following form for some real positive numbers $p$ and $q$:

$$|\tilde{R}^{(\text{c})}(\omega + \mathrm{i}\eta)| \leq C \frac{(1 + |\omega|^2 + \eta^2)^q}{\eta^p} \qquad [12]$$

We thus conclude from eqn [10] that each phenomenon of linear response is represented very simply in the frequency variable by the multiplicative operator $\tilde{R}(\omega)$, whose analytic continuation $\tilde{R}^{(\text{c})}(\omega^{(\text{c})})$ is called the (causal) response function.

### A Typical Illustration: The Damped Harmonic Oscillator

We consider the motion $x = x(t)$ of a damped harmonic oscillator of mass $m$ submitted to an external force $F(t)$. The force is the input ($f_{\text{in}} = F$) and the resulting motion is the output, namely $f_{\text{out}}(t) = x(t)$. All the previous general postulates (P1)–(P4) are then satisfied, but this particular model is, of course, governed by its dynamical equation

$$x''(t) + 2\gamma x'(t) + \omega_0^2 x(t) = \frac{F(t)}{m} \qquad [13]$$

where $\omega_0$ is the eigenfrequency of the oscillator and $\gamma$ is the damping constant ($\gamma > 0$). The relevant solution of this second-order differential equation with constant coefficients is readily obtained in terms of the Fourier transforms $\tilde{x}(\omega)$ of $x(t)$ and $\tilde{F}(\omega)$ of $F(t)$. One can in fact replace eqn [13] by the equivalent equation

$$(-\omega^2 - 2\mathrm{i}\gamma\omega + \omega_0^2)\tilde{x}(\omega) = \frac{\tilde{F}(\omega)}{m} \qquad [14]$$

whose solution is of the form [10], namely $\tilde{x}(\omega) = \tilde{R}(\omega)\tilde{F}(\omega)$, with

$$\begin{aligned} \tilde{R}(\omega) &= -\frac{\tilde{F}(\omega)}{m(\omega^2 + 2\mathrm{i}\gamma\omega - \omega_0^2)} \\ &= -\frac{\tilde{F}(\omega)}{m(\omega - \omega_1)(\omega - \omega_2)} \end{aligned} \qquad [15a]$$

$$\omega_{1,2} = \pm(\omega_0^2 - \gamma^2)^{1/2} - \mathrm{i}\gamma \qquad [15b]$$

It is clear that the rational function defined by eqns [15] admits an analytic continuation in the full complex plane of $\omega^{(c)}$ minus the pair of simple poles $(\omega_1, \omega_2)$ which lie in the lower half-plane. In particular, it is holomorphic (and decreasing at infinity) in $\mathcal{I}_+$, as expected from the previous general result. Moreover, this example suggests that for any particular phenomenon of linear response, the details of the dynamics are encoded in the singularities of the holomorphic scattering function $\tilde{R}^{(c)}(\omega^{(c)})$, which all lie in the lower half-plane. The validity of a dispersion relation only expresses the analyticity (and decrease at infinity) of that function in the upper half-plane, which is model independent.

**Remark** The same mathematical analysis applies to any electric oscillatory circuit, in which the capacitance, inductance, and resistance are involved in place of the parameters $m$, $\omega_0$ and $\gamma$: $f_{\text{in}}$ and $f_{\text{out}}$ correspond respectively to an external electric potential and to the current induced in the circuit; the response function is the admittance of the circuit.

### Application to the Kramers–Krönig Relation

The background of the Kramers–Krönig relation [6], namely the analyticity and boundedness properties of the complex refractive index $\hat{n}'(\omega^{(c)})$ in $\mathcal{I}_+$, is provided by the previous axiomatic framework. However, it is not the quantity $\hat{n}'(\omega^{(c)})$ itself but appropriate functions of the latter which play the role of causal response functions; two phenomena can in fact be exhibited, which both contribute to proving the relevant properties of $\hat{n}'(\omega^{(c)})$.

1. *Propagation of light in a dielectric slab with thickness* $\delta$. One considers the wave front $f_{\text{in}}(t)$ of an incoming wave normally incident upon the slab, with Fourier decomposition

$$f_{\text{in}}(t) = \frac{1}{2\pi}\int_{-\infty}^{+\infty} \tilde{f}(\omega)\, \mathrm{e}^{-\mathrm{i}\omega t}\, \mathrm{d}\omega \qquad [16]$$

After having traveled through the medium, it gives rise to an outgoing wave $f_{\text{out}}(t)$ on the exit face of the slab, whose Fourier decomposition can be written as follows (provided the thickness $\delta$ of the slab is very small):

$$f_{\text{out}}(t) = \frac{1}{2\pi}\int_{-\infty}^{+\infty} \tilde{f}(\omega)\, \mathrm{e}^{-\mathrm{i}\omega(t - n'(\omega)/c\delta)}\, \mathrm{d}\omega \qquad [17]$$

In the latter, the real part of $n'(\omega)/c$ is the inverse of the light velocity in the medium, while its imaginary part takes into account the exponential damping of the wave. The output $f_{\text{out}}$ thus appears as a causal linear response with respect to $f_{\text{in}}$ (since $f_{\text{out}}$ "starts after" $f_{\text{in}}$). According to the general formula [10], the corresponding response function $\tilde{R}_\delta^{(c)}$ can be directly computed from eqns [16] and [17], which yields:

$$\tilde{R}_\delta^{(c)}(\omega^{(c)}) = \mathrm{e}^{\mathrm{i}\omega^{(c)}\hat{n}'(\omega^{(c)})\delta/c} \qquad [18]$$

In view of the previous axiomatic analysis, $\tilde{R}_\delta^{(c)}$ has to be holomorphic and of moderate growth in $\mathcal{I}_+$, and since this holds for all $\delta$'s sufficiently small, it can be shown that the function $\hat{n}'(\omega^{(c)})$ itself is holomorphic and of moderate growth in $\mathcal{I}_+$ (no logarithmic singularity can be produced).

2. *Polarization of the medium produced by an electric field*. The dielectric polarization signal $P(t)$ produced at a point of a medium by an external electric field $E(t)$ is also a phenomenon of linear response which obeys the postulates (P1)–(P4); the corresponding formula [10] reads

$$\tilde{P}(\omega) = \chi'(\omega)\tilde{E}(\omega) \qquad [19a]$$

where $\chi'$ is the complex dielectric susceptibility of the medium, which is related to $n'$ by Maxwell's relation

$$\tilde{\chi}'(\omega) = \frac{[n'^2(\omega) - 1]}{4\pi} \qquad [19b]$$

One thus recovers the fact that $\chi'$ admits an analytic continuation in $\mathcal{I}_+$; one can also show by a physical argument that $\tilde{\chi}'(\omega)$, and thereby $n'(\omega) - 1$, tends to zero as a constant divided by $\omega^2$ when $\omega$ tends to infinity. This behavior at infinity extends to $\hat{n}'(\omega^{(c)}) - 1$ in $\mathcal{I}_+$ in view of the Phragmen–Lindelöf theorem, since $\hat{n}'$ is known (from (1)) to be of moderate growth. This justifies the analytic background of Kramers–Krönig's relation.

## From Relativistic QFT to the Dispersion Relations of Particle Physics: Historical Considerations and General Survey

In the quantum domain, the derivation of dispersion relations for the two-particle scattering (or collision) amplitudes of particle physics has represented, since 1956 and throughout the 1960s, an important conceptual progress for the theoretical treatment of that branch of physics. These phenomena are described in a quantum-theoretical framework in which the basic kinematical variables are the energies and momenta of the particles involved. These variables play the role of the frequency of light in the optical scattering phenomena. Moreover, since large energies and momenta are involved, which allow the occurrence of particle creation

according to the conservation laws of special relativity, it is necessary to use a relativistic quantum-mechanical framework. Around 1950, the success of the quantum electrodynamics formalism for computing the electron–photon, electron–electron, and electron–positron scattering amplitudes revealed the importance of the concept of relativistic quantum field for the understanding of particle physics. However, the methods of perturbation theory, which had ensured the success of quantum electrodynamics in view of the small value of the coupling parameter of that theory (namely the electric charge of the electron), were at that time inapplicable to the strong nuclear interaction phenomena of high-energy physics. This failure motivated an important school of mathematical physicists for working out a model-independent axiomatic approach of relativistic QFT (e.g., Lehmann, Symanzik, Zimmermann (1954), Wightman (1956), and Bogoliubov (1960); *see* Axiomatic Quantum Field Theory). Their main purpose was to provide a conceptually satisfactory treatment of relativistic quantum collisions, at least for the case of massive particles. Among various postulates expressing the invariance of the theory under the Poincaré group in an appropriate quantum-mechanical Hilbert-space framework, the approach basically includes a certain formulation of the principle of causality, called microcausality or local commutativity. This axiomatic approach of QFT was followed by a conceptually important variant, namely the algebraic approach to QFT (Haag, Kastler, Araki 1960), whose most important developments are presented in the book by Haag (1992) (*see* Algebraic Approach to Quantum Field Theory). From the historical viewpoint, and in view of the analyticity properties that they also generate, one can say that all these (closely related) approaches parallel the axiomatic approach of linear response phenomena with, of course, a much higher degree of complexity. In particular, the characterization of scattering (or collision) amplitudes in terms of appropriate structure functions of the basic quantum fields of the theory is a nontrivial preliminary step which was taken at an early stage of the theory under the name of "asymptotic theory and reduction formulae" (Lehmann, Symanzik, Zimmermann 1954–57, Haag–Ruelle 1962, Hepp 1965). There again, in the field-theoretical axiomatic framework, causality generates analyticity through Fourier–Laplace transformation, but several complex variables now play the role which was played by the complex frequency in the axiomatics of linear response phenomena: they are obtained by complexifying the relativistic energy–momentum variables of the (Fourier transforms of the) quantum fields involved in the high-energy collision processes. In fact, the holomorphic functions which play the role of the causal response function $\tilde{R}(\omega)$ are the QFT structure functions or "Green functions in energy–momentum space." The study of all possible analyticity properties of these functions resulting from the QFT axiomatic framework is called the analytic program (*see* Scattering in Relativistic Quantum Field Theory: The Analytic Program). The primary basic scope of the latter concerns the derivation of analyticity properties for the scattering functions of two-particle collision processes, which appears to be a genuine challenge for the following reason. The basic Einstein relation $E = mc^2$, which applies to all the incoming and outgoing particles of the collisions, operates as a geometrical constraint on the corresponding physical energy–momentum vectors: according to the Minkowskian geometry, the latter have to belong to mass hyperboloids, which define the so-called "mass shell" of the collision considered. It is on the corresponding complexified mass-shell manifold that the scattering functions are required to be defined as holomorphic functions. In the analytic program of QFT, the derivation of such analyticity domains and of corresponding dispersion relations in the complex plane of the squared total energy variable, $s$, of each given collision process then relies on techniques of complex geometry in several variables. As a matter of fact, the scattering amplitude is a function (or distribution) of two variables $F(s,t)$, where $t$ is a second important variable, called the squared momentum transfer, which plays the role of a fixed parameter for the derivation of dispersion relations in the variable $s$. The value $t = 0$ corresponds to the special kinematical situation which has been described above (for the case of equal-mass particles $\Pi_1$ and $\Pi_2$) under the name of forward scattering and the variable $s$ is a simple affine function of the energy $\omega$ of the colliding particle $\Pi_1$ in the laboratory Lorentz frame, (namely $s = 2m^2 + 2m\omega$ in the equal-mass case). It is for the corresponding scattering amplitude $T_0(\omega) \doteq F_0(s) \doteq F(s,t)_{|t=0}$ that a dispersion relation such as eqn [7] can be derived, although this derivation is far from being as simple as for the phenomena of linear response in classical physics: even in that simplest case, it already necessitates the use of analytic completion techniques in several complex variables. The first proof of this dispersion relation was performed by K Symanzik in 1956. In the case of general kinematical situations of measurements, the direction of observation of the scattered particle includes a nonzero angle with the incidence direction, which always corresponds to a negative value of $t$. The derivation of dispersion relations at fixed $t = t_0 < 0$, namely for the scattering amplitude

$F_{t_0}(s) \doteq F(s,t)_{|t=t_0}$ requires further arguments of complex geometry, and it is submitted to subtle limitations of the form $t_1 < t_0 \le 0$, where $t_1$ depends on the mass spectrum of the particles involved in the theory. The first rigorous proof of dispersion relations at $t < 0$ was performed by N N Bogoliubov in 1960.

Three conceptually important features of the dispersion relations in particle physics deserve to be pointed out.

1. In comparison with the dispersion relations of classical optics, a feature which appears to be new is the so-called "crossing property," which is characteristic of high-energy physics since it relies basically on the relativistic kinematics. According to that property, the boundary values of the analytic scattering function $\hat{F}_t(s)$ at positive and negative values of $s$ from the respective half-planes $\mathrm{Im}\, s > 0$ and $\mathrm{Im}\, s < 0$ are interpreted, respectively, as the scattering amplitudes of two physically different collision processes, which are deduced from each other by replacing the incident particle by the corresponding antiparticle; one also says that "these two collision processes are related by crossing." A typical example is provided by the proton–proton and proton–antiproton collisions, whose scattering amplitudes are therefore mutually related by the property of analytic continuation. This type of relationship between the values of the scattering function at positive and negative values of $s$ generalizes in a nontrivial way the symmetry relation ($S$) satisfied by the forward scattering function $\hat{T}_0(\omega^{(c)})$ when each particle coincides with its antiparticle (see the second basic example above). No nontrivial crossing property holds in that special case and the fact that $\hat{T}_0$ is an even function of $\omega^{(c)}$ precisely expresses the identity of the two-collision processes related by crossing. In the general case, for $t = 0$ as well as for $t = t_0 < 0$ for any value of $t_0$, the analyticity domain that one obtains for the scattering function is not the full cut-plane of $s$: in its general form, a "crossing domain" may exclude some bounded region $B_{t_0}$ from the cut-plane, but it always contains an infinite region which is the exterior of a circle minus cuts along the two infinite parts of the real $s$-axis (Bros, Epstein, Glaser 1965): these cuts are along the physical regions of the two collision processes related by crossing. In that general case, the scattering function $\hat{F}_t(s)$ still satisfies what can be called a quasi-dispersion-relation, in which the right-hand side contains an additional Cauchy integral, taken along the boundary of $B_t$.

2. A second important feature concerns the behavior at large values of $s$ of the scattering functions $\hat{F}_t(s)$ in their analyticity domain. As indicated in the presentation of the second basic example, a "precise-increase" property was expected to be satisfied by the forward scattering amplitude $T_0(\omega)$ for $\omega$ (or $s$) tending to infinity. This "precise-increase" property implied the necessity of writing the corresponding dispersion relation [7] for the function $(T_0(\omega) - T_0(0))/\omega^2$: this is what one calls a "dispersion relation with a subtraction." As a matter of fact, the existence of such restrictive bounds on the total cross sections at high energies had been discovered in 1961 by M Froissart: his derivation relied basically on the use of the unitarity of the scattering operator (expressing the quantum principle of conservation of probabilities), but also on a strong analyticity postulate for the scattering function not implied by the general field-theoretical approach (namely the Mandelstam domain of "double dispersion relations"). In the general framework of QFT, Froissart-type bounds appeared to be closely linked to a further nontrivial extension of the range of "admissible" values of $t$ for which $\hat{F}_t(s)$ can be analytically continued in a cut-plane or crossing domain. In fact, the extension of this range to positive (i.e., "unphysical") and even complex values of $t$, and as a second step the proof of Froissart-type bounds in $s(\log s)^2$ for $F_t(s)$ at all these admissible values of $t$, were performed in 1966 by A Martin. They rely on a subtle conspiracy of the analyticity properties deduced from the QFT axiomatic framework and of positivity and unitarity properties expressing the basic Hilbertian structure of the quantum collision theory. The consequence of these bounds on the exact form of the dispersion relations is that, as in formula [7] of the case $t = 0$, it is justified to write a (the so-called "subtracted") dispersion relation for $(F_t(s) - F_t(0) - sF_t'(0))/s^2$: for the general case when the crossing property replaces the symmetry ($S$), such a dispersion relation involves two subtractions (since $F_t'(0) \neq 0$). Detailed information concerning the interplay of analyticity and unitarity on the mass shell and the derivation of refined forms of dispersion relations and various boundedness properties for the scattering functions are given in the book by Martin (1969).

3. Constraints imposed by dispersion relations and experimental checks. The conceptual importance of dispersion relations incorporating the above features (1) and (2) is displayed by such spectacular application as the relationship between the high-energy behaviors of proton–proton and proton–antiproton cross sections. Even though the closest forms of relationship between these cross sections (e.g., the existence of equal high-energy limits) necessitate for their proof some extra assumption concerning, for instance, the behavior

of the ratio between the dispersive and absorptive parts of the forward scattering amplitude, one can speak of an actual model-independent implication of general QFT that imposes nontrivial constraints on phenomena. Otherwise stated, checking experimentally the previous type of relationship up to the limits of high energies imposed by the present technology of accelerators constitutes an indirect, but important test of the validity of the general principles of QFT.

As a matter of fact, it has also appeared frequently in the literature of high-energy physics during the last 40 years that the Froissart bound by itself was considered as a key criterion to be satisfied by any sensible phenomenological model in particle physics. As already stated above, the Froissart bound is one of the deepest consequences of the analytic program of general QFT, since its derivation also incorporates in the most subtle way the quantum principle of probability conservation. Would it be only for the previous basic results, the derivation of dispersion relations (and, more generally, the results of the analytic program) in QFT appear as an important conceptual bridge between a fundamental theoretical framework of relativistic quantum physics and the phenomenology of high-energy particle physics.

## Basic Concepts and Main Steps in the QFT Derivation of Dispersion Relations

The rest of this article outlines the derivation of the analytic background of dispersion relations for the forward scattering amplitudes in the framework of axiomatic QFT. After a brief introduction on relativistic scattering processes and the problematics of causality in particle physics, it gives an account of the Wightman axioms and the simplest reduction formula which relates the forward scattering amplitude to a retarded product of the field operators. Then it describes how the latter can be used for justifying a certain type of analyticity domain for the forward scattering functions, namely a crossing domain or in the best cases a cut-plane in the squared energy variable $s$. This is the basic result that allows one to write dispersion relations (or quasi-dispersion-relations) at $t=0$; the exact form of the latter, including at most two subtractions, relies on the use of Hilbertian positivity and of the unitarity of the scattering operator.

### Relativistic Quantum Scattering as a Phenomenon of Linear Response

Collisions of quantum particles may be seen as phenomena of linear response, but in a way which differs greatly from what has been previously described.

**Particles in Minkowskian geometry** Each state of a relativistic classical particle with mass $m$ is characterized by its energy–momentum vector or 4-momentum $p=(p_0,\boldsymbol{p})$ satisfying the mass-shell condition $p^2 \doteq p_0^2-\boldsymbol{p}^2=m^2$ (in units such that $c=1$). In view of the condition of positivity of the energy $p_0>0$ the "physical mass shell" thus coincides with the positive sheet $H_m^+$ of the mass hyperboloid $H_m$ with equation $p^2=m^2$.

The set of all energy–momentum configurations characterizing the collisions of two relativistic classical particles with initial (resp. final) 4-momenta $p_1,p_2$ (resp. $p_1',p_2'$) is the mass-shell manifold $\mathcal{M}$ defined by the conditions

$$p_i^2=m^2,\quad p_i'^2=m^2,\quad p_{i,0}>0,\quad p'_{i,0}>0,\quad i=1,2$$
$$p_1+p_2=p_1'+p_2'$$

where the latter equation expresses the relativistic law of total energy–momentum conservation. $\mathcal{M}$ is an eight-dimensional manifold, invariant under the (six-dimensional) Lorentz group: the orbits of this group that constitute a foliation of $\mathcal{M}$ are parametrized by two variables, namely the squared total energy $s=(p_1+p_2)^2=(p_1'+p_2')^2$ and the squared momentum transfer $t=(p_1-p_1')^2=(p_2-p_2')^2$ (or $u=(p_1-p_2')^2=4m^2-s-t$). In these variables, called the Mandelstam variables, the "physical region" $\Phi$ of the collision is represented by the set of pairs $(s,t)$ (or triplets $(s,t,u)$ with $s+t+u=4m^2$) such that $t\leq 0, u\leq 0$, and therefore $s\geq 4m^2$.

Correspondingly, each state of a relativistic quantum particle with mass $m$ is characterized by a wave packet $\hat{f}(p)$ on $H_m^+$, which is an element of unit norm of $L_2(H_m^+;\mu_m(p))$, with $\mu_m(p)=d\boldsymbol{p}/(\boldsymbol{p}^2+m^2)^{1/2}$. In Minkowskian spacetime with coordinates $x=(x_0,\boldsymbol{x})$, any such state is represented by a wave function $f(x)$ whose Fourier transform is the tempered distribution (with support in $H_m^+$) $\hat{f}(p)\times\delta(p^2-m^2)$: $f(x)$ is a positive-energy solution of the Klein–Gordon equation $(\partial^2/\partial x_0^2-\Delta_{\boldsymbol{x}}+m^2)f(x)=0$. A free two-particle state is a symmetric wave packet $\hat{f}(p_1,p_2)$ on $H_m^+\times H_m^+$ in the Hilbert space $L_2(H_m^+\times H_m^+;\mu_m\otimes\mu_m)$.

**Scattering kernels as response kernels: distribution character** While the input to be considered is a free wave packet $\hat{f}_{\text{in}}(p_1,p_2)$ on $H_m^+\times H_m^+$, representing the preparation of an initial two-particle state, the output corresponds to the detection of a final two-particle state also characterized by a wave packet $\hat{g}_{\text{out}}(p_1',p_2')$ on $H_m^+\times H_m^+$. In quantum mechanics, linearity is linked to the "superposition principle" of states,

which allows one to state that collisions are described by a certain bilinear form $(\hat{f}_{\text{in}}, \hat{g}_{\text{out}}) \to S(\hat{f}_{\text{in}}, \hat{g}_{\text{out}})$, called the "scattering matrix." This bilinear form is bicontinuous with respect to the Hilbertian norms of the wave packets, and it then results from the Schwartz nuclear theorem that it is represented by a distribution kernel $S(p_1, p_2; p'_1, p'_2)$, namely a tempered distribution with support contained in $\mathcal{M}$, in such a way that (formally)

$$S(\hat{f}_{\text{in}}, \hat{g}_{\text{out}}) = \int \hat{f}_{\text{in}}(p_1, p_2)\overline{\hat{g}_{\text{out}}}(p'_1, p'_2) S(p_1, p_2; p'_1, p'_2) \times \mu_m(p_1)\mu_m(p_2)\mu_m(p'_1)\mu_m(p'_2) \quad [20]$$

If there were no interaction, $S(\hat{f}_{\text{in}}, \hat{g}_{\text{out}})$ would reduce to the Hilbertian scalar product $<\hat{g}_{\text{out}}, \hat{f}_{\text{in}}>$ in $L_2(H_m^+ \times H_m^+; \mu_m \otimes \mu_m)$ and the corresponding kernel $S$ would be the identity kernel

$$I(p_1, p_2; p'_1, p'_2) = \frac{1}{2}\left[\delta(p_1 - p'_1)\delta(p_2 - p'_2) + \delta(p_1 - p'_2)\delta(p_2 - p'_1)\right]$$

In the general case, the interaction is therefore described by the scattering kernel $T(p_1, p_2; p'_1, p'_2) \doteq S(p_1, p_2; p'_1, p'_2) - I(p_1, p_2; p'_1, p'_2)$. The action of $T$ as a bilinear form (defined in the same way as the action of $S$ in eqn [20]) may be seen as the quantum analog of the classical response formula [10]. Note, however, the difference in the mathematical treatment of the output: instead of being considered as the direct response $(\tilde{f}_{\text{out}})$ to the input, it is now explored by Hilbertian duality in terms of detection wave packets $\hat{g}_{\text{out}}$, in conformity with the principles of quantum theory. Finally, in view of the invariance of the collision process under the Lorentz group, the scattering kernel $T$ is constant along the orbits of this group in $\mathcal{M}$ and it then defines a distribution $F(s, t) \doteq T(p_1, p_2; p'_1, p'_2)$ with support in the physical region $\Phi$: this is what is called the scattering amplitude.

**What becomes of causality?** One can show that the positive-energy solutions of the Klein–Gordon equation cannot vanish in any open set of Minkowski spacetime; they necessarily spread out in the whole spacetime. This makes it impossible to formulate a causality condition comparable to eqn [9] in terms of the spacetime wave functions $f_{\text{in}}$ and $g_{\text{out}}$ corresponding to the input and output wave packets $\hat{f}_{\text{in}}, \hat{g}_{\text{out}}$. In this connection, it is, however, appropriate to note that (after various attempts of "weak causality conditions") a certain condition called "macrocausality" (Iagolnitzer and Stapp 1969; see the book by Iagolnitzer (1992)) has been shown to be equivalent to some local properties of analyticity of the scattering kernel $T$; but it is not our purpose to develop that point here for two reasons: (1) the interpretation of that condition is rather involved, because it integrates a very weak form of causality together with the spatial short-range character of the strong nuclear interactions between the elementary particles; (2) the domains of analyticity obtained are by far too small with respect to those necessary for writing dispersion relations. The reason for this failure is that the scattering kernel only represents an asymptotic quantum observable, in the sense that it is intended to describe observations far apart from the extremely small spacetime region where the particles strongly interact, namely in regions where this interaction is asymptotically small. Although well adapted to what is actually observed in the detection experiments, the concept of scattering kernel is not sufficient for describing the fundamental interactions of physics: it must be enriched by other theoretical concepts which might explicitly take into account the microscopic interactions in spacetime. This motivates the introduction of quantum fields as basic quantities in particle physics.

### Relativistic Quantum Fields: Microcausality and the Retarded and Advanced Kernels; Analyticity in Complex Energy–Momentum Space

By an idealization of the concept of quantum electromagnetic field and a generalization to all types of microscopic interactions of matter, one considers that all the phenomena involving such interactions can be described by fields $\Phi_i(x)$, whose amplitude can, in principle, be measured in arbitrarily small regions of Minkowski spacetime. In the quantum framework, one is thus led to the notion of local observable $\mathcal{O}$ (emphasized as a basic concept in the axiomatic approach of Araki, Haag, and Kastler). In the Wightman field-theoretical framework, a local observable corresponds to the measuring process of a ponderated average of a field $\Phi_i(x)$ of the form $\mathcal{O} \doteq \Phi_i[f] = \int \Phi_i(x) f(x)\, dx$. In the latter, $f(x)$ denotes a smooth real-valued test-function with (arbitrary) compact support $K$ in spacetime; the observable $\mathcal{O}$ is then said to be localized in $K$. Each observable $\mathcal{O} = \Phi_i(f)$ has to be a self-adjoint (unbounded) operator acting in (a dense domain of) the Hilbert space $\mathcal{H}$ generated by all the states of the system of fundamental fields $\{\Phi_i\}$; therefore, the correct mathematical concept of relativistic quantum field $\Phi(x)$ is an "operator-valued tempered distribution on Minkowski spacetime." Here the additional "temperateness assumption" is a convenient technical assumption which in particular allows the passage to the energy–momentum space by making use of the Fourier transformation.

In this QFT framework, it is natural to express a certain form of causality by assuming that two observables $\Phi(f)$ and $\Phi(f')$ commute if the supports of $f$ and $f'$ are spacelike-separated regions in spacetime, which means that no signal with velocity smaller or equal to the velocity of light can propagate from either one of these regions to the other. This expresses the idea that these two observables should be independent, that is, "compatible as quantum observables." This postulate is equivalent to the following condition, called microcausality or local commutativity, and understood in the sense of operator-valued tempered distributions:

$$[\Phi(x_1), \Phi(x_1')] = 0, \quad \text{for } (x_1 - x_1')^2 < 0 \qquad [21]$$

where $(x_1 - x_1')^2$ is the squared Minkowskian pseudonorm of $x = x_1 - x_1' = (x_0, \boldsymbol{x})$, namely $x^2 = x_0^2 - \boldsymbol{x}^2$. It follows that for every admissible pair of states $\Psi, \Psi'$ in $\mathcal{H}$, the tempered distribution

$$C_{\Psi,\Psi'}(x_1, x_1') \doteq \langle \Psi, [\Phi(x_1), \Phi(x_1')]\Psi' \rangle \qquad [22]$$

has its support contained in the union of the sets $\mathcal{V}^+ : x_1 - x_1' \in \overline{V^+}$ and $\mathcal{V}^- : x_1 - x_1' \in \overline{V^-}$, where $\overline{V^+}$ and $\overline{V^-}$ are, respectively, the closures of the forward and backward cones $V^+ \doteq \{x = (x_0, \boldsymbol{x}); x_0 > |\boldsymbol{x}|\}$, $V^- \doteq -V^+$ in Minkowski spacetime. It is always possible to decompose the previous distribution as

$$C_{\Psi,\Psi'}(x_1, x_1') = R_{\Psi,\Psi'}(x_1, x_1') - A_{\Psi,\Psi'}(x_1, x_1') \qquad [23]$$

in such a way that the supports of the distributions $R_{\Psi,\Psi'}(x_1, x_1')$ and $A_{\Psi,\Psi'}(x_1, x_1')$ belong, respectively, to $\mathcal{V}^+$ and $\mathcal{V}^-$. $R_{\Psi,\Psi'}$ and $A_{\Psi,\Psi'}$ are called, respectively, retarded and advanced kernels and they are often formally expressed (for convenience) as follows:

$$R_{\Psi,\Psi'}(x_1, x_1') = \theta(x_{1,0} - x_{1,0}')C_{\Psi,\Psi'}(x_1, x_1')$$
$$A_{\Psi,\Psi'}(x_1, x_1') = -\theta(x_{1,0} - x_{1,0}')C_{\Psi,\Psi'}(x_1, x_1')$$

in terms of the Heaviside step function $\theta(t)$ of the time-coordinate difference $t = x_{1,0} - x_{1,0}'$. For every pair $(\Psi, \Psi'), R_{\Psi,\Psi'}(x_1, x_1')$ appears as a relativistic generalization of the retarded kernel $R(t - t')$ of eqn [10]: its support property in spacetime, similar to the support property of $R$ in time, expresses a relativistic form of causality, or "Einstein causality."

There exists a several-variable extension of the theory of Fourier–Laplace transforms of tempered distributions which is based on a formula similar to eqn [11]. We introduce the vector variables $X = (x_1 + x_1')/2, x = x_1 - x_1'$ and a complex 4-momentum $k = p + iq = (k_0, \boldsymbol{k})$ as the conjugate vector variable of $x$ with respect to the Minkowskian scalar product $k \doteq k_0 x_0 - \boldsymbol{k} \cdot \boldsymbol{x}$, and we define

$$\tilde{R}^{(c)}_{\Psi,\Psi'}(k, X) = \int_{\overline{V}^+} R_{\psi,\Psi'}\left(X + \frac{x}{2}, X - \frac{x}{2}\right) e^{ik\cdot x}\, dx \qquad [24]$$

Since $q \cdot x > 0$ for all pairs $(q, x)$ such that $q \in V^+$, $x \in \overline{V}^+$, it follows that $\tilde{R}^{(c)}_{\Psi,\Psi'}(k, X)$ is holomorphic with respect to $k$ in the domain $\mathcal{T}^+$ containing all $k = p + iq$ such that $q$ belongs to $V^+$. Moreover, in the limit $q \to 0$ this holomorphic function tends (in the sense of distributions) to the Fourier transform $\tilde{R}_{\Psi,\Psi'}(p, X)$ of $R_{\Psi,\Psi'}(X + x/2, X - x/2)$ with respect to $x$. The domain $\mathcal{T}^+$, which is called the "forward tube," is the analog of the domain $\mathcal{I}_+$ of the $\omega$-plane; bounds of moderate type comparable to those of [12] apply to the holomorphic function $\tilde{R}^{(c)}_{\Psi,\Psi'}$ in $\mathcal{T}^+$. Similarly, the advanced kernel $A_{\Psi,\Psi'}(X + x/2, X - x/2)$ admits a Fourier–Laplace transform $\tilde{A}^{(c)}_{\Psi,\Psi'}(k, X)$, which is holomorphic and of moderate growth in the "backward tube" $\mathcal{T}^-$ containing all $k = p + iq$ such that $q$ belongs to $V^-$. In view of [23], the Fourier transform $\tilde{C}_{\Psi,\Psi'}(p, X)$ of $C_{\Psi,\Psi'}(X + x/2, X - x/2)$ then appears as the difference between the boundary values of $\tilde{R}^{(c)}_{\Psi_1,\Psi_2}$ and $\tilde{A}^{(c)}_{\Psi_1,\Psi_2}$ on the reals (from the respective domains $\mathcal{T}^+$ and $\mathcal{T}^-$).

### The Field-Theoretical Axiomatic Framework and the Passage from the Structure Functions of QFT to the Scattering Kernels (Case of Forward Scattering)

**The postulates (Wightman axioms)** Apart from the causality postulate, which we have already presented above in view of its distinguished role for generating analyticity properties in complex energy–momentum space, the field-theoretical axiomatic approach to collision theory is based on the following postulates (for all the fundamental developments of axiomatic field theory, the interested reader may consult the books by Streater and Wightman (1980) and by Jost (1965); *see* Axiomatic Quantum Field Theory).

1. There exists a unitary representation $g \to \mathcal{U}(g)$ of the Poincaré group $G$ in the Hilbert space of states $\mathcal{H}$; in this representation, the abelian subgroup of translations of space and time has a Lie algebra whose generators are interpreted as the four self-adjoint (commuting) operators $P_\mu$ of total energy–momentum of the system.
2. The quantum field operators $\Phi(x)$ transform covariantly under that representation; in the simplest case of scalar fields (considered here), $\Phi(gx) = U(g)\Phi(x)U(g^{-1})$.
3. There exists a unique state $\Omega$, called the vacuum, such that the action of all polynomials of field operators on $\Omega$ generates a dense subset of $\mathcal{H}$;

moreover, $\Omega$ is assumed to be invariant under the representation $\mathcal{U}$ of $G$, and thereby such that $P_\mu \Omega = 0$.

4. Spectral condition or positivity of energy in all physical states. The joint spectrum $\Sigma$ of the operators $P_\mu$ is contained in the closed forward cone $\overline{V^+}$ of energy–momentum space. In order to perform the collision theory of massive particles, one needs a more detailed "mass-gap assumption": $\Sigma$ is the union of the origin $O$, of one or several positive sheets of hyperboloid $H^+_{m_i}$ and of a region $V^+_M$ defined by the conditions $p^2 \geq M^2, p_0 > 0$, with $M$ larger than all the $m_i$.

The Hilbert space $\mathcal{H}$ is correspondingly decomposed as the direct sum of the vacuum subspace (or zero-particle subspace) generated by $\Omega$, of subspaces of stable one-particle states with masses $m_i$ isomorphic to $L_2(H^+_{m_i}, \mu_{m_i})$, and of a remaining subspace $\mathcal{H}'$. As a result of the construction of "asymptotic states," $\mathcal{H}'$ can be shown to contain two subspaces $\mathcal{H}'_{\text{in}}$ and $\mathcal{H}'_{\text{out}}$, generated, respectively, by $N$-particle incoming states (with $N$ arbitrary and $\geq 2$) and by $N$-particle outgoing states. The collision operator $S$ is then defined as the partially isometric operator from $\mathcal{H}'_{\text{out}}$ onto $\mathcal{H}'_{\text{in}}$, which maps a reference basis of outgoing states onto the corresponding basis of incoming states.

**An independent postulate: asymptotic completeness** (*see* **Scattering, Asymptotic Completeness and Bound States and Scattering in Relativistic Quantum Field Theory: Fundamental Concepts and Tools**) The theory is said to satisfy the property of asymptotic completeness if all the states of $\mathcal{H}$ can be interpreted as superpositions of various $N$-particle states (either in the incoming or in the outgoing state basis), namely if one has $\mathcal{H}' = \mathcal{H}'_{\text{in}} = \mathcal{H}'_{\text{out}}$. This property is not implied by the previous postulates on quantum fields, but its physical interpretation and its role in the analytic program are of primary importance (see Scattering in Relativistic Quantum Field Theory: The Analytic Program). Let us simply note here that asymptotic completeness implies as a by-product the unitarity property of the collision operator $S$ on the full Hilbert space $\mathcal{H}'$ (i.e., $SS^* = S^*S = I$).

**Connection between retarded kernel and scattering kernel for the forward scattering case; a simple "reduction formula"** We consider the scattering of a particle $\Pi_1$ with mass $m_1$ on a target consisting of a particle $\Pi_2$ with mass $m_2$ and denote by $T(p_1, p_2; p'_1, p'_2)$ the corresponding scattering kernel (defined similarly as for the case of equal-mass particles considered earlier). Equations [22]–[24] are then applied to the case when $\Psi$ and $\Psi'$ coincide with a one-particle state of $\Pi_2$ at rest, namely with 4-momentum $p_2 = p'_2$ along the time axis: $p_2 = ((p_2)_0, 0), (p_2)_0 = m_2$. This describes in a simple way the case of forward scattering, since in view of the energy–momentum conservation law $p_1 + p_2 = p'_1 + p'_2$, the choice $p_2 = p'_2$ also implies that $p_1 = p'_1$. (The possibility of restricting the distribution $T(p_1, p_2; p'_1, p'_2)$ to such fixed values of the energy–momenta is shown to be mathematically well justified). The advantage of this simple case is that the corresponding kernels [22], [23] of $(x_1, x'_1)$ are invariant under spacetime translations and therefore depend only on $x$ (and not on $X$). We can thus rewrite eqns [22], [23] with simplified notations as follows:

$$\begin{aligned} C_{p_2}(x) &\doteq <p_2, \left[\Phi\left(\frac{x}{2}\right), \Phi\left(-\frac{x}{2}\right)\right] p_2> \\ &= R_{p_2}(x) - A_{p_2}(x) \end{aligned} \qquad [25]$$

which can be shown to give correspondingly by Fourier transformation

$$\begin{aligned} \tilde{C}_{p_2}(p) &= <p_2, \tilde{\Phi}(p)\tilde{\Phi}(-p)p_2> - <p_2, \tilde{\Phi}(-p)\tilde{\Phi}(p)p_2> \\ &= \tilde{R}_{p_2}(p) - \tilde{A}_{p_2}(p) \end{aligned} \qquad [26]$$

If the particle $\Pi_1$ appears in the asymptotic states of the field $\Phi$, the scattering kernel $T(p_1, p_2; p'_1, p'_2)$ is then given in the forward configurations $p_1 = p'_1 \in H^+_{m_1}, p_2 = p'_2 \in H^+_{m_2}$, by the following reduction formula in which $s = (p_1 + p_2)^2$:

$$\begin{aligned} F_0(s) &= T(p_1, p_2; p_1, p_2) \\ &= \left[(p_1^2 - m_1^2)\tilde{R}_{p_2}(p_1)\right]_{|H^+_{m_1}} \end{aligned} \qquad [27]$$

## Analyticity Domains in Energy–Momentum Space: From the "Primitive Off-Shell Domains" of QFT to the Crossing Manifolds on the Mass Shell

For simplicity, we shall restrict ourselves to the consideration of forward scattering amplitudes, namely to the derivation of crossing analyticity domains and (quasi-)dispersion relations at $t = 0$ for two-particle collision processes of the form $\Pi_1 + \Pi_2 \to \Pi_1 + \Pi_2$, $\Pi_1$ and $\Pi_2$ being given massive particles with arbitrary spins and charges.

**The holomorphic function $H_{p_2}(k)$ and its primitive domain $D$. Nontriviality of dispersion relations for the scattering amplitudes** As suggested by eqn [24], we can exploit the analyticity properties of the Fourier–Laplace transforms of the retarded and advanced kernels $R_{p_2}$ and $A_{p_2}$: in fact, $\tilde{R}_{p_2}(p)$ and

$\tilde{A}_{p_2}(p)$ are, respectively, the boundary values of the holomorphic functions

$$\begin{aligned}\tilde{R}^{(c)}_{p_2}(k) &= \int_{\overline{V}^+} R_{p_2}(x)\,\mathrm{e}^{\mathrm{i}k\cdot x}\,\mathrm{d}x \\ \tilde{A}^{(c)}_{p_2}(k) &= \int_{\overline{V}^-} A_{p_2}(x)\,\mathrm{e}^{\mathrm{i}k\cdot x}\,\mathrm{d}x\end{aligned} \qquad [28]$$

from the corresponding domains $\mathcal{T}^+$ and $\mathcal{T}^-$. According to the reduction formula [27], it is appropriate to consider correspondingly the functions $H^+_{p_2}(k) \doteq (k^2 - m_1^2)\tilde{R}^{(c)}_{p_2}(k)$ and $H^-_{p_2}(k) \doteq (k^2 - m_1^2)\tilde{A}^{(c)}_{p_2}(k)$, which are also, respectively, holomorphic in $\mathcal{T}^+$ and $\mathcal{T}^-$. Then the forward scattering amplitude $F_0(s) = F(s, 0) = T(p_1, p_2; p_1, p_2)$ appears as the restriction to the hyperboloid sheet $p \in H^+_{m_1}$ of the boundary value $H^+_{p_2}(p)$ of $H^+_{p_2}(k)$ on the reals.

Moreover, it can be seen that the two boundary values $H^+_{p_2}(p) = (p^2 - m_1^2)\tilde{R}_{p_2}(p)$ and $H^-_{p_2}(p) = (p^2 - m_1^2)\tilde{A}_{p_2}(p)$ coincide as distributions in the region

$$\begin{aligned}\mathcal{R} = \{p \in \mathbf{R}^4; (p + p_2)^2 < (m_1 + m_2)^2;\\ (p - p_2)^2 < (m_1 + m_2)^2\}\end{aligned} \qquad [29]$$

This follows from the intermediate expression in eqn [26] and from the fact that a state of the form $(p^2 - m_1^2)\Phi(\pm p)p_2 >$ is a state of energy–momentum $\pm p + p_2$ and therefore vanishes (in view of the spectral condition) if $(\pm p + p_2)^2 < (m_1 + m_2)^2$ (here we also use a simplifying assumption according to which no one-particle bound state is present in this channel).

The situation obtained concerning the holomorphic functions $H^+_{p_2}(k)$ and $H^-_{p_2}(k)$ parallels (in complex dimension four) the case of a pair of holomorphic functions in the upper and lower half-planes whose boundary values on the reals coincide on a certain interval playing the role of $\mathcal{R}$. As in this one-dimensional case there is a theorem, called the "edge-of-the-wedge theorem" (see below), which implies that $H^+_{p_2}(k)$ and $H^-_{p_2}(k)$ have a common analytic continuation $H_{p_2}(k)$: this function is holomorphic in a domain $D$ which is the union of $\mathcal{T}^+, \mathcal{T}^-$ and of a complex neighborhood of $\mathcal{R}$; $D$ is called the primitive domain of $H_{p_2}(k)$.

Moreover, it follows from the postulate of invariance of the field $\Phi(x)$ under the action of the Poincaré group (see postulate (2)) that the holomorphic function $H_{p_2}(k)$ only depends of the two complex variables $\zeta = k^2 (= k_0^2 - \boldsymbol{k}^2)$ and $k \cdot p_2$ or equivalently $s = (k + p_2)^2 = \zeta + m_2^2 + 2k \cdot p_2$; it thus defines a corresponding holomorphic function $\hat{H}_{p_2}(\zeta, s) \doteq H_{p_2}(k)$ in the image of $D$ in these variables.

In view of the reduction formula [27], the scattering function $\hat{F}_0(s)$ should appear as the restriction of the holomorphic function $\hat{H}_{p_2}(\zeta, s)$ to the physical mass-shell value $\zeta = m_1^2$. However, it turns out that the section of $D$ by the complex mass-shell manifold $\mathcal{M}^{(c)}$ with equation $k^2 = m_1^2$ is empty: this geometrical fact is responsible for the nontriviality of the proof of dispersion relations for the physical quantity $\hat{F}_0(s)$ on the mass shell. In fact, the tube $T^+ \cup T^-$ which constitutes the basic part of the domain $D$ and is given by the field-theoretical microcausality postulate, is a "purely off-shell" complex domain, as it can be easily checked: if a complex point $k = p + \mathrm{i}q$ is such that $q^2 > 0$, the corresponding squared mass $\zeta = k^2 = p^2 - q^2 + 2\mathrm{i}p \cdot q$ is real if and only if $p \cdot q = 0$, which implies $p^2 < 0$ (i.e., $p$ spacelike) and therefore $\zeta = p^2 - q^2 < 0$.

**"Off-shell dispersion relations" as a first step** The starting point, which is easy to obtain from the domain $D$, is the analyticity of the holomorphic function $\hat{H}_{p_2}(\zeta, s)$ in a cut-plane of the variable $s$ for all negative values of the squared mass variable $\zeta$. This cut-plane $\Delta_\zeta$ is always the complement in $\mathbf{C}$ (i.e., the complex $s$-plane) of the union of the $s$-cut ($s$ real $\geq (m_1 + m_2)^2$) and of the $u$-cut ($u = 2\zeta + 2m_2^2 - s$ real $\geq (m_1 + m_2)^2$). This analyticity property thus justifies "off-shell dispersion relations" at fixed negative values of $\zeta$ for the field-theoretical structure function $\hat{H}_{p_2}(\zeta, s)$.

The latter property and the subsequent analysis concerning the process of analytic continuation of $\hat{H}_{p_2}$ to positive values of $\zeta$ will be more easily understood geometrically if one reduces the complex space of $k$ to a two-dimensional complex space, which is legitimate in view of the equality $H_{p_2}(k) = \hat{H}_{p_2}(\zeta, s)$.

Having chosen the $k_0$-axis along $p_2$, we reduce the orthogonal space coordinates $\boldsymbol{k}$ of $k$ to the radial variable $k_r$. One thus gets the following expressions of the variables $\zeta$ and $s$ (resp. $u$):

$$\zeta = k_0^2 - k_r^2, \quad s = \zeta + m_2^2 + 2m_2 k_0$$
$$(\text{resp. } u = \zeta + m_2^2 - 2m_2 k_0)$$

Then we can write $\hat{H}_{p_2}(\zeta, s) \doteq \mathrm{H}_{p_2}(k_0, k_r) = \mathrm{H}_{p_2}(k_0, -k_r)$, and describe the image $D_r$ of the domain $D$ in the variables $k = (k_0, k_r) = p + \mathrm{i}q$ as $T_r^+ \cup T_r^- \cup \mathcal{N}(\mathcal{R}_r)$, where:

1. $T_r^\pm$ is defined by the condition $q^2 \doteq q_0^2 - q_r^2 > 0$, $q_0 > 0$ or $q_0 < 0$,
2. $\mathcal{N}$ is a complex neighborhood of the real region $\mathcal{R}_r$ defined as follows. Let $h_s^+, h_u^-$ be the two branches of hyperbolae with respective equations:

$$h_s^+ : \ (p_0 + m_2)^2 - p_r^2 = (m_1 + m_2)^2, \ p_0 + m_2 > 0$$
$$h_u^- : \ (p_0 - m_2)^2 - p_r^2 = (m_1 + m_2)^2, \ p_0 - m_2 < 0$$

Then $\mathcal{R}_r$ is the intersection of the region situated below $h_s^+$ and of the region situated above $h_u^-$.

Let us now consider any complex hyperbola $h^{(c)}[\zeta]$ with equation $k^2 \doteq k_0^2 - k_r^2 = \zeta$. On such a complex curve either one of the variables $k_0$ or $s$ or $u$ is a good parameter for holomorphic functions which are even in $k_r$, like $\mathrm{H}_{p_2}(k_0, k_r)$. If $\zeta$ is real, any complex point $k = p + iq$ of $h^{(c)}[\zeta]$ is such that $p^2$ and $q^2$ have opposite signs (since $p \cdot q = 0$). Therefore, the sign of $q^2$ is always opposite to the sign of $\zeta(= p^2 - q^2)$: if $\zeta$ is negative, all the complex points of $h^{(c)}[\zeta]$ thus belong to $T_r^+ \cup T_r^-$; the union of all these points with the real points of $h^{(c)}[\zeta]$ in $\mathcal{R}_r$ is therefore a subset of $D_r$, which is represented in the complex plane of $s$ by the cut-plane $\Delta_\zeta$. The function $\hat{H}_{p_2}(\zeta, s)$ is therefore analytic (and univalent) in $\Delta_\zeta$ for each $\zeta < 0$. Moreover, the existence of moderate bounds of type [12] on $H_{p_2}$ in $D$ (resulting from the temperateness assumption) then implies the validity of dispersion relations (with subtractions) for $\hat{H}_{p_2}(\zeta, s)$ in $\Delta_\zeta$.

**The problem of analytic completion to the complex mass-shell hyperbola $h^{(c)}[m_1^2]$: what is provided by the Jost–Lehmann–Dyson domain** A basic fact in complex geometry in $n$ variables, with $n \geq 2$, is the existence of a distinguished class of domains, called holomorphy domains: for each domain $\mathcal{U}$ in this class, there exists at least one function which is holomorphic in $\mathcal{U}$ and cannot be analytically continued at any point of the boundary of $\mathcal{U}$. In one dimension, every domain is a holomorphy domain. In dimension larger than one, a general domain $\mathcal{U}$ is not a holomorphy domain, but it admits a holomorphy envelope $\hat{\mathcal{U}}$, which is a holomorphy domain containing $\mathcal{U}$, such that every function holomorphic in $\mathcal{U}$ admits an analytic continuation in $\hat{\mathcal{U}}$.

It turns out that the domain $D_r$ considered above in the last subsection) is not a holomorphy domain; its holomorphy envelope $\hat{D}_r$ (obtained geometrically by Bros, Messiah, and Stora in 1961) coincides with a domain introduced by Jost–Lehmann (1957) and Dyson (1958) by methods of wave equations. This domain can be characterized as the union of $D_r$ with all the complex points of all the hyperbolae with equations $(k_0 - a)^2 - (k_r - b)^2 = c^2$ (for all $a, b, c$ real, including the complex straight lines for which $c = 0$) whose both branches have a nonempty intersection with the real region $\mathcal{R}_r$.

In particular, one easily sees that all the hyperbolae $h^{(c)}[\zeta]$ with $0 \leq \zeta < m_1^2$ belong to the previous class. It follows that for any $\zeta$ in this positive interval, the function $\hat{H}_{p_2}(\zeta, s)$ can still be analytically continued as a holomorphic function of $s$ in the cut-plane $\Delta_\zeta$ and thereby satisfies the corresponding dispersion relations.

The physical mass shell hyperbola $h^{(c)}[m_1^2]$ thus appears as a limiting case of the previous family (for $\zeta$ tending to $m_1^2$ from below). The analyticity of $\hat{H}_{p_2}(m_1^2, s)$ in $\Delta_{m_1^2}$ can then be justified provided one knows that this function is analytic at at least one point of $\Delta_{m_1^2}$: but this additional information results from a more thorough exploitation of the analyticity properties resulting from the QFT postulates. This will be now briefly outlined below.

**Further information coming from the four-point function in complex momentum space** It is possible to obtain further analyticity properties of $\hat{H}_{p_2}(\zeta, s) \doteq H_{p_2}(k)$ by considering the latter as the restriction to the submanifold $k_1 = -k_3 = k$; $k_2 = -k_4 = p_2$ of a master analytic function $H_4(k_1, k_2, k_3, k_4)$, called the four-point function of the field $\Phi$ in complex energy–momentum space (*see* Scattering in Relativistic Quantum Field Theory: The Analytic Program). This function is holomorphic in a well-defined primitive domain $D_4$ of the linear submanifold $k_1 + k_2 + k_3 + k_4 = 0$. It is then possible to compute some local parts situated near the reals of the holomorphy envelope of $D_4$, which implies, as a by-product, that the function $\hat{H}_{p_2}(\zeta, s)$ can be analytically continued in a set $\Sigma$ of the form

$$\Sigma = \{(\zeta, s);\ \zeta \in \delta,\ s \in \mathcal{V}_{s_1}(\zeta)\} \cup \{(\zeta, s);\ \zeta \in \delta,\ u = 2\zeta + 2m_2^2 - s \in \mathcal{V}_{u_1}(\zeta)\} \quad [30]$$

with the following specifications:

1. $\delta$ is a domain in the $\zeta$-plane, which is a complex neighborhood of a real interval of the form $-a < \zeta < M_1^2$; here $M_1$ denotes a spectral mass threshold in the theory such that $M_1 > m_1$;
2. for each $\zeta, \mathcal{V}_{s_1}(\zeta)$ (resp. $\mathcal{V}_{u_1}(\zeta)$) is a cut-neighborhood in the $s$-plane of the real half-line $s > s_1$ (resp. of the half-line $u = 2\zeta + 2m_2^2 - s$ real $> u_1$); $s_1$ and $u_1$ denote appropriate real numbers independent of $\zeta$.

**The final analytic completion: crossing domains on $h^{(c)}[m_1^2]$. Dispersion relations for $\pi_0$–$\pi_0$ meson scattering and "quasi-dispersion-relations" for proton–proton scattering** We now wish to describe briefly the final step of analytic completion, which displays the existence of a "quasi-cut-plane domain" in $s$ for the function $\hat{H}_{p_2}(m_1^2, s)$, even in the more general case when the $s$-cut and $u$-cut are associated with different scattering channels, whose respective mass thresholds $s = M_{12}^2$ and $u = M_{12}'^2$ are unequal.

This general situation may occur as soon as one charged particle $\Pi_1$ of the $s$-channel is replaced by the corresponding antiparticle $\overline{\Pi}_1$ in the $u$-channel, in contrast with the case of neutral particles (like the $\pi_0$ meson) which coincide with their own antiparticles. Here it is important to note that the two real branches $h^+[m_1^2]$ and $h^-[m_1^2]$ of the mass shell hyperbola $h^{(c)}[m_1^2]$ correspond, respectively, to the physical region of the "direct scattering channel" of the reaction $\Pi_1 + \Pi_2 \to \Pi_1 + \Pi_2$ with squared total energy $s$, and to the physical region of the "crossed scattering channel" of the reaction $\overline{\Pi}_1 + \Pi_2 \to \overline{\Pi}_1 + \Pi_2$ with squared total energy $u$. A typical and important example is the case of proton–proton scattering in the $s$-channel, where $M_{12}$ equals twice the mass $m(=m_1=m_2)$ of the proton, while the corresponding $u$-channel refers to the proton–antiproton scattering, whose threshold $M'_{12}$ equals twice the mass $\mu$ of the $\pi$ meson.

In that general case, the analysis of the subsection "'Off-shell dispersion relations' as a first step" still applies, so that the function $\hat{H}_{p_2}(\zeta, s)$ is always analytic in a set of the form

$$S_0 = \{(\zeta, s);\ -a < \zeta < 0,\ s \in \Delta_\zeta\} \qquad [31]$$

Then, the additional information described above in the last subsection allows one to use the following crucial property of analytic completion, which we call

**Crossing lemma** *If a function $G(\zeta, s)$ is holomorphic in a domain which contains the union of the sets $\Sigma$ and $S_0$ (see eqns [30] and [31]), then it admits an analytic continuation in a set of the following form*:

$$\{(\zeta, s);\ \zeta \in \delta,\ s \in \Delta_\zeta;\ |s - \zeta - m_2^2| = |u - \zeta - m_2^2| > R(\zeta)\}$$

By applying this property to the function $\hat{H}_{p_2}(\zeta, s)$ and restricting $\zeta$ to the mass-shell value $m_1^2$ which belongs to $\delta$, one obtains the analyticity of the scattering function $\hat{F}_0(s) \doteq \hat{H}_{p_2}(m_1^2, s)$ in a crossing domain of the complex mass shell hyperbola $h^{(c)}[m_1^2]$: the crossing between the two physical regions $h^+[m_1^2]$ $(s \geq M_{12}^2)$ and $h^-[m_1^2]$ $(u \geq M'^2_{12})$ is ensured by a complex domain of $h^{(c)}[m_1^2]$ whose image in the $s$-plane is the "cut-neighborhood of infinity" $\{s; s \in \Delta_{m_1^2}, |s - m_1^2 - m_2^2| = |u - m_1^2 - m_2^2| > R(m_1^2)\}$. Note that the relevant boundary values of $\hat{F}_0$ for obtaining the scattering amplitudes of the two collision processes with respective physical regions $h^+[m_1^2]$ and $h^-[m_1^2]$ have to be taken from the respective sides $\operatorname{Im} s > 0$ and $\operatorname{Im} u = -\operatorname{Im} s > 0$ of the corresponding $s$- and $u$-cuts.

It is only for the neutral case, where $M_{12} = M'_{12} = m_1 + m_2$, that a more favorable scenario occurs, as explained earlier: in this case, the interval $\{\zeta \in ]-a, 0[\}$ of the set $S_0$ is replaced by $\{\zeta \in ]-a, m_1^2[\}$, so that the whole cut-plane domain $\Delta_{m_1^2}$ is obtained in the result of the previous crossing lemma. The scattering amplitudes of $\pi_0$–$\pi_0$ meson scattering and of $\pi$ meson–proton scattering enjoy this property and, therefore, satisfy genuine dispersion relations in which the scattering function is even (see the second basic example described at the beginning of this article). In the general case of crossing domains obtained above, corresponding Cauchy integral relations have been written and used under the name of "quasi-dispersion-relations."

**Complementary results** Some comments can now be added concerning the passage from the purely geometrical results (i.e., analyticity domains) described above to the writing of precise (quasi-) dispersion relations with two subtractions:

*Polynomial bounds and dispersion relations with N subtractions* The previous methods of analytic completion also allow one to control the bounds at infinity in the relevant complex domains. As it has been noticed after eqn [24], the Fourier–Laplace transforms of the retarded and advanced kernels, and thereby the holomorphic functions $H^{\pm}_{p_2}(k)$ discussed at the start of this section are bounded at most by a power of a suitable norm of $k$ in their respective tubes $\mathcal{T}^{\pm}$. Correspondingly, the holomorphic function $H_{p_2}(k)$ (resp. $\mathrm{H}_{p_2}(k_0, k_r)$) admits the same type of bound in its primitive analyticity domain $D$ (resp. $D_r$). These bounds are a consequence of the tempered distribution character of the structure functions of the fields which is built-in in the Wightman field-theoretical framework. Then it can be checked that in the holomorphy envelope $\hat{D}_r$ of $D_r$, and thereby in the cut-plane (or crossing) domains obtained in the intersection of $\hat{D}_r$ and of the complex mass shell $h^{(c)}[m_1^2]$, the same type of power bound is still valid: $\hat{F}_0(s)$ is therefore bounded by some power $|s|^{N-1}$ of $|s|$ and thus satisfies a (quasi-)dispersion relation with $N$ subtractions. The same type of argument holds for all the similar cut-domains (or crossing domains) in $s$ obtained for $\hat{F}_t(s)$ for all negative value of $t$.

It is also worthwhile to mention that a similar remarkable (since not at all predictable) result was also obtained in the Haag, Kastler, and Araki framework of algebraic QFT (Epstein, Glaser, Martin, 1969; *see* Scattering in Relativistic Quantum Field Theory: The Analytic Program for further comments).

In this connection, one can also mention a more recent result. In the Buchholz–Fredenhagen axiomatic approach of charged fields (1982), in which

locality is replaced by the more general notion of "stringlike locality" (*see* Algebraic Approach to Quantum Field Theory, Axiomatic Quantum Field Theory, and Scattering in Relativistic Quantum Field Theory: Fundamental Concepts and Tools), a proof of forward dispersion relations has again been obtained (Bros, Epstein, 1994).

*The extension of the analyticity domains by positivity and the derivation of bounds by unitarity* (Martin 1966; see the book by Martin (1969)). The following ingredients have been used:

1. Positivity conditions on the absorptive part of $F(s,t)$, which are expressed by the infinite set of inequalities $(\mathrm{d}/\mathrm{d}t)^n \operatorname{Im} F(s,t)_{|t=0} \geq 0$ (for all integers $n$),
2. The existence of a two-dimensional complex neighborhood of some point $(s=s_0, t=0)$ in the analyticity domain resulting from QFT.

The following results have then been obtained:

(a) It is justified to differentiate the forward (subtracted) dispersion relations with respect to $t$ at any order.
(b) $\hat{F}(s,t)$ can be analytically continued in a fixed circle $|t| < t_{\max}$ for all values of $s$. The latter implies the extension of dispersion relations in $s$ to positive (and complex) values of $t$.
(c) In a last step, the use of unitarity conditions for the "partial waves" $f_\ell(s)$ of $F(s,t)$ (*see* Scattering in Relativistic Quantum Field Theory: The Analytic Program) allows one to obtain Froissart-type bounds on the scattering amplitudes and thereby to justify the writing of (quasi-)dispersion relations with at most two subtractions for all the admissible values of $t$.

## Introduction

A dynamical system (DS) is a system which evolves with respect to the time. To be more precise, a DS $(S(t), \Phi)$ is determined by a phase space $\Phi$ which consists of all possible values of the parameters describing the state of the system and an evolution map $S(t): \Phi \to \Phi$ that allows one to find the state of the system at time $t > 0$ if the initial state at $t=0$ is known. Very often, in mechanics and physics, the evolution of the system is governed by systems of differential equations. If the system is described by ordinary differential equations (ODEs),

$$\frac{\mathrm{d}}{\mathrm{d}t} y(t) = F(t, y(t)), \quad y(0) = y_0, \\ y(t) := (y_1(t), \ldots, y_N(t)) \qquad [1]$$

for some nonlinear function $F: \mathbb{R}_+ \times \mathbb{R}^N \to \mathbb{R}^N$, we have a so-called finite-dimensional DS. In that case, the phase space $\Phi$ is some (invariant) subset of $\mathbb{R}^N$ and the evolution operator $S(t)$ is defined by

$$S(t)y_0 := y(t), \quad y(t) \text{ solves } [1] \qquad [2]$$

We also recall that, in the case where eqn [1] is autonomous (i.e., does not depend explicitly on the time), the evolution operators $S(t)$ generate a semigroup on the phase space $\Phi$, that is,

$$S(t_1 + t_2) = S(t_1) \circ S(t_2), \quad t_1, t_2 \in \mathbb{R}_+ \qquad [3]$$

Now, in the case of a distributed system whose initial state is described by functions $u_0 = u_0(x)$ depending on the spatial variable $x$, the evolution is usually governed by partial differential equations (PDEs) and the corresponding phase space $\Phi$ is some infinite-dimensional function space (e.g., $\Phi := L^2(\Omega)$ or $\Phi := L^\infty(\Omega)$ for some domain $\Omega \subset \mathbb{R}^N$.) Such DSs are usually called infinite dimensional.

The qualitative study of DSs of finite dimensions goes back to the beginning of the twentieth century, with the pioneering works of Poincaré on the $N$-body problem (one should also acknowledge the contributions of Lyapunov on the stability and of Birkhoff on the minimal sets and the ergodic theorem). One of the most surprising and significant facts discovered at the very beginning of the theory is that even relatively simple equations can generate very complicated chaotic behaviors. Moreover, these types of systems are extremely sensitive to initial conditions (the trajectories with close but different initial data diverge exponentially). Thus, in spite of the deterministic nature of the system (we recall that it is generated by a system of ODEs, for which we usually have the unique solvability theorem), its temporal evolution is unpredictable on timescales larger than some critical time $T_0$ (which depends obviously on the error of approximation and on the rate of divergence of close trajectories) and can show typical stochastic behaviors. To the best of our knowledge, one of the first ODEs for which such types of behaviors were established is the physical pendulum parametrically perturbed by time-periodic external forces,

$$y''(t) + \sin(y(t))(1 + \varepsilon \sin(\omega t)) = 0 \qquad [4]$$

where $\omega$ and $\varepsilon > 0$ are physical parameters. We also mention the more recent (and more relevant for our topic) famous example of the Lorenz system which is defined by the following system of ODEs in $\mathbb{R}^3$:

$$\begin{cases} x' = \sigma(y - x) \\ y' = -xy + rx - y \\ z' = xy - bz \end{cases} \qquad [5]$$

where $\sigma, r,$ and $b$ are some parameters. These equations are obtained by truncation of the Navier–Stokes equations and give an approximate description of a horizontal fluid layer heated from below. The warmer fluid formed at the bottom tends to rise, creating convection currents. This is similar to what happens in the Earth's atmosphere. For a sufficiently intense heating, the time evolution has a sensitive dependence on the initial conditions, thus representing a very irregular and chaotic convection. This fact was used by Lorenz to justify the so-called "butterfly effect," a metaphor for the imprecision of weather forecast.

The theory of DSs in finite dimensions had been extensively developed during the twentieth century, due to the efforts of many famous mathematicians (such as Anosov, Arnold, LaSalle, Sinai, Smale, etc.) and, nowadays, much is known on the chaotic behaviors in such systems, at least in low dimensions. In particular, it is known that, very often, the trajectories of a chaotic system are localized, up to a transient process, in some subset of the phase space having a very complicated fractal geometric structure (e.g., locally homeomorphic to the Cartesian product of $R^m$ and some Cantor set) which, thus, accumulates the nontrivial dynamics of the system (the so-called strange attractor). The chaotic dynamics on such sets are usually described by symbolic dynamics generated by Bernoulli shifts on the space of sequences. We also note that, nowadays, a mathematician has a large amount of different concepts and methods for the extensive study of concrete chaotic DSs in finite dimensions. In particular, we mention here different types of bifurcation theories (including the KAM theory and the homoclinic bifurcation theory with related Shilnikov chaos), the theory of hyperbolic sets, stochastic description of deterministic processes, Lyapunov exponents and entropy theory, dynamical analysis of time series, etc.

We now turn to infinite-dimensional DSs generated by PDEs. A first important difficulty which arises here is related to the fact that the analytic structure of a PDE is essentially more complicated than that of an ODE and, in particular, we do not have in general the unique solvability theorem as for ODEs, so that even finding the proper phase space and the rigorous construction of the associated DS can be a highly nontrivial problem. In order to indicate the level of difficulties arising here, it suffices to recall that, for the three-dimensional Navier–Stokes system (which is one of the most important equations of mathematical physics), the required associated DS has not been constructed yet. Nevertheless, there exists a large number of equations for which the problem of the global existence and uniqueness of a solution has been solved. Thus, the question of extending the highly developed finite-dimensional DS theory to infinite dimensions arises naturally.

One of the first and most significant results in that direction was the development of the theory of integrable Hamiltonian systems in infinite dimensions and the explicit resolution (by inverse-scattering methods) of several important conservative equations

of mathematical physics (such as the Korteweg–de Vries (and the generalized Kadomtsev–Petiashvilli hierarchy), the sine-Gordon, and the nonlinear Schrödinger equations). Nevertheless, it is worth noting that integrability is a very rare phenomenon, even among ODEs, and this theory is clearly insufficient to understand the dynamics arising in PDEs. In particular, there exist many important equations which are essentially out of reach of this theory.

One of the most important classes of such equations consists of the so-called dissipative PDEs which are the main subject of our study. As hinted by this denomination, these systems exhibit some energy dissipation process (in contrast to conservative systems for which the energy is preserved) and, of course, in order to have nontrivial dynamics, these models should also account for the energy income. Roughly speaking, the complicated chaotic behaviors in such systems usually arise from the interaction of the following mechanisms:

1. energy dissipation in the higher part of the Fourier spectrum;
2. external energy income in its lower part;
3. energy flux from lower to higher Fourier modes provided by the nonlinear terms of the equation.

We chose not to give a rigorous definition of a dissipative system here (although the concepts of energy dissipation and related dissipative systems are more or less obvious from the physical point of view, they seem too general to have an adequate mathematical definition). Instead, we only indicate several basic classes of equations of mathematical physics which usually exhibit the above behaviors.
